Similar information as regards hand-hammered or forged steel, square flat or half flat, which appears in these lists under numbers 1 to 17, at prices varying from 1s. 8d. to 6s. per lb., would be equally useful. Such wire and rectangular steel would be very useful in making drills and other tools; and now that we have the Parcel Post up to 7lb., if the exact weight of each size was given in a tabular form, amateurs would know what to write for, and could make up a selection of useful tools and material.

I would suggest that someone who has access to such a stock should publish a table in the following form. Such a table would have a commercial value, and be worthy of a place in Molesworth's "Engineers' Handbook," or in Calvert's "Almanac"; and its value would be increased by having the diameter of each stated in decimals of an inch.

Large Gauge: A to Z.			Small Gauge: 1 to 25.			Small Gauge: 26 to 50.			Small Gauge: 51 to 70.		
Size	Weight in grains of each length.	No. of lengths in 1lb. avoir.	Size	Weight in grains of each length.	No. of lengths in 1lb. avoir.	Size	Weight in grains of each length.	No. of lengths in 1lb. avoir.	Size	Weight in grains of each length.	No. of lengths in 1lb. avoir.

G. A.

A MARVELLOUS FIREWORK.

[22010.]—As the Fifth of November is upon us, many will, no doubt, be wasting their time with gunpowder to the imminent risk of their own fingers and their neighbours' property. Any suggestion, therefore, which may enable persons to turn a few drachms of powder to the best advantage, though hardly of value, may, nevertheless, possess a certain interest.

Go to a bonnet shop and buy a small bundle of straws for fourpence. These will be found to have a length of about 10in., and to be smooth and clear. Close one end of each with a small drop of sealing-wax. Fill them to the brim with common sporting powder and drop a piece of touch-paper loosely over the mouth of each. All of these are rockets of surprising power.

Lay one at a time in a trough of paper about a foot long, fitted to any desired angle, and light the touch-paper. The straw will start away with amazing velocity, and may well clear the houses on the opposite side of the street, or go in at their open windows. If one of these rockets strikes a piece of soft wood near the end of its flight the tremendous force with which it travels is well shown, for the straw penetrates the wood, cutting a clean sharp ring upon it, and is itself split like glass; moreover, all the gunpowder still unburnt explodes with a sharp report. If a lead shot be stuck to the sealing-wax at the top and covered with an ordinary gun cap, the rocket becomes a detonating apparatus when it strikes a wall on the opposite side of the road.

It is impossible to tell precisely in what direction these rockets will fly. The difficulty is at the start, for having once started they go well enough. A clean glass tube a foot long and three-eighths of an inch bore is in this respect superior to a trough. It is worthy of remark that perfectly straight straw will not fly well, whereas a curved one, in consequence of a spinning action which seems to be set up, flies almost perfectly true. When, however, absolute precision is desired, it is best to make a line rocket of the straw. For this purpose take at least fifty yards of fine iron wire and stretch it between two fixed points; twist two pieces of very fine copper wire around the straw, one very near the closed end and the other about 3in. off; bend the free ends loosely over the line wire, so that the straw hangs parallel to it and is quite free to move. This is an entertaining firework which may be let off safely in a long corridor. If one of these is observed from near the finishing end some idea may be gathered of the fearful rapidity with which they travel. They may be made to spin as they go by hanging them at an angle.

These straw rockets, though insignificant in comparison with those of the usual sort, nevertheless, from the ease with which they are made and their perfect safety, very well repay anyone who will take the trouble to try them. **Old Moss.**

TO MR. ALLEN—ALBUMINOIDS OF MILK—LIQUIDS IMMISCIBLE WITH OIL—CHEMICAL—AMMONIUM SALTS—CALCIUM SULPHIDE—NAPHTHOLS—ANILINE.

[22011.]—In answer to query No. 52005, page 161, headed "To Mr. Allen," the albuminoids of milk are not habitually isolated in milk-analysis. For ordinary purposes it suffices to determine the ash, the fat, and the "solids not fat," which, of course, consist chiefly of the albuminoids and milk-sugar. I do not know what particular method the querist refers to as that in which "use is made of a funnel and cooler." The best method of determining the albuminoids of milk is to dry up a known weight of the sample, extract the fat with ether, treat the residue with absolute alcohol, and then exhaust it [illegible] insoluble [illegible] portion in the [illegible] milk, [illegible] which [illegible] the one to which the querist alludes. If he will explain his meaning a little more fully, I will try to assist him.

"Liquids immiscible with oil" (query 52058, page 162) are to be found in common brine and all saline solutions. Syrup and acids also satisfy the conditions of the query.

In reply to unanswered query, No. 51622, page 45, headed "Chemical," the bisulphate of ammonia can be readily prepared by dividing a quantity of sulphuric acid into two equal parts, saturating one with ammonium carbonate (using litmus paper as the indicator of neutrality) and adding the other portion. The salt will crystallise from a very strong solution. An alternative method is to add three parts by weight of oil of vitriol to a strong solution of four parts of commercial sulphate of ammonia.

The "bisulphite of ammonia" is best obtained by saturating a solution of the commercial carbonate with the gas evolved on heating sulphuric acid with wood charcoal. The composition of the product is somewhat uncertain.

The "hyposulphite of ammonia" is best obtained by precipitating a solution of the calcium salt with one of carbonate of ammonia, filtering and concentrating the filtrate.

The "conversion of calcium sulphide" (unanswered query No. 51650, page 46) into the hyposulphite readily occurs by blowing air through the moist substance. On lixiviating with water, a solution is obtained which may be further oxidised, if necessary, by treatment with air, avoiding a high temperature. The complete conversion of the sulphide is indicated by the solution giving no precipitate with zinc or manganese sulphate. Considerable formation of the sparingly-soluble sulphate and sulphite of calcium occurs at the same time with that of the hyposulphite, which is very readily soluble.

"A and B-naphthols" (unanswered query, No. 51651, page 46) are both colourless, crystalline substances, easily soluble in alcohol, ether, chloroform, or benzene, but sparingly soluble in hot water, and almost insoluble in cold water. A-naphthol crystallises from water in small needles; B-naphthol in laminæ. The former melts at about 95° C., boils at 278° to 280°, and has a faint odour like that of phenol. The latter body melts at 123° C., boils at 285° to 290°, and is almost odourless. A-naphthol readily volatilises with the vapour of water; the B-compound only very slightly. The aqueous solution of the A-compound becomes dark violet on adding bleaching-powder solution; and red, passing to violet, on addition of ferric chloride. The solution of B-naphthol is coloured pale yellow by bleaching-powder solution, and pale green by ferric chloride.

I don't see why the potassium sulpho-naphthalene salt should be preferable to the sodium compound. There may be some practical advantage. At the end of the reaction, the fused mass is dissolved in water, the filtered solution mixed with hydrochloric acid, and the separated naphthol recrystallised from water and purified by sublimation.

"Aniline" (unanswered query No. 51652, page 46) is now manufactured by distilling nitrobenzene with hydrochloric acid and iron filings, when the following reaction takes place: — $4C_6H_5NO_2 + 9Fe + 4H_2O = 3Fe_3O_4 + 4C_6H_5NH_2$. My impression is, that the advantage possessed by hydrochloric acid over acetic acid is that, while an excess of the latter led to a formation of acetanilide, with the former there is no tendency to a loss from a similar cause. I am not certain, however, that this is the true explanation. Of course, the use of a large excess of hydrochloric acid would result in the formation of the hydrochlorate of aniline.

Sheffield, Oct. 27. **Alfred H. Allen.**

M. J. R. Bourguignat continues and completes in the *Annales des Sciences Naturelles*, tome xv., his valuable memoir on the "Malacologie de l'Abyssinie." The Messrs. Milne-Edwards have devoted the entire number of the *Annales* to this paper, which is well illustrated by plates of the mollusca of Abyssinia and a "Carte Malaco-Stratigraphique de l'Afrique."

Some notes on verification of the atomic weights of zinc and magnesium have been contributed to the *Archives of the Physical and Natural Sciences*, Geneva, by M. C. Marignac. The atomic weight of zinc, fixed by Erdmann at 65·05 and by Favre and Jacquelain raised to 66, is approximately determined at 65·33, a figure which further analysis may show to be slightly too low. For magnesium, calculated by MM. Marchand and Scheerer at 24, and by others at 24·5, the number of 24·37 results from the author's fresh experiments.

[illegible] is proposed to establish a permanent industrial [illegible] on the banks of the Hudson, within [illegible] of Central Park, New York city. [illegible] company has been formed with [illegible]

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51251.]—**Sulphuretted Hydrogen (U.Q.)**—The querist asked for information as to making sulphuretted hydrogen, and he is told by Mr. W. E. Haden, on p. 155, to act upon FeS by H_2SO_4. I should imagine if he can read the formulæ given, that it would have been unnecessary for him to ask how to make the gas. He is also told that he can do away with the offensive odour by burning the H_2S (to insure which he would require a good pressure of gas, and a specially constructed precipitating apparatus) to SO_2 and H_2O, or by mixing with chlorine from hydrochloric acid and potassic permanganate. Mr. Haden does not inform "Zelia Naien" how he is to mix the gases, or in what volume to mix them, to insure perfect decomposition of the H_2S. If Mr. Haden has ever worked in an analytical laboratory he will know very well that such a process to do away with the odour, however correct in theory, requires in practice what no student would attempt to put in operation. The cure would be "worse" than the disease, to use a common phrase. If "Zelia Naien" requires sulphuretted hydrogen for manufacturing purposes, his best material, or the cheapest, would be alkali waste, which yields a copious supply of H_2S when treated with sulphuric acid. The waste he can obtain from any alkali works by paying the carriage, as the alkali makers are only too glad to pay for removal in many instances. If his neighbours complained about the odour arising from the escape of any of the gas, he might precipitate in a covered vat, connected to a furnace by an exhaust pipe terminating in a perforated coil, so as to insure perfect combustion of the excess of gas.—PRACTICAL CHEMIST.

[51253.]—**New Zealand.**—To those who may feel inclined to adopt the advice of Wm. H. C., and take the handbook of Mr. Berry as a guide, I commend the following extract from *The Auckland Evening Star*, one of the leading papers of the North Island. "An Aucklander on his Travels.—Travels in Scotland.—Glasgow is very dirty, and as I shall allude to it again, I pass on to the country, which is very similar in its features to New Zealand . . . The Rev. Mr. Berry has issued a pamphlet on New Zealand, which is, I think, altogether too glowing, and consequently has shot a little beyond the mark. It is a mistake to allow the imagination to go so far as Mr. B. has done, as it only tends to make emigrants dissatisfied when they arrive and find they have to work as hard in the colonies as they have in England." That no dispute may arise as to the truth of the above, I have inclosed the cutting to the Editor; and that it shall not be stated that the paper in which it appeared was edited by a person whose sentiments were anti-colonial, I give the following extracts from two of the leaders that appeared in it about the same date. "Monday, Nov. 22, 1880.—The dead-set made against N. Z. by *Truth*, and some other London papers, will no doubt do the country injury in the eyes of the very class which the colony desires most ardently to secure, and for which it offers *bonâ-fide* attractions. Every number of *Truth* received by the last mail contains a violent onslaught on N.Z. finance and prospects. The very smallest fact that can be turned against the colony is strained and twisted to appear to its greatest possible disadvantage. The correspondence of every anonymous scribbler, however ignorant of his subject, is set out in leaded type, and its weight and importance exaggerated. The letter of some person signed 'John Foster,' who is described as 'recently the pastor of the Congregational Church at Kirton, Bristol,' which contains the most diabolical series of groundless and unmitigated slanders on the colony ever put together in the same space, is quoted almost as a voice from heaven."—Wednesday, Jan. 26th, 1881. From a copy of the London *Globe*, which is a widely circulated evening paper with considerable influence, the following paragraph is taken:—"In a letter to the Secretary of the United Kingdom Alliance, dated September 10th, Sir William Fox, formerly Prime Minister of New Zealand, writes:—'Our colony (N.Z.) is at present in an unprecedented state of depression, even proportionately worse than any part of the old world has suffered from.' That Sir William Fox should be writing to the Secretary of the United Kingdom Alliance is exceedingly probable, though why he should thrust this gratuitous detraction of the colony into his letter does not appear. Possibly it may have served to point some moral. Be that as it may, the circumstance is sufficiently remarkable to call for an observation or two. It is a great pity that Sir William Fox did not exhibit more wisdom. He has held the next to the highest office under the Crown in N.Z. He has lately been serving on an important commission. He is a prominent supporter of the present Government, and it is not impossible that he may some day take a portfolio again. In fact, Sir William Fox is so important a figure in our politics that a statement from his pen cannot fail to have great weight and influence in England. This consideration, which is, of course, as evident to himself as to anyone else, ought surely to have been present to inspire caution when writing a letter of a semi-public character. But it seems that it was not, and the injurious report went forth at a time which may be deemed almost critical. It was when the English Press was conspiring with provoking unanimity to throw discredit upon the resources and financial capabilities of the colony; when the most dolorous accounts of the state of affairs here were being industriously circulated throughout the length and breadth of England. One would imagine that at such a juncture a N.Z. statesman, with the interests of his adopted country at heart, would either hold his peace, or, at any rate, say nothing which might produce untoward results. But whether the statement was true or not, it is clear enough that there was nothing to justify or excuse the circulation of it by such a personage at such a time." If the statements of an eminent colonial statesman, and an English Clergyman, meet with this scurrilous abuse, and the whole English nation are charged with conspiracy, &c., I think the readers of the MECHANIC will excuse any attempt upon my part to remove the dirt thrown upon—LONDON STONE.

[51421.]—**Microscopical (U.Q.)**—If the pollens are small and transparent, they should be mounted dry—*i.e.*, a thin glass cover should be cemented over them with gold size, four pieces of thin cardboard having been previously cemented round the edge of the thin glass cover, which should then be cemented over the pollen, which must have been previously placed in the middle of the slide. The slide can then be covered with an ornamental paper cover, or left plain as desired. If opaque, they should be mounted in a shallow cell in essential oil of lemon. The cell is placed under the glass cover, and cemented to the slide on one side and the cover on the other with gold size, as the paper is in the dry method. The essential oil of lemon is to be poured over the pollen, which must have been previously placed in the centre of the cell, and the glass cover is then lowered gently over it till in position. The oil which oozes over the edge of the cover during this operation must be wiped carefully up with a cloth, and a rim of gold size painted round the edge of the cover to seal it to the cell. When this is dry another layer of gold size is put on, and so on till quite secure. Glycerine may be used instead of essential oil of lemon. Petals of flowers should be mounted in the same way, using glycerine, but before immersing them in glycerine they must be soaked in alcohol to remove some of the colouring matter contained in the cells. —R. A. R. BENNETT.

[51613.]—**Knapp's Solution (U.Q.)**—As this query does not appear to have been answered I send the following extract from Miller's "Elements of Chemistry," Vol. III., p. 607, which may be of use to querist:—"Sachsse finds that Knapp's solution does not give accurate results. Knapp found that 100 parts of dextrose reduce 400 parts of mercuric cyanide, which is in the ratio of 1 molecule of the former to somewhat less than 3 of the latter . . . . but Sachsse states that the amount of cyanide reduced depends on the rate at which the dextrose is added to the boiling mercuric cyanide solution, the reduction being greater the more rapidly the titration if effected. He finds, however, that an alkaline solution of another mercuric salt—viz., the iodide—yields constant results. The solution is prepared by dissolving 18grm. pure mercuric iodide in water with the aid of 80grm. of potassic iodide, adding to this 80grm. of potassic hydrate solution in water, and diluting to 1,000 cubic centimètres. Of this solution 40c.c., containing ·72grm. of mercuric iodide, are heated to boiling in a porcelain dish, and solution of the carbo-hydrate of about half a per cent. strength is added, at first in quantities of 5c.c. at a time, then in quantities of 1c.c., and lastly by tenths of a cubic centimètre, until the whole of the mercury is precipitated, which is ascertained by means of a saturated solution of stannous chloride in alkali, a number of drops of which are placed on a porcelain plate, and one of them mixed with a drop of liquid from the dish after each addition of the carbo hydrate solution. At first a black precipitate is produced which becomes less and less evident as the reduction proceeds, and the titration, is regarded as complete when the addition of a drop of the titrated liquid no longer produces even a brown colouration. It is found in this manner that on an average ·1501grm. of dextrose is required to effect the reduction of 40c.c. of mercuric iodide solution containing ·72grm. of mercuric iodide.—R. A. R. BENNETT.

[51697.]—**Crystoleum Pictures.**—The defects complained of must be due to something in the process followed by the querist.—PHOTO. ARTIST.

[51708.]—**Restoring Ink Writing.**—It depends so much on the nature of the ink and the substance used for bleaching, that one can only venture to suggest that the querist should try washing over portions with a solution of green copperas—that is, sulphate of iron.—NUN. DOR.

[51723.]—**Oxide of Copper Battery.**—The querist ought to find an answer on p. 500 of the last volume. How many cells depends upon the kind of lamp. At a guess, I should say 30, if the lamp is of high resistance. The other questions must remain unanswered until someone has experimented.—NUN. DOR.

[51739.]—**Waterproofing Sheets.**—If only for covering the creases, use the best double boiled linseed oil, coloured with lampblack. If you really want the quantity mentioned (95 gallons), you will have no difficulty in getting it from any large oil and paint warehouse.—NUN. DOR.

[51743.]—**Staining.**—I presume you know it is done with beer or with umber and other pigments, varnishing afterwards. If I wanted to do it, I should use the ready prepared stain, sold by oilmen, and wax well after thoroughly dry. If you do not want that stain, try the effect of strong solution of potash, bichromate of potash, or permanganate of potash, on one corner first; but remember that the full effect is not brought out until light has had its effect, and the wax, polish, or varnish is added. —NUN DOR.

[51745.]—**Voice Missing.**—No one can say what is the cause of the querist losing his voice, except that it is some affection of the chords. He should be examined with the laryngoscope.—J. T. M.

[51746.]—**Weak Ankles.**—Bathing with salt and water, rubbing in hartshorn and sweet oil, &c., might help. Better than elastic stockings, because the object is to stimulate the ankle, not to artificially support it, which it will then always need. —B. W. R.

[51747.]—**Coal Saver.**—I have used a piece of flat iron placed obliquely behind the fire; but that was to reduce the space in which the coals were consumed. What querist means must, I think, be one of the many devices for heating air which is thrown into the room through passages arranged around the mantelshelf and the jambs of the fireplace.—N. E. CHILD.

[51752.]—**Tricycle Making.**—If I wanted to make one I should not make the one referred to by querist. I should get a set of fittings (often advertised in these pages) and work away at them. A front steerer with moderate-sized wheels, with double driving gear, is about as good a machine as you will find.—N. E. CHILD.

[51768.]—**Joy's Valve Gear.**—This was illustrated on a locomotive a little time ago (p. 411, last volume) and was fully described in a paper, p. 611, Vol. XXXI. If querist will look at those figures, knowing what his own engine is like, he will be able to see whether it can be altered.—ESSAR.

[51771.]—**Painting.**—I think Lockwood and Co. publish such a book, by E. A. Davidson.—NUN. DOR.

[51780.]—**Cue-tip Cement.**—"Querist" should keep his cement well corked. Is it coaguline—isinglass and acetic acid? If so, it wants standing in warm water.—NUN. DOR.

[51783.]—**White Metal.**—Will one of the alloys given on p. 134 answer? Zinc should always be melted before mixing it with copper or brass—the latter being melted first of course. If Mr. Dixon will refer to the reply p. 134, and fails to find anything suitable, I will help him if he will give some idea what the metal is for or what it is to do.—NUN. DOR.

[51798.]—**Educational.**—One way is to article the lad to a civil engineer. He might attend the classes at University or King's College. See prospectuses.—ESSAR.

[51843.]—**American Locomotives.**—"S. J." had better procure an American Railway Guide; surely he could obtain one in London. Even the shortest statement of mileage and routes of American railways would occupy far too much valuable space, and be of interest to a very few of our readers. As regards the latter part of this query, I do not think that such subjects as the financial positions of railways are intended for insertion in the "E. M."—GUIDE YOKE, U.S.A.

[51858.]—**L. and S.W.R. Locos.**—Dimensions and a sketch of the 136 class appeared in the "E. M." for April 19, 1881.—GUIDE YOKE, U.S.A.

[51858.]—**L. & S.-W. Engines.**—The 12 engines, Nos. 136—147, were built by Beyer, Peacock, and Co., in 1880. The coupled wheels are 6ft. 6in. diameter; bogie wheels, 3ft. 3in. The cylinders are 18 by 24; heating surface of firebox, 104 square feet; of tubes (234 in number, 1¾in external diameter, 10ft. long), 1,112 square feet; weight of engine, road-worthy, 47 tons.—W. B. P.

[51874.]—**Stone in Specification.**—The object of the specification is to insure the builder doing his work in a proper manner, and using proper materials. If a "bedstone" merely had been specified, he might have put in any irregular-shaped boulder, and therefore he is required to put in a "tooled" stone—i.e., dressed with the hammer and chisel. It is taken for granted that he will not "tool" it into an unsuitable shape out of "pure cussedness." It must be evident that a naturally-shaped stone would form a very bad bed for a pillar, compared with a flat "tooled" stone.—Murano.

[51899.]—**Medical Coil.**—Will "Watt" please state if his coil was as powerful in the tube as when uncovered? Also with regard to battery—1. What is the power of a ch. of silver cell compared with a bichromate of same size? 2. Instructions to make one to go into handle would much oblige, either chloride or Marie Davy, which latter seems a very fair one. Mons. A. Niaudet, in his work "Traité de la Pile Electrique," mentions one used by Gaiffe for coils, with no free liquid to sodden blotting-paper. Is this of any sufficient power for purpose?—Thor.

[51910.]—**Canadian Locos.**—With the Editor's permission I shall be glad to send a paper or two on "Modern American Loco. Practice," giving chief dimensions of remarkable types, and if desirable, a few construction notes.—Guide Yoke, U.S.A.

[Please send.—Ed.]

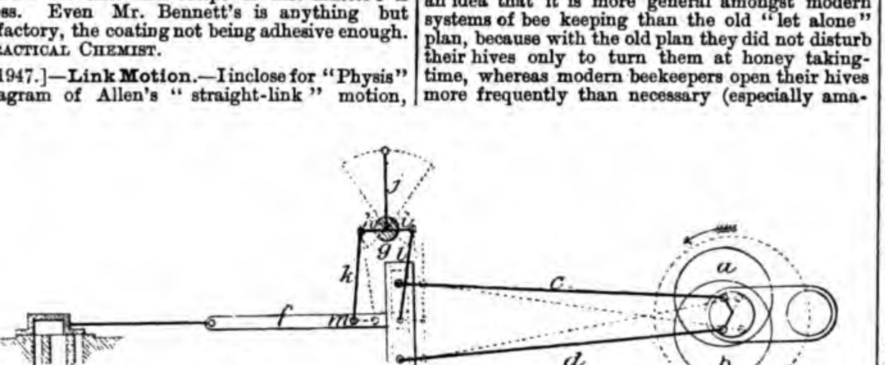
[51924.]—**Golf Balls.**—I should think a bright red paint, carefully put on the balls, would answer your purpose very well. But, in my opinion, no good will be gained by changing the colour from white to red, as the former is quite as easy, if not easier, to be seen on grass as the latter.—W. Henley Richmond.

[51930.]—**Teazles.**—There is a very interesting account of the cultivation of this plant in "The Journal of a Naturalist"—a book which used to be nearly as popular as "White's Selborne."—R. C. D.

[51939.]—**Renovating Silk Mantle.**—Benzine will probably remove it. Dip a bit of flannel in the benzine and rub the place. Lay a piece of cloth, several times double, under the place to be cleaned, so that the benzine may wash the dirt out of the mantle into the cloth. Do it at daylight, as benzine is as inflammable as gas. A teacupful will evaporate in a very short time. Benzoline will clean just as well, and is very much cheaper; but it leaves an oily residue in the fabric to which dirt sticks, and consequently looks dirty again almost directly.—Murano.

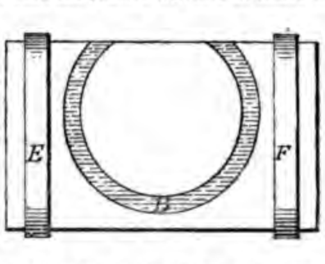
[51944.]—**Coppered Wire.**—W. Henry asks how to coat iron goods with copper. S. Austel tells him to dip in a solution of copperas. Is not this sulphate of iron? I send the Editor a sample which has been in a solution of what Mr. Austel means 51944 to use, that is sulphate of copper or blue vitriol. I also send for comparison a sample treated by Mr. Bennett's method. It does not—as the Editor will see—look very coppery. You will now see that this recipe of Mr. Austel's is useless. Even Mr. Bennett's is anything but satisfactory, the coating not being adhesive enough.—Practical Chemist.

[51947.]—**Link Motion.**—I inclose for "Physis" a diagram of Allen's "straight-link" motion,



which I hope will almost explain itself. *a b* the forward and backward eccentrics, *c d* eccentric rods, *e* expansion link, *f* valve rod link, *g* reversing shaft with arms *h i* keyed upon it, moved by a connection from the foot plate, taking hold of the extremity of the lever *j*; *k l* the two suspending links, the first attached to the valve-rod link at *m*, and the other attached to the expansion link *e*. The advantages are that the motion necessary for reversing is divided between the expansion link and the valve-rod link, so that the actual vertical motion is only half that of the ordinary forms of link motion, and the angular position of the valve-rod is consequently less, so that the strain is more direct; again, it is obvious that the parts can be made to balance one another, so that the customary heavy counterbalance weight can be dispensed with.—A. A. Myall.

[51949.]—**Zoophyte Trough.**—You can re-cement this with thick shellac varnish, with glucine, with "cement of Pompeii," or with marine glue; but there is a form of trough so simply constructed and so easily cleaned that the microscopist may be satisfied with it. Get two pieces of glass about 3in. by 2in., between them lay flat an indiarubber ring, having the upper portion cut off; bind the glasses together at either end with



an indiarubber band. E F show the indiarubber bands; B is the band laid flat between the glasses.—E. B. Fennessy.

[51951.]—**Astronomical.**—In this it is stated that there is an inequality in the longitude of Mars produced by the Earth, amounting to five minutes in two centuries. The querist asks what is the displacement of the Earth by the action of Mars in the same time. Now, if there is any such displacement of Mars there will certainly be a corresponding one for the Earth; but it will be very much larger than any which actually exists. Many years ago I was at the pains to calculate an inequality of long period (about 17 hundred years) in the place of Mars, produced by the joint action of the Earth and Jupiter, and it amounted in that time to about 45 seconds, with a corresponding one for the Earth of about 7·3 seconds. The latter was also calculated by Leverrier and Hansen, with nearly the same result, especially by M. L. There may be an inequality for Mars amounting to five seconds in 200 years; but there certainly is none such, or anything at all like it, as that spoken of by your querist.—W. G. P.

[51974.]—**Engine.**—"To Glatton."—I am sorry that I have been unable to convey to "Glatton" the proper meaning; but I will try to do so now. When the valve is in the middle of its stroke its faces fall short of covering the ports a ¼in. at each side; with this the exhaust has a 1¼in. lead, although the steam side has only ¾in. lap and ¼in. lead.—Thomas Blackburn.

[52001.—**Wheel Grease.**—The following is a recipe of a wheel grease which may possibly be of some use to "Simplex." It is, I believe, nearly similar to that used by railway companies in summer weather:—Russian tallow, about 19lb.; palm oil, about 12lb.; soda, about 1lb.; water, about 3gal.—T. M. R.

[52013.]—**Bees.**—1. It is so reported by some of the most experienced beemasters, but until recently I have not seen any cases of it; but have an idea that it is more general amongst modern systems of bee keeping than the old "let alone" plan, because with the old plan they did not disturb their hives only to turn them at honey taking-time, whereas modern beekeepers open their hives more frequently than necessary (especially amateurs) and thereby get brood chilled. I read a little time ago of one case where a new beginner said he only kept his hive open for half an hour, and was surprised that the brood got chilled. Then, again, feeding I think is at the root of many of the ills that bees are subject to, that is, feeding either at a wrong time with unsuitably prepared food or unsuitable quantity, which fills the hive with damp vapour at a time when cold weather coming on causes the bees to cluster closer and leave the outside combs uncovered, and sometimes brood is left to die and rot. Then, again, good as artificial food is, I cannot think that any food is so good for them as honey collected, stored, and sealed in their own way. The old skeppist never takes any honey out of hive (only from super at top), and, providing the hive stands on good floor board, and is well covered from rain, it has every chance to keep healthy, especially as he generally takes early swarms and leaves the stock, which, having a young queen, does well. Foul brood has a bad smell. You can only detect it by finding the bad brood and bad smell. More likely some months earlier, as few hives have brood in now, except those suffering from the plague earlier on in the year. Several bee masters have had the disease break out, and with the utmost care have only been able to save a few stocks—many having perished altogether. I should like some one who has had much experience to write, as "J." suggests; but I believe thorough cleansing of hives, spraying with dilute salicylic acid, feeding with S. acid in syrup, and other similar measures, often get rid of the disease. 2. I prefer sugar cake for winter or early spring assistance, but have not much faith in feeding at all in winter. 3. Honey and pollen, if sealed over, will keep if kept in a dry place, but not otherwise. Do as I have, and make an extractor out of large meat tins, &c. 4. The Abbot frame and hive is a little larger, and is rather narrower at bottom, to avoid crushing bees, when taking bars out or putting them in.—J. I. S.

[52019.]—**Gas-Engine.**—In reply to this query, page 182, please read Vol. LXIX. (instead of XCIX.), Session 1881—2, part 3.—R.A.

[52020.]—**Raising Lid of Iron Box.**—I should try the following: A spring made up the same way as put on doors to keep them shut, say, three, one on each end and one in the centre. Fix the spring to the side of box, and the tail end pressing against the lid.—Blacksmith.

[52031.]—**Dynamo.**—I am obliged to "Watt" and "Light" for their replies. In reply to the first-named, I had originally eight turns of wire on F.M.'s; these I reduced to four, making the R. nearly equal to A. Result: A deflection of galvanometer of 10°. Then I gradually increased the winding on both A. and F.M.'s to eight turns on former and six turns on latter, and get the best results with this, which shows the rule quoted by "Watt," that the R.'s should be equal, does not apply here. Comparing with other machines, the distance between A. and poles' clearance is not too great. In reply to "Light," I have tried all kinds of connections with the wire on F.M.'s, and in one way only can I get a current. The F.M.'s are both wound same way, and the inner end of wire on each limb of magnets coupled to brushes, and the outer ends to terminals on machine base. The magnets are secured to the cast-iron base plate, and not insulated from it. Since my query was inserted, I have managed, by winding two more turns on A. to get a little better result; but still I do not get sufficient current to light a lamp. In consequence of the interest taken in dynamo construction, I should prefer all suggestions and advice on my machine to appear in "ours." For my part, I shall have much pleasure in acknowledging the same, and giving the results of any alteration that may be suggested short of making a new machine.—Labor Omnia Vincit.

[52037.]—**Freehold Property and Building Societies.**—No question need be raised by the building society as to the person to whom they can give a release; all they have to do is to endorse a receipt upon the mortgage deed in the form prescribed by the Building Societies Act, 1874, if the society is incorporated under that Act; if the society is not incorporated, then in the form provided in its rules, and authorised by 6 & 7 Will. IV. c. 32, sec. 5. For an incorporated society there is authority (Wright v. The Monarch Building Society, L.R. 5 Ch. Div. 796, which has been confirmed in other recent cases by the Court of Appeal), that any dispute arising upon such a point as that raised in the question would have to be settled in the manner provided for the settlement of disputes by the rules of the society.—E. F. Brabrook.

[52043.]—**Induction Coil.**—To L. W. Willis.—You should make your coil 8 or 9 inches long and diameter ½in. For primary, two evenly wound layers of No. 18 cotton-covered wire, well insulated from secondary. If you use 12 or 13oz. of secondary you will be able to get a 1in. spark. Any more information, if wanted, with pleasure.—A. V. Nicholls.

[52045.]—**Checks upon Tramway Fares.**—The checking of fares is very carefully and well managed on the Liverpool tramways. Every conductor has a way-bill, which is filled up with numerals—say, from 1 to 25—and it also contains a few particulars as to time of starting, the guard's name, &c. For every passenger that enters the car one of these figures is stamped, beginning of course at No. 1. At various places during the journey, men called "checkers" examine the way-bill, and affix their stamp to the number of persons then in the car, and also to the number that were originally in. For example, if 15 persons were in the tram at starting, and six got out before the register was examined, there would be nine remaining when the checker got on the car, so that he would stamp the 9 as the present number of passengers, and 15 as the original number. The next checker would proceed in a similar manner; and as there are often three or four of these officials in a journey of about three miles, any attempt at fraud would be almost sure to be detected. But this is not the only precaution taken. Every conductor is supplied with tickets which vary in colour to represent the different fares. For instance, a buff colour for a 1d. fare, white for a 2d., pink for a 3d., and so on. The guard has also a machine for punching the tickets. As each passenger pays his fare, the conductor hands him a ticket, having first clipped a piece out of it. Now the piece so cut off falls into a receptacle in the machine, and there remains till it is taken by the proper authorities. Every ticket is numbered, so that it is very easy to tell the exact number of tickets given away and the number of fares taken. If the guard commences at No. 224 and ends at 244, there ought to be 20 of these small pieces, each of which represents so much money; so that with the checking of the way-bill and the clipping of the tickets everything is almost certain to go on in a straightforward manner. Of course, I am only alluding to one particular city in England, but it is perhaps the most important as regards tramway systems. I cannot say whether this mode of working is adopted in other English towns, or foreign ones either, and I am afraid you will not find many readers of "ours" whose knowledge of the subject is so extensive as to answer that part of the question. As to the omnibuses, the fares are almost exclusively checked by the way-bill process. A few of them have a bell or indicator which is rung every time a passenger enters; so that by looking at the number on the indicator when starting, and substracting it from the figure shown at the conclusion of the journey the number of passengers is ascertained.—W. HENLEY RICHMOND.

[52057.]—**Imitation Glass.**—If "Advertiser" will observe the following he will no doubt succeed: Size over the pasteboard with vellum size. Let this get thoroughly dry, then give it three or four coats of good white paper varnish. Let each coat get dry and somewhat hard before applying a second coat. Gelatine is hardly suitable for the purpose, but paper varnish is not much affected by the damp, and is infinitely superior to gelatine.—G. FRYER.

[52058.]—**Liquids Immiscible with Oil.**—Would treacle, or a solution of gum, tragacanth or arabic, answer? These two gums sink in water, and are, therefore, heavier. I think treacle sinks also, and would, perhaps, be heavier than dissolved gum. Or would nitric acid answer?—MURANO.

[52059.]—**Telephonic.**—In part reply to this query I may say, *re* Blake transmitters. 1. Ferrotype plate to be obtained from any photo-apparatus depot. 2. Don't know. 3. Primary about No. 30; secondary No. 36. 4. Battery named would be about the thing.—THOR.

[52062.]—**End Bearing for High-speed Spindle.**—Repolish end of spindle and leave it very slightly rounded, also polish the plug and leave it flat, then be certain that no emery or grit is left in the bearing, and fill oil-well with mercury. This has cured a similar case.—W. A. T. C. H.

[52062.]—**End Bearing for High-Speed Spindle.**—It seems to me that you have made no provision for the oil running down to bottom of footstep. You should cut a groove down and half way across the bottom. Use sperm oil, and with a cast-iron or hard gunmetal footstep, I don't think you will have any trouble.—LABOR OMNIA VINCIT.

[52063.]—**Feed Pump.**—This is one of those queries that no one can answer with any certainty without either an indicator diagram or a pressure gauge on valve-box. The pressure in a pump depends a very great deal on the resistance to the passage of the water caused by crooked passages and bends in the delivery pipe, that the pressure necessary to force the water against any given head is often very much greater than is apparently necessary. I could give you lots of cases where the pressure in pump was twice the actual pressure in the delivery pump.—LABOR OMNIA VINCIT.

[52064.]—**Exhaust.**—The following formula will enable "Pressure" to determine the distance the piston is from the end of its stroke when the exhaust begins to open:—*From* the lap and lead on one side of the exhaust subtract the lap on the other side, divide remainder by the stroke of slide, square the quotient, and multiply it by the stroke of the piston, and the product will be the distance that the piston is from the end of its stroke when the exhaust begins to open.—ENGINEER, Dewsbury.

[52068.]—**Fairy Lamps.** The fairy lamps at theatres are lighted by means of small accumulators. You will find descriptions of them in back vols.—WATT.

[52072.]—**Crayfish.**—Crayfish are to be found in most of the Midland brooks with deep holes, and a little mud. I once pulled up some basket putchins in the stream running past the waterworks at Oxford, and found them all full of crayfish.—STRETTON.

[52072.]—**Crayfish.**—Rather late in the season, I am afraid. August and September are the months to catch them. The way fully described in former numbers. I have caught them in Herts, Berks, Hants, and Wilts, in the Kennet and Avon, and in canals and small outlets from them. They can be easily propagated in any clear running stream, not too deep, with weeds at the bottom, by procuring a hundred or so and putting them in the stream, and to keep them to about the same spot by putting sheep's entrails in the stream occasionally, or any refuse of the kind. A good plan is to get a faggot and put the entrails inside, and fasten a rope to it, and put in the water, occasionally replenishing. In July the females deposit their young. I have caught them covered with young by the hundred, like you may see shrimps. If R. Enis will advertise his address, I will try and send him some at a small cost. I have never caught them in rivers where the tide ebbs and flows: perhaps salt water will not do for them. Any further information in "ours" I will gladly give. I have had them running away with my bait when fishing for trout at the bottom with a worm, much to my annoyance.—TIT SANDERS.

[52074.]—**Lathe.**—Your drawing is not complete enough to enable one to give very precise directions as to the making of the pattern and core box. A longitudinal view, as well as a section, is necessary. Simpler beds than yours appears to be are cored out, and you had better adopt the same method. I do not see why the fillet C should cause trouble—if in the top it will be fast, if in the bottom loosely wired on. ¾in. is thick enough for the bed; but if you will give a sketch longitudinally I will furnish information.—J. H.

[52075.]—**Legal.**—The wife in this case having obtained a magistrate's protection order, is in fact a feme sole, or single woman, in regard to any property which she becomes possessed of after the order is made, provided the order was entered with the registrar of the county court within ten days after the making thereof. Therefore I think "Dubius" would be perfectly safe in paying the legacy of £100 to the wife on her receipt alone, as the protection order makes her a single woman, and this whether the legacy was bequeathed before or after the date of order.—F. A. S.

[52076.]—**Paint for Tin Pots.**—I think a thick varnish, made of shellac dissolved in naphtha or methylated spirit, would answer well. I have one which I painted with this, and is used for salt water, which does not affect it at all. Give it two or three coats of the varnish.—R. A. R. BENNETT.

[52078.]—**Granule Battery.**—You can use the carbon as many times as you like: it only wants washing in warm water after being used.—WATT.

[52079.]—**Waterclosets.**—The rats may have assisted, but leaden soilpipes are most dangerous, as the gas usually corrodes them sooner or later, and then the foul air escapes into the house. Glazed earthenware pipes are infinitely the cleanest, best, and most durable, but require careful fixing. They are to be had at the Birmingham Sanitary Association, 47, Colmore-row, who also supply the hopper basin and trap, which is far superior to the disgusting trap lever basin usually used. If there is a garden near, and soil handy, nothing is cleaner, simpler, and healthier, than an earth closet. There is a capital little illustrated pamphlet on house drainage for 1s. or 1s. 6d.; but I have lost mine, so I cannot say where it is to be obtained. Every soilpipe should have a ventilating pipe, not under 4in. diameter, to convey all foul air to the top of the roof. If wanted, I can ascertain the address of the pamphlet, and send it.—STRETTON.

[52079.]—**Watercloset.**—The probable cost of glazed drainage pipes is very small. You might get them at 6d. apiece. They would last a very long time if protected from breakage. I am afraid, however, that with these materials and the labour of a good carpenter you would not be able to make a good job of the repairs. The holes in the lead pipe may have resulted from either of the causes you mention, but perhaps the first is the more likely one, especially if the soil-pipe is not carried up beyond the upper closet, and if it does not terminate with an open end, so as to form a free communication with the outer air. Whatever the soil-pipe be made of this is necessary, and it should be carried up of the full size all the way and terminate above the roof, the closet outlet pipes forming so many junctions with the main vertical soil-pipe. You ask for a book. I do not know that you can do all you wish to do from book knowledge; but if you can—that is, if you dare, from the nature of the bad case you have stated—wait a few weeks, Messrs. Crosby Lockwood and Co. will have ready the second edition of a small book written by myself, which may afford you some information. Your best way, however, is to have the place thoroughly examined at once.—C. S.

[52080.]—**Water Main.**—I do not see that you need take out the pipe at all. You could easily have the new connecting pipe flange made to same radius as your 20in. pipe, and drill a hole to the required size. You will see that this is a much cheaper and readier way than what you proposed, and only one joint to make in 20in. main, instead of three, as you would have with a new pipe.—LABOR OMNIA VINCIT.

[52080.]—**Water Main**—No, do not "take sledge and break pipe." Remove "pipe" more gently by taking out the bolts of the nearest flange joint; remove the back-flap valve, if there is one, and draw back the socket of the pipe you want to remove; clear off the end of the next one, and replace it with a new pipe with proper outlet, which you will have ready to put in without delay. —C. S.

[52081.]—**Marks on Silver Plate, &c.**—"Real" silver is the term used to distinguish silver from nickel, Nevada, and other imitations of silver, while "fine," "sterling," and "standard" are used to denote silver of the Government coinage, or standard fineness. The mark of a "lion passant" is used by the Assay Office to certify that the article has been assayed and is up to the standard.—W. A. T. C. H.

[52083.]—**Punching Machine.**—The pressure required for shearing or punching may be calculated by means of the following formula:—

$$P = fct;$$

t is the thickness of the plate; c the length of the cut; that is the breadth of the plate for shearing, or the circumference of the hole for punching; so that ct is the area of the shorn surface, and f the co-efficient of ultimate resistance to shearing; which may be estimated for steel at 30 tons per square inch. Therefore the pressure required to punch a 2in. hole 2in. deep is 377 tons.—LOANHEAD.

[52087.]—**Pressure on Crank-Pin.**—Usually, in beam engines, the weight of the transmitting parts is balanced—that is, the weight of the connecting-rod, cold water pump, &c., equals the weight of piston, air-pump, &c., so that there is no weight either for or against the piston. In such a case, the strain or pressure on the crank-pin is equal to the areas of the pistons multiplied by the effective pressures upon them. Now, if we apply this to your case, we shall obtain the following results:—Area of low-pressure cylinder = 490·875 sq. in. × 62lb. = 30,434¼lb., and area of high-pressure cylinder = 268·8 sq. in. × 18lb. = 4838·4lb.; but half of this can only be taken as effective, it having only half the leverage of the other end. Hence, the total weight on the crank-pin is equal to 32853·45lb., or a little over 14½ tons. Of course, should there be any weight acting for or against the piston, such weight will want adding or subtracting to get the true weight on crank-pin.—ENGINEER, Dewsbury.

[52088.]—**Black Stain.**—I don't think you will be able to get a stain to stand hot or cold water. Have you tried Stephens's black stain coated over with varnish?—A. BEST.

[52089.]—**Frosted Tin Tubes.**—This is done by washing the tin tube first with alcohol, which removes any grease, &c., on it, and afterwards sponging it with a mixture of one part hydrochloric acid, one part nitric acid, and three parts of water. (See "Moire Metal," Vol. XXXVII., p. 320.)—R. A. R. BENNETT.

[52089.]—**Frosting Tin Tubes.**—Under the heading of "Moire Metal," this query was answered in No. 950, p. 320. I believe the best method is to heat the tin plate until rather too hot to hold; then dip in a mixture of hydrochloric acid, 1; nitric acid, 1; water, 4. Rinse, dry in hot sawdust (which must be from non-resinous wood), and lacquer—the plate being still hot enough, so as to do everything at one operation as it were. I think Mr. Wenham was the first to describe this process some years ago in these pages, under the head of crystallising tin plates.—NUN. DOR.

[52094.]—**Lost Watch Wheel.**—To "R. E. B." —I cannot give you any information about the acid. As regards the second query, you do not say if it be a pendulum or balance clock. Firstly, assuming it to be a pendulum, perhaps the m.s. is too strong, as when wound up to the top it may cause the pallets to "bottom"—i.e., cause so great an arc of vib. as to dip the pallets into the spaces of the escape wheel until they butt or jam, and then rebound, causing quicker vibs. until the force of m.s. is relaxed: then the pendulum will vibrate naturally, and of course go slower than before, and this is very likely to be the case with a deadbeat pair of pallets. You must carefully look to this. Again, if there be banking pins to the crutch, the latter may touch the former; if recoil pallets, the *time* of vibration of pendulum will be shorter with more power, and slower when the m.s. is weaker. Secondly, if a balance, it may vibrate too much, and strike the bankings, or the outer coil of the balance spring may touch the stud or curb-pins when clock is wound up, and not do so when having gone down four or five days; curb pins may be too far apart, balance spring touching them when m.s.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "Practical Chemist" has replied to 51231; R. A. R. Bennett, 51421, 51613.

QUERIES.

[52118.]—**Tarring Posts.**—Is the application of gas tar a preservative to a redwood paled fence in the open air? I have always thought it was; but the principal of a large country joinery firm, who does a good deal in gates and fencing amongst farmers, says it is best to leave the fence in its natural condition, as the fir will last longer untarred. Who is right?—M. C. H.

[52119.]—**Misshapen Chest.**—Would any of your medical correspondents inform me if anything could be done for my son (18, and striking to a smith) who, unlike anyone else that I know of, has a sharp boney ridge in the centre of his chest, and says his head often aches in connection with this unnatural formation of his chest? Any information that would relieve him would greatly oblige.—T. T.

[52120.]—**Engine Query.**—Will the condensing power of the engine be reduced by cutting off the exhaust at an earlier part of the stroke?—C. Guillaume.

[52121.]—**Scribing Block.**—I shall be obliged if some of the readers will give me sketch and dimensions of a scribing block such as they use in most engineers' shops?—A. G. Bilcliffe.

[52122.]—**Phosphor Bronze.**—What is the best method of reducing an inch bar of cast phosphor bronze to No. 6 wire?—A.

[52123.]—**Oxide of Copper Battery.**—Would any of the readers, who have made and used this battery, give me information how to make it?—also their experience with its use, and if it can be applied to the working of electric bells with success? Is the "Sutton" storage cell any good to an amateur for working a motor and an incandescent light? Ivanhoe.

[52124.]—**Precipitation of Copper.**—Mr. Allen states in "ours" of last week, that by using zinc, a purer precipitate of copper is obtained than by using iron as a precipitant. In the practical assay of copper by the cyanide of potassium process, Steinbeck's, described in Mitchell's "Practical Assaying," last edition, I find it almost impossible to extract the salts of zinc previous to titration, and consequently, for years past have used iron. Will Mr. Allen or any of ours kindly tell me how to purify the copper in an easy and rapid manner when thrown down by zinc, or to prevent it from being contaminated by the latter? Mine Agent.

[52125.]—**Harmonium.** Would any of the readers of the "E. M." please state what should be the size of the apertures in the valve-board for a 2½ set harmonium, and the best way of fixing the valves?—also, whether it would be practicable to include an octave coupler on the instrument, and if so, give particulars for constructing the same?—Phono.

[52126.]—**Microscopical.**—Putting aside the question of cost, what is the best form of camera lucida to (1) work with the microscope vertical?—and (2) work with eyepieces of different power? Does Grunow's fulfil those conditions?—W. Lamont.

[52127.]—**Platinum Crucibles.**—Will any of our chemical readers kindly say what substances may not be fused in platinum crucibles? Has sulphur any detrimental effect, upon the metal platinum when heated to great heat, such as over the Herapath blowpipe?—Platinum.

[52128.]—**M.S. and L. Engines.**—Can any correspondent give the dimensions of the new M.S. and L. single engines running between Grantham and Manchester?—Lincoln.

[52129.]—**Polishing Tiles.**—Can any reader kindly inform me if it is possible to give a permanent polish to common red and black kitchen tiles? They are very dull, and in consequence show every spot of dirt, which requires a great deal of scrubbing to remove, whereas the polished ones are very easily kept clean.—H[illegible].

[52130.]—**Water Rate.**—The Water Company have sent to me a "revised rate" claiming four shillings per annum more than hitherto. In answer to inquiry, they have an anticipatory printed reply, quoting thereon Act 15 and 16 Vic. cap. 156, and they now make a charge of 4s. for the water closet, independently of five per cent. upon the full rental. My question is this:—Inasmuch as the w.c. forms *per se* a part of the house on which a percentage is already charged, does the law protect them in thus surcharging their customers? Will Mr. Wetherfield or other legal friend of "ours" kindly advise?—Markwell.

[52131.]—**Boiler Query.**—I have been making a model boiler. The plate is 1-16in. thick; all rivets ½in. apart; height of boiler 15in. by 6in.; firebox 5in. deep; inside casing, copper, 1-16in. thick. What pressure should it stand? It is a model beam engine I want it to work. Size of cylinder 1½in. bore, 3in. stroke, and condenser. What power should it have, and is one pound pressure of steam equal to an ordinary pound weight? If not, what is the difference?—Blacksmith.

[52132.]—**An Excellent Yeast.**—Although "E. R. D." has followed the directions as given by "Barley Bread," in reference to the above, from some cause the result hitherto has not been sufficiently satisfactory. Its colour and general appearance is certainly that of excellent yeast, but, so far as my experience has gone, it does not possess the requisite strength. It answers very well mixed with an equal quantity of other yeast, but useless by itself. As I am very anxious in the matter, any further information respecting it from "B. B." will oblige.—E. R. D.

[52133.]—**Sulphur in Coal Shaft.**—I am working in a shaft in which there is a large amount of sulphur which nearly blinds all the men and myself. I am obliged to lose two or three days frequently and be closed in a dark room. Symptoms are like sand in your eyes, smarting pain, and excessive moisture. What can I do to prevent or alleviate the symptoms?—Colonial Collier.

[52134.]—**Cabinet-Making.**—To "J. P."—As one who is much interested in the articles on cabinet making, I beg to ask "J. P." if he will kindly include in his pages the way to make a mahogany wardrobe of 4ft. or 4ft. 6in. in width? Nothing of the sort has yet been given in the "E. M.," and doubtless many would be glad to receive help and instructions in this besides—G. W. J.

[52135.]—**Mechanical Race Course.**—I shall be extremely obliged if any correspondent will inform me how the interior mechanism of this interesting toy is arranged? The mechanical race course I allude to is at the Royal Aquarium, Westminster.—A Seven Years' Subscriber.

[52136.]—**Galvanising Wrought Iron.**—In galvanising wrought iron are there any points to be borne in mind so as to reduce the injury to the iron as much as ever possible? In galvanising small forgings, some people dip the article into water immediately it comes out of the bath. Has this any effect on the iron?—T. B.

[52137.]—**Electro - Magnet.**—A 4in. signal bell whose magnet core was 2in. long by ⅜in. dia., wound with 7 layers of No. 28 wire, has been replaced by a 6in. bell, whose magnet core is 3in. long by ⅜in. dia., the bobbins 2¼in. dia., wire No. 20, 15 layers on each limb: weight of wire about 2½lb. A battery of 6 large size Leclanchés worked the 4in. bell powerfully, but the 6in. instead of being as expected (very much louder), can only be heard the same distance off. Was it a mistake to have wound with wire so stout as No. 20? Should a better result be expected by connecting the bobbins so that current divides and traverses each simultaneously? Would a Fuller's battery be more suitable for the magnet wound with No. 20 wire, or would two bobbins wound with about seven layers of No. 28 be more likely to get the full power out of the core with the existing battery of Leclanchés? It should be added that the six cells have, as an experiment, been coupled up for quantity; but with no better result. The line wire is only about 100 yards of No. 20, earth return. The advice of a practical reader would be much appreciated.—James Edwards.

[52138.]—**Copying Negatives for Lantern Slides.**—Can any kind reader give me full and explicit instructions for making good lantern transparencies from ordinary quarter dry-plate negatives?—Dozey G.

[52139.]—**Bearings.**—I have an upright shaft 6in. diam. with two bevel wheels and plummer block on top. The brasses in plummer block have worn about ⅛in. oval where the two brasses join, and it throws shaft out of plumb. I have turned brasses round about so as to put the shaft plumb, but the bearing is still larger than the shaft, and the shaft trembles. What can I do to make the bearing smaller? I cannot let the brasses together as they are worn the wrong way. There is no provision made to let plummer block cover together. Perhaps some of our readers have had bearings of the same, who will let us know what they did to them. I have been told that metal can be run into bearing. Hope some one will let us know how to use that metal and oblige.—C.

[52140.]—**Spinning-Mule Ropes Wearing.**—Will any reader kindly say what is put on to mule rim ropes, that drive the tin rollers, in the shape of grease (?), &c., to keep them from wearing away? Perhaps "J. P., of Burnley," having been 15 years in the spinning-room, will kindly say?—G. Hartley.

[52141.]—**L. & S.W. Engines.**—Could "C. R. M., of New Zealand," or any one else, give an account of Beattie's firebox, boiler, and feed-water heating apparatus at one time on this line? Also, were they adopted by any other co.? What sort of engines were those of Mr. Gooch, loco. supt. 1841—50?—W. B. P.

[52142.—**Resistance Coils.**—I am at present making a resistance box to contain 15 coils from ·1 ohm up to 5,000 ohms resistance The coils are to increase by the numbers 1, 2, 3 and 4. The box is 6 by 6 by 3½in. inside. Please let me know the thickness of G.S. wire for each coil? Wire wanted as thick as possible.—Volt.

[52143.]—**Chemical.**—I have been working out Thorpe's "Chemical Problems," but have been stopped by No. 43, and should be obliged by information as to the way to work it. Question 43: Determine the amount of aqueous vapour in a sample of air which yielded the following numbers on analysis Bunsen, :—

Air saturated with moisture.

Observation at lower level of mercury...	565·9
" " upper " in eudiometer	317·3
Volume corresponding to division 317·3 =	292·7
Correction for the meniscus....................	·4
Temperature of the air	20·2° C.
Height of the barometer	0·7469m.

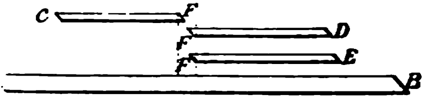
The same volume of air dried by calcium chloride.

Observation at lower level of mercury...	565·9
" " upper " in eudiometer	310·7
Volume corresponding to 310·7 =	286·0
Correction for the meniscus	·4
Temperature of the air	20·2° C.
Height of the barometer	0·7474m.

Also question 31. At what point are the numbers on the scales of Fahrenheit and Celsius identical?—Castor.

[52144.]—**Gun Query.**—For the last eight years I have shot with a gun made specially for me, and although it has not more than ordinary recoil, about four years ago I was punished with it, and this season at first day's shooting was quite crippled. I find that unconsciously I get the gunstock upon the muscle of the arm below the shoulder, where I am bruised at each shot fired. Have tried lengthening and padding stock and coat, and lessening charge—considerably deteriorating my shooting thereby. My gun would be none the worse if stock were shortened; but I am afraid that reducing the weight would increase recoil, besides destroying the balance of gun. Can any one tell me with certainty the effect of shortening stock, as it possibly might enable me to shoot more from the shoulder? Gun is 12 G.C.F., weight 7lb. 1oz., usual charge 3drm. powder, 1oz. shot.—H.

[52145.]—**Springs.**—Perhaps one of your readers will kindly give me some advice in the selection of a spring? The sketch will enable the matter to be better understood. A and B represent two pieces of wood about an inch wide and an inch apart; C, D and E are three brass blades lying between A and B. I want to find the most compact and suitable springs to fix in positions F, to turn the blades, when not held back, from right to left (thus describing a semicircle), as C is supposed to have done in the sketch. They need not be very powerful ones.—Inexperienced.



[52146.]—**Telegraph Wires.**—I have some buildings, and also a plot of land that may or may not be built upon in twelve years' time, which are networked over with telegraph wires. I shall be glad to learn if a twelve years' user of these wires, without acknowledgement or a special agreement, will give the Post Office authorities the right to keep the wires in position, notwithstanding that the altitude of the wires is so low as to prevent me from erecting high buildings on the plot, or elevating existing ones. This is a very important question, affecting, as it does, property all over the United Kingdom.—Blackburn.

[52147.]—**Chilled Roll Turning.**—What travel should a gauge have to secure a good tight fit?—A. R. Wilkinson.

[52148.]—**Testing Lightning Conductors.**—What is the practical method of testing a lightning conductor for good earth? If I connect one pole of a battery through a galvanometer to the lightning conductor, and the other pole temporarily to earth, with no gas or water pipes available so as to be sure that this second (temporary) earth is a good one, supposing I get a weak deflection or none at at all, how am I to be sure that the fault does not lie in the temporary earth connection, and not in the permanent earth of the lightning conductor? Or is there some other better mode of testing?—H. E. H.

[52149.]—**Cotton Spinning.**—Can any reader inform me of what steel cotton spindles are made? Would it be suitable for making cutting chisels or drills?—J. C.

[52150.]—**Poor Law.**—To Mr. Wetherfield or "Lex."—A man leaves his wife; she goes to the union; the guardians take proceedings against him; the magistrate makes an order for him to pay so much per week; he pays it for some time, then stops payment. Can the magistrate enforce his order without the wife again applying to the union, and is she bound to make a statutory declaration or affidavit that she is destitute?—P. M.

[52151.]—**Ammonia and Alcohol as Sources of Motive Power.**—I have latterly been experimenting with various gases, such as ammonia, alcohol, &c., with the view of ascertaining if they can be used as a means of producing motive power in engines, and I supposed I had attained satisfactory proof that these, and similar gases, might be used as a vehicle of heat in lieu of steam. On looking over the records of the patent office, I find, however, that several scores of patents have, at various times, been taken out for modes of using these and other gases and vapours as motive agents, and several of these patents give descriptions of engines which, apparently, would fulfil all the conditions required. Nevertheless, no engine working by the expansion of these chemical gases is at present in use, as far as I am acquainted with. It might be of general interest to your readers, as well as to myself, if you, Sir, or any of your correspondents would kindly inform me, through your columns, why engines working by such gases have hitherto all proved failures? Theoretically, there ought to be a great saving of fuel, as these substances have a very low boiling point, and at temperatures much below 212° give a pressure of double or treble that of steam at 212°. I am inclined to suspect that the reason of the failures has hitherto been on account of the difficulty of confining the gaseous fumes within the present form of steam-engine and packings now used. Any information you can give will oblige.—EXPERIMENTER.

[52152.]—**Frush Dynamo Machine.**—Will "Light" accept my best thanks? In the winding of my machine at first, I think I wound it similar to his suggestion, connecting the inner end of one coil to opposite coil's commencing end, the wires running diagonally across ring, with very poor success. The description given in *Engineering* is this: Wind all coils in one direction, and connect all inner ends together, and carry outer ones to commutator. This I've done without meeting with any better results. The arms or boss which carry ring are not insulated from each other. Is this necessary? If so, the fault is here. The arms are in one piece, and driven tight into ring. Will "Light" kindly assist me in this?—WILLIAMS.

[52153.]—**Lens.**—Will Mr. Lancaster kindly help me with the following? I intend grinding a compound condensing lens, 8in. diameter, for photographic enlargements. The front combination I purpose using with the condenser, is a good half-plate portrait lens of 8in. focus. I shall be glad to know what are the best curves to grind each lens, and what glass to use? Will ordinary plate-glass answer for this purpose?—JAVAN.

[52154.]—**The Ross Battery.**—This battery for the electric light is mentioned by Lord Bury in the July number of *Nineteenth Century*. The inventor is Mr. O. C. Ross, C.E. Can any obliging reader tell me how it is made? A still more convenient battery is mentioned in the *Times* of Oct. 27th, as being employed on the Great Northern Railway in lighting Swan's incandescence lamps. It is said to be charged with a chemical which absorbs the hydrogen that is given off.—DYNAMO.

[52155.]—**Bicarbonate of Soda.**—Will some reader kindly give the details of the process for manufacturing bicarbonate of soda from soda crystals by means of carbonic acid?—A. D. C.

[52156.]—**Photographic.**—Lately I have had a great difficulty in taking my negatives clean, for when the plates have been developed and fixed, I find there is something forms upon the film like scum, which, when dry, appears to be like chalk. I find I can remove it by gently rubbing with a piece of wool; but the film being tender, it gets scratched, which causes further trouble. My bath appears to be quite bright and clear. My developer is always new; I use Mawson's collodion. Could any of ours tell me the cause and how I can correct it? And could you also inform me if cyanide should be thrown away as useless if it turns the colour of sherry: I find it does do so, when the redeveloper turns dark upon the plates? A developer giving great density, such as would be suitable for taking advertising bills, copying testimonials, &c., will oblige.—G. D. A.

[52157.]—**Legal.**—To MR. F. WETHERFIELD.—A daughter possesses property from her deceased parents; she dies unmarried; her brothers and sisters are also deceased. The next of kin is advertised for to her mother, in consequence of the father being illegitimate. Which is entitled to the property, the grandson of her mother's sister by first marriage, or son of her mother's sister by second marriage?—and are the sisters of the son entitled to a share, or the son to all, if any? Parents of son and grandson deceased.—W. S.

[52158.]—**Slide Rest.**—The bottom slide of my rest has a defect which I cannot understand. In surfacing with a fine point tool, at regular intervals, it seems to spring from the work and not to cut so deep, giving a corrugated appearance, and this is the case in working outwards from the centre, more than in working inwards to the centre. The screw thread is 10 to the inch, and the corrugated appearance is about the same distance apart; yet the slide appears to fit well and tight, and there is very little backlash. Can any of the readers of the "E. M." say what is the cause, and suggest a remedy? It is not enough to signify in ordinary turning, but in facing up work for ornamental turning ivory it is a great nuisance.—G. H. R.

[52159.]—**Speed of Dash Wheel.**—Will any of "ours" direct me how I am to proceed in the following matter? I am erecting a cylinder 6ft. diameter by 3ft. wide, divided into four compartments like a dash-wheel, and made of wood. I want the material that I am going to work to be knocked about from one side to the other, and I want the machine to revolve at a good speed, but not at that rapid rate that the centrifugal force will cause the material to circulate round with the periphery of the wheel. Neither do I want a speed that the material will only slip round and not be thrown—which is of the utmost importance that it should be. What size tooth wheel shall I want on the cylinder?—size of tooth-wheel and rigger in connection with same?—also size of rigger from main shaft, to produce the effect I desire?—or shall I want any tooth-wheels at all, but simply riggers?—if so, what size? Understand the material I shall work is heavy. My engine is a 3 h.p. vertical worked at 30lb.—POOR MAN.

[52160.]—**Battery.**—I have made some electric clocks which answer well while the battery lasts; the one now in use lasts about five or six weeks; by that time the zinc plates are eaten away—some of them completely through. The battery is, I believe, known as the Walker battery, and consists of a carbon and zinc plate in sulphuric acid and water. Is there any battery that will last longer than this one? The circuit is closed for a half-second twice a minute, and the current needed to drive the clocks is about equal to that given by ten No. 2 Leclanche cells.—SALOPIAN.

[52161.]—**Spectacles.**—In using spectacles to correct the defect of short sight I find that many make the type appear much smaller than it really is. Will Mr. Lancaster, or some other optician, kindly say if this should be thus? I also find that after using the specs. for a time, on removing them vision is for a moment or two misty. What No. spectacles should be used by one who cannot see to read this query clearly at a greater distance than 6in., the object being a pair of specs. that will enable him to read it, or music, at a distance of 2ft.?—S. R.

[52162.]—**Legal.**—A grocer licensed to sell spirits, &c., supplies the wife of a customer with some (say) brandy, and at her request he puts it down in the bill as "sugar" supplied. The husband, after paying for it, discovers the real state of affairs. Has he any legal power to prosecute the grocer, and if so, under what category would such a case come—as "fraud," "obtaining money under false pretences," or what?—AN ANXIOUS ONE.

[52163.]—**Pile Work.**—Could any one kindly inform me what is the best way to make looped or terry work without using wires?—WEAVER.

[52164.]—**Leather versus American Cloth.**—I have seen it stated that "the American cloth used for covering perambulator hoods is dangerous to health, owing to a poisonous lead compound used in its manufacture." Is this correct? For this reason, and on account of the cracking, I wish to re-cover mine with real leather. Will some practical subscriber of ours please give me a few hints, and the name of the correct leather to use?—F. W. P.

[52165.]—**Slide-Rule Formulæ.**—I should be glad if someone will point out the broad principles on which these are constructed. I can make my own formulæ in cases which can be solved by simple proportion; but I do not yet grasp the mode of tackling formulæ involving quantities which vary as the square or square root of other numbers. For instance, what would be the steps leading to the following setting of the rule?—

A. 183
B. Ft. per min. of piston
C. Cub. ft. per minute
D. Dia. of pump in inches

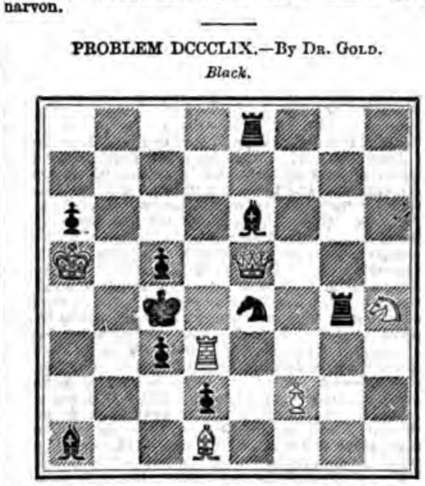
This setting gives the diameter of a pump direct, and I should like to know the principle on which such settings are determined.—GLATTON.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Bryn Rhedyn, Llandwrog, Carnarvon.

PROBLEM DCCCLIX.—By DR. GOLD.

Black.



White. [6+10

White to play and mate in three moves.

IN the last number the name of the second prize-winner should have been G. J. Slater, that of the third D. Mackay. C. Planck is fourth in order.

SOLUTION TO 857.

White.	*Black.*
1. Kt to Q B 7	1. Anything
2. Q, R, Kt or B mates or Kt discs. mate	

(Eight variations.)

NOTICES TO CORRESPONDENTS.

CORRECT Solutions to 856 by F. T. Bidlake, Dicky Sam, Rev. W. Anderson; to 855 by W. Anderson; to 857 by R. A. Bennett, S. Seymour Follwell, F. V. P., Dicky Sam, F. T. Bidlake, C. Planck (its main points are the near ties by 1. B-Q R 3 and B-Q 6, and the neat idea embodied in the play of Black's Queen's Pawn. There is a bad dual if 1. $\frac{\quad}{\text{B-B 5}}$ and minor duals to two moves with Q; still, I consider it an extremely fine problem).

J. JOWETT.—We will find you an opponent as soon as possible.

A. SEWELL.—We should advise you to get Gossip's "Analysis of the Openings" and study them carefully. Also a good collection of games, such as "Chess Masterpieces" or Staunton's "Chess Praxis." We are not sure of the prices. Join some club and play frequently with better players than yourself, accepting odds.

C. E. B.—Your four-mover can be done thus 1. $\frac{\text{Kt-K4 (ch)}}{\text{K-B4(best)}}$ 2. $\frac{\text{P-Kt 4 (ch)}}{\text{K-B 5}}$ 3. R-B 5 (ch) and 4. R mates.

WE have received Mr. J. P. Taylor's report of the two-move tourney. He found it exceedingly difficult to settle the order of the first four problems; but the following is the result:—

Motto.	No. of Problem.	Marks.	Author.
1. Chacun à son Gout	849	30	D. Mackay.
2. R. I. P.	838	29	F. O'N. Hopkins.
3. Timeo Danaos	853	28	A. E. Studd.
4. What's in a Name?	846	27	C. Planck.

Mr. Mackay therefore wins the first prize, a copy of "English Chess Problems," and Mr. Hopkins the second, which should be "Chess Chips"; but as the work is out of print, one of equivalent value must be substituted.

THIS Tourney has also been a great success as regards the *quality* of the problems entered: we only wish the number had been greater.

NEXT week we shall publish the result of the Solution Tourney.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Batteries: Nos. 715, 718, 721, 724, 728, 731, 734, 741.
Bellows camera: Nos. 475, 480, 894, 897.
Bookbinding: Nos. 613, 627, 770.
Cements: Nos. 377, 729.
Coils, induction: Nos. 620, 640, 779, 797, 832, 885
Coils, medical: Nos. 844, 898.
Copying processes: Nos. 750, 753, 761, 762.
Electric bells: Nos. 545, 558, 797.
Electric machines: Nos. 368, 380, 628, 759, 840, 846.
Electro-magnets: Nos. 756, 772, 783, 864, 872.
Electro-plating: No. 833.
Lacquers: Nos. 429, 475, 622, 866.
Magneto-electric machine: Nos. 376, 589, 783, 826.
Nickel-plating: No. 808, 811.
Silver-plating: Nos. 830, 868, 869, 870, 871, 874.
Telephones: Nos. 692, 695, 747, 781, 809, 825, 846, 853, 865, 894.
Varnishes: 321, 478, 619, 675, 691, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Oct. 31, **and unacknowledged elsewhere:—**

W. H. HARLING.—W. Lachlan.—Mawson and Swan.—J. B. Bowman.—J. W. and W. Grimshaw.—Experimenter.—Good Time.—A Fellow of the Royal Astronomical Society.—A. W. Nicholls.—S. E. Kelf.—J. Nicholls.—C. R. T.—J. R.—Clock Star.—J. R. Pridham.—A. S. L.—One who is Perplexed.—A. Laundry.—A. Best.—W. R. H.

A. S. (There is no known method of doing what you require. That is the reason the carbon paper is used.)—H. NETTLETON. (See several recipes in back volumes. Slightly damp the spots and expose to sulphur fumes; or try solution of chloride of lime, carefully washing off afterwards. It is not easy work, for something depends on the nature of the spots, and very much on the experience of the operator.)—JACK, THE POOR BOY. (The only way is to make a flue somehow or the other, for even the oil-stove will necessitate ventilation. Perhaps a fire could be lighted outside, and be made to warm the office by heating the air supply, or by radiating heat from a metal screen let into the wall. It depends entirely on the construction of the office.)—INQUIRER. (You want a medical coil, we suppose. See the index of the last volume.)—FLEUR DE LIS. (Read up the subject in back volumes, or the present series on "How to Make a Dynamo.")—CHOIR MASTER. (It is made of glycerine 4, glue 1, and sufficient whiting to colour, known by several names. See list of Back Numbers above, inserted in this column first number in each month.)—AMATEUR SMITH. (The degrees of temperature of steel at various colours have been frequently given; but if you will read an article on p. 561, No. 842, it may give you the information you require. The other temperatures are estimated only. 2. Your rule is quite correct for any degrees above freezing point. We do not understand how you could find it incorrect, for each degree C. is equal to 1·8 degree Fahr. Your thermometers must be deranged. 3. Use a crucible; but the best way is to make a solution of the borax, and crystallise it out at a temperature between 60° and 80°. The octahedral crystals are better than the crude borax for all purposes of soldering. Some smiths boil 16 parts of borax with one of sal-ammoniac for an hour, and when cold grind into powder. That is said to be excellent for welding cast steel.)—Etna. (See previous answer, and several replies in back volumes. There are many tables of the kind; but as to the weight that has generally to be worked out for every beam, &c.: something, too, depends on the quality of the iron. Molesworth's Pocketbook would be useful to you.)—Mechanic. (See Dr. Edmunds's paper on Acne, p. 543, No. 881.)—Sanitary. (It is used as the basis of a disinfectant, but it is doubtful whether it has much power. It is solid at ordinary temperatures, but vapourised, and mixed with air, forms an explosive atmosphere. It is slightly soluble in boiling water, and is not poisonous.)—Bunsen, Edinburgh. (How can we suggest without seeing it? Try the effect of the luminous flame by stopping the air supply through the pipes.)—American Organ. (Must run a rod across to take hold of all the mutes by levers; but no one could give explicit directions without examining the instrument.)—Young Glasgow. (Alum water would be the answer; but you had better ascertain the cause before applying any remedy—that is, obtain the advice of a medical man.)—Melbourne. (We know of nothing better than starch paste.)—N. M. D. (Certainly; portable steam cranes, for instance.)—J. B., Stainbro'. (Indiarubber solution we suppose you mean. That will adhere firmly to fresh-cut or clean surfaces of leather. 2. Soak in water and hammer while still wet.)—G. Smith. (Try French polishing. See pp. 175, 227, Vol. XXXII. You will find that in all probability the organ was purposely polished what you call "badly.")—R. G. (The method of putting invisible patches on boots with a solution of guttapercha in bisulphide of carbon was described on p. 560, No. 960. Indiarubber solution will do as well—perhaps better.)—Phythis. (There is no difficulty in getting needle manganese from any respectable dealer in chemicals or electrical sundries. See advertisements. 2. We scarcely understand, because if you have been a reader since 1876, you must have seen the very illustrations to which we should refer you. Try, however, pp. 38, 65, 90, last volume, and say what it is you wish to know, if not there.)—Plato. (There is nothing the matter with it, except that it is not a first-class watch. You should keep it as much as possible in one position. If you wish to know the cause, see the indices of recent volumes.)—R. J. P., Port Said. (We know of nothing better. Heat in an iron ladle and stir quickly with an iron rod. If it is inclined to be sticky add a little rosin. 2. It can only be liquefied by great pressure and low temperature. 3. If you mean the common rosin or colophony, it is soluble in turpentine, ether, alcohol, the volatile oils, and the fixed oils when aided by heat.)—Enquirer. (Molesworth's Pocketbook and similar works give table of weights. We do not know of any special tables.)—J. P. (You can apply for the surplus paid. Your local surveyor of taxes or collector will put you in the way.)—Edwards. (Much too serious for amateur homœopathic treatment. The disease is probably of a scrofulous character.)—W. H. Clarke. (We have no volumes on sale earlier than Vol. XXIV.; but you would probably get them by advertising in the "Sale" column for them, though we expect you would have to pay more than the published price, as they are scarce. The *British and Foreign Mechanic* was published separately till we incorporated it. It only published forty-three numbers separately.)—Fiddler. (Very glad to hear from you again; but sorry we are unable to insert a tenth of the letters that reach us on "Thought Reading," "Matter and Life," &c. The fact is, we have had almost enough of the subject, and are, besides, terribly pressed for space just now.)—Tradesman. (The city authorities can demolish your premises; but will, of course, compensate you. If you are dissatisfied with the amount they offer, and think you have a good case, you had better instruct your solicitor to sue them for the amount you claim, and let a court of law decide the matter. If the amount offered is anything near the honest value of your premises, take it and avoid litigation.)—Beehive. (Yes; publication would make the use of the additional substance public property.)—Alfred Slater. (Summon him before the magistrate, who will order him to abate the nuisance.)—Enquirer. (Mechanics, geometry, arithmetic (the higher branches), and some knowledge of the physical sciences, chemistry, &c. 2. See any list of books, such as that issued by Mr. Calvert, Great Jackson-street, Manchester. 3. There is no examination. 4. Seven is the usual term. Wages vary with the circumstances—particularly whether a premium is paid or not.)—Old Subscriber. (You are hard to please. If you want the substances named at all, you require only a few grains.)—Amateur Electrical Engineer. (We can only refer you to the indices, where you will find references to a number of transmitters.)—Apprentice Draughtsman. (The blue process was described so recently as p. 325, No. 950; also p. 64, No. 914.)—J. H. (You must first make the pattern, then the mould in proper sand, all of which details have been explained recently. For so small a quantity, one of Fletcher's furnaces would be best. See p. 394, Vol. XXXVII.)—J. (What do you want to do with it? See p. 455, last volume.)—J. W. B. (We gave a brief note on p. 36, and know no more than we found in the *Times*. We do not think it at all probable that the "inventor" will submit his motor to the criticism of experts. The account given in the *Times* is simply absurd.)—Warragul. (See p. 316, No. 924, and the indices. We cannot help you in the matter of "moon-dials.")—A. S. (You will find recipes for non-conducting compositions in many of the back numbers. It would be useless to quote, because you might not find the substances where you are going. Soda ash, or caustic soda, is useful for boilers, but much depends on the nature of the water.)—La Bouchere. (All your queries have been answered many times. For the mirrors, spread mercury on tinfoil, laid on a flat surface. Push the cleaned glass on to it in such a manner that it skims the mercury, and then weight down. The object is to bring a perfectly clean surface of mercury into contact with the equally clean surface of the glass. 2. For silvering, see p. 544, Vol. XXXV. The silvering paste you apparently mean is made of chloride of silver 3½oz., cream of tartar 7oz., common salt 10½oz. Reduce to a paste, and rub on the cleaned articles with a cork. 3. For regilding picture frames, see p. 258, No. 870.)—J. S. B. (If you cannot use one of Fletcher's gas burners, the water can be kept hot a very long time by inclosing the can in an airtight vessel, thickly lined with felt or other nonconductor. See indices.)—C. T. Ball. (If it lasted five or six hours you ought to be well satisfied. None of the bichromate cells are capable of running for a month (!) at full power—nor any other. Read up the subject in back volumes.)—H. E. H. (It is a defect inherent in the instrument, the exact cause of which is not known. It has very little to do with the matter to which you refer, because that is common to any one note, whilst in the telephone a number of notes, so to speak, crowd on one another. Read up the question in back volumes.)—Rosicrucian. (We do not understand what it is you wish to study. The spectroscope is explained in many textbooks, and there is a great deal about it in back volumes. Mr. Browning publishes a little book which may be useful to you.)—Pumper. (Your queries are much too vague or too wide. We cannot afford space to illustrate the details of a waterworks. You will find much information in "Waterworks for Cities and Towns," published by Lockwood and Co., Stationers' Hall-court, E.C.)—J. E. A. (So far as is possible your questions have been frequently answered recently. Lamps are now made of different power from one candle up to forty and more. The battery power required would depend on the lamps. Look up your indices.)—W. Ainsworth. (The preliminary rules refer to others, which can be had from the office. You had better wait until the new rules are published in their entirety.)—Bromide. (Perhaps it is given in the part "to be continued.")—A. G. D. (They are first carefully coated with isinglass size, and when that is thoroughly dry with best paper varnish. See that every part is covered with the size.)—Carrossier. (It was "chilled," that is the cause. Try what you can do with a light rubber moistened with spirits, or with a mixture of spirits and turpentine. 2. A series of articles on the subject of cart and wheel making was concluded in Vol. XXXVI.)—The Only Jones. (A variety of telephones have been described in back volumes; but to use one for business purposes would no doubt be infringing the patent. How would you obtain permission to erect the wire? 2. Gower-Bell transmitter, Bell receiver, and a switch board devised by some of the officials. They are all so sensitive that we doubt whether anyone has compared them. 3. Remove with putty-powder or rouge, and rub the wax on when the pipe is warm.)—Chelmsford. (You should have referred to number of reply, or at least to page. If it is the fault of the paper, surely that ends it. The second question is answered in effect in many back volumes, and in any handbook of the art. We should need to enlarge the paper to insert replies such as that solicited.)—P. J. D. (We do not remember the figures, but there are more acres in Yorkshire than letters in the Bible.)—Steam Ship. (At any mercantile marine office, or from the Registrar-General of Seamen, Adelaide-place, London-bridge.)—Broin. (Cover it with Leroy's composition. 2. Doubtful if any varnish will last long.)—A New Start in Photography. (Must be some fault in the burnisher, or in your method of handling it. 2. Due to over exposure and too much pyro.)—A Punt Maker. (Will not the sketch on p. 560, last volume, help you?)—T. R. S. (How can any one tell you how to introduce a brake that does not exist! If you wait until January next you will be able to obtain provisional protection for a sovereign, and then you can explain your ideas and show a model to any of the railway managers; but they have so many designs of the kind submitted to them that you will do well not to be disappointed if they decline to take up your invention.)—Inventor. (The question is not sufficiently definite. Under the new Act, notice will be given to both applicants where a second invention is entered before a patent has been granted to the first. If a patent is granted to the second, it will be as valid as any patent—that is, it will be void if when tested in the courts a prior patent covers it. 2. The sale of the article made under the first invention will not affect the patent.)—T. F. (We forget the exact sizes; but you can ascertain by writing to the office.)—W. E. Callaway. (One was illustrated on p. 112, so recently as Oct. 5.)—H. D. (Many metals when remelted lose their properties to a certain extent. Copper is not an exception.)—Tremolo. (See p. 330, Vol. XXI., and answer to "One in a Fix" on p. 139. It cannot be easily added unless there is a board between bellows board and reeds.)—Onward. (The manganese is mixed with carbon. See the indices under "Manganese" and "Leclanché.")—Electrician. (Nothing.)—Ignoramus, An Old Subscriber. (We answered you in this column on p. 162. Mixtures of coal gas and air, or of hydrogen and oxygen, will do. Other mixtures will also explode. It seems strange that the lecturer did not mention what he used.)—Anxious. (If you have subscribed to this journal for "some 20 years," you appear to forget that there is such a column as this, and when you write a second time add to our work by using another signature. Your question was answered on p. 139, to the signature "H." See pp. 527, 552, Vol. XXIX.; but take medical advice in time. See Dr. Edmunds' reply on p. 310, Vol. XXXV.)—Plum Rule. (We know of no rule except rule of thumb, which varies in different shops. Surely you can see some at the tool shops, and make yours to somewhere about the same dimensions.)—Intending Emigrant. (We cannot advise emigrants, especially when they have "no trade." For your ailment Australia would be a good climate, so would any of the countries having a dry and clear atmosphere. See p. 171, Vol. XXXIII., and the indices for remedies.)—Thos. Nicholls. (Read up the articles on the subject in recent volumes, and those now in course of publication.)—M. C. H. (Merely indicate the number of leaves in a sheet; the dimensions depend on whether foolscap, demy, crown, &c., sized paper is used, and even then only approximate measurements can be given.)—J. J. Clipsham. (You must burnish them if you want higher polish. See p. 169, Vol. XXXV.)—Learner. (Get Mr. Calvert's catalogue from Great Jackson-street, Manchester. The paper named is published in New York; can be had here only by subscribing for it.)—P. H. R. (Is not your query answered on p. 113?)—Chesterfield. (What with the ink you use and your handwriting your letter is nearly illegible. As far as we can see, the marriage was legal. If you have not the means to spare, keep out of Chancery and let the property go.)—J. E. H. (We have heard of similar cases before, but can hardly account with any certainty for them. Several hypotheses might be offered, but we have not the space to spare—nor, we regret, for the letter on "Life and Matter.")—Bertie. (Into a shop by all means.)—One of Ours. (We think the Statute of Limitations bars any claim by the executors.)—Silex. (The firm is a good one, and the contributor named is a member; but you cannot expect what you want for 6s. 6d.)—Caution. (He is, of course, not liable. If he had exposed the child in the carriage he would have been punishable, and justly: but do you really think fathers of families are to stay away from work when their children are down with scarlatina? With proper care the risk of infection is slight. Second query shall be inserted next week.)—Murano, Tasman. (In type.)

E. R. B.—J. N.—Thor.—A. R. S. M.—W. Turvey, and others have replied to queries already similarly or adequately answered.

Sixteen words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions, and in cases where the amount sent exceeds One Shilling, the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O's.

The address is included as part of the advertisement, and charged for.

Advertisements must reach the office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 1d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 1d. each copy, to cover extra postage.

Vols. XXIV., XXVII., XXVIII., XXX., XXXI., XXXII., XXXIII., XXXIV., XXXV., and XXXVI., bound in cloth, 7s. each. Post free, 7s. 9d.

Vol. XXXVII. now ready, price 7s.; post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI. and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Ointment.—A cure for all.—This invaluable Remedy, if well rubbed into the system, will reach any internal complaint. It cures sores or ulcers in the throat, stomach, liver, spine or other parts. For bad legs, old wounds, sores, gout, rheumatism, and all skin diseases, it is unequalled.

OUR EXCHANGE COLUMN.

AND WORLD OF SCIENCE AND ART.
FRIDAY, NOVEMBER 9, 1883.

THE DUKE OF ARGYLL ON GEOLOGY.

THE jubilee of the Edinburgh Geological Society was celebrated last week with a conversazione and an address by the Duke of Argyll, who took for his subject some of the more interesting problems which have been presented to us by our knowledge (such as it is) of the geological history of the globe. In his review of the salient features of modern geology, the Duke preferred to dwell on the immense extent of our ignorance compared with the little area over which our knowledge has been established, and he did not hesitate to point out that those very views which he regards as erroneous have been the means of immensely increasing our knowledge of facts. That is the great advantage of rival theories when supported by men capable of putting their own views forward in definite shape and based upon observed facts. In fifty years—since the establishment of the Edinburgh Society—we have made great advances in geological knowledge, and views then held with much show of reason have given place to others based upon a more intimate acquaintance with the strata and life-remains of the earth. The leading idea of the Huttonian hypothesis was the uniformity of geological causation — an hypothesis which led to the famous formula that in geology there is no trace of a beginning, no symptom of an end. It is not to be wondered at that such a doctrine was at once stamped as atheistic, a charge that was not withdrawn altogether even when it was explained that Hutton meant only exactly what his words said, and that for a beginning we must seek beyond the boundaries of geological phenomena as then known. The Duke of Argyll says that it was not possible to be really satisfied with the Huttonian hypothesis as a full and final account, for some other key to geological facts than mere mechanical repetition was needed, and that has been found within the last fifty years in the recognition that the rocky records contain indubitable evidence of a rising and expanding fauna. Following Hutton and Playfair, came Lyell, the great law-giver in the philosophy of geology, as the Duke calls him, although he immediately afterwards states that Murchison never did accept Lyell's doctrines as an adequate or consistent explanation of numberless facts respecting the succession and condition of the rocks. Murchison could not conceive of those facts being all accounted for on what he termed the "bit by bit" theory. The Duke, however, does full justice to the work of Lyell, and remembers the keenness and enthusiasm with which the great geologist often related to him some new discovery illustrating the vast antiquity of even the last and latest changes upon the surface of the earth; but he suspects that Lyell, like most of us at times, confounded two very different things—the continuity of causes and the uniformity of effects. In the first of those the Duke believes, but he cannot believe in the second, and it is because he accepts the former that he finds it impossible to believe in the latter. Everything that appears to us to be in stable equilibrium is being attacked by causes acting with infinite slowness; but a time must come, with more or less suddenness, as we call it, when, the equilibrium being overthrown, a "catastrophe" follows. These catastrophes have homely illustrations in every-day life, and the traveller not infrequently sees them on a larger but still small scale in volcanic eruptions, tidal waves, and disruptions of apparently permanent mountains of ice in the Polar regions. The energy which produces those effects is of secondary magnitude to that which has given a definite direction of dip and strike to whole masses of sedimentary deposits, which is far deeper seated and more powerful than that which has brought about the raising or destruction of a volcanic cone at some comparatively isolated part of the globe. The outburst of a volcano is only the sudden revelation of causes which have long been silent, but have never ceased to work, and it is reasonable, arguing from the known effects of volcanic eruptions, to believe that similarly sudden revelations of a more central force have produced the effects we witness on the crust of the earth. Such catastrophes as human beings have witnessed and recorded are measured by the scales of pigmies, and are really of but infinitesimal magnitude on the scale of Nature. The upheaval of such a mound as that of Mont Blanc, depicted on a circle 64ft. in diameter, looks almost infinitesimal; the greatest irregularity on the earth's surface, reckoning from the highest height to the deepest depth, is less than 60,000ft., and, stupendous as that may seem, it is really very small compared to the size of the earth. As regards any visible effect of subterranean forces upon the crust, there is no so-called catastrophe which is not well within the reach and compass of the forces to which it has been ascribed; and if we cannot interpret with any approach to agreement those changes which have taken place in, as it were, our own time, how shall we attempt to interpret those which occured in palæozoic and mesozoic ages? The doctrine of uniformity, as understood and applied in England, has, the Duke of Argyll believes, long exercised a most injurious effect on some of the more pressing of geological problems—those concerning the most recent events—such as, e.g., the coming on of the glacial age; the great submergence which accompanied it; the coming in of the great Pleistocene mammalia; their destruction, and the breaking up of old surfaces which accompanied that destruction; the distribution of gravels and muds; and so on—all questions concerning which various discordant theories are advanced, which the Duke thinks are directly due to the prejudices and prepossessions of the Uniformitarian Theory. He accepts as one of the most certain conclusions arrived at by geologists that there has been, very lately in the scale of geological time, a period when the climate in these latitudes was glacial: he lives amongst the facts which prove it, and he has no doubt that ice has worked on the Argyleshire hills in the two forms of glaciers and floating masses. It is also fairly certain that the ice worked at two levels, one about 30ft. above the present sea-level, the other at a level much higher up the flanks of the hills, and, as regards the lower ranges, at or above their summits. The conclusions which have been arrived at as to the higher level do not agree altogether with the Uniformitarian hypothesis, for the glacial sea, if it ever existed, has not left any evidence of a prolonged stay on the mountains of Argyleshire. There are no beds containing marine shells, the relics of animals which might have lived and died on the spot; and in the rare cases in which they are found at all they are generally broken, or are so grouped as to show that they were empty shells when drifted and imbedded where they rest. In view of those facts, the Duke of Argyll says that the submergence of the mountains under a glacial sea must have been essentially transitory in its character, whilst the extreme recency of both the submergence and the re-emergence, belonging as both do to the times of the existing fauna, compels the supposition of movements which have been relatively very rapid. That is one phase where, he thinks, the Uniformitarian shoe pinches; he finds another in the boulders, for, as he says, for one perched boulder in the Highlands which can be accounted for by the lateral moraines of a glacier there are hundreds of thousands which lie where no glacier can ever have placed them; further, he urges that there is no proof that an ice-cap ever existed, or that if it did it could have placed boulders where they are now seen. The glaciation of the mountains was, he thinks, accomplished by the infringement of floating sheets or masses upon particular portions only of the surface. Speaking of the Loess, the Duke does not pretend to solve all the difficulties; but he is sure that many would be removed if we did but face the conclusion that there was over a large area of the northern hemisphere a great depression and a great re-emergence of land towards the close of the glacial epoch.

As to the cave deposits—those of the countries bordering on the Mediterranean—which consist of a closely-packed mass of remains of the great Pleistocene mammalia, it is certain that no agency but that of water could have brought them and huddled them up together in such heaps at one spot. Lyell's explanation, however, seems to the Duke of Argyll to be very unsatisfactory. He does not conceive it possible that the animals fell into rivers and the latter into swallow-holes or subterranean passages, which, in time, became choked with the skeletons; but he does think it feasible that some movement of the earth's crust simultaneously opened swallow-holes, produced an inundation, and swept the animals from their haunts to the caves in which they are found. These caves and fissures so packed with bones are now almost universally dissociated and broken off from the old lines of drainage, and it is pertinently asked whether the dissociation may not have been contemporaneous with the inundation which swept the animals to their tomb. Let any man go even to the cave of Brixham, says the Duke of Argyll, and he will see at a glance that since that cave can have been the bed of a stream, as beyond all question it was very lately in geological time, the whole physical geography of that part of the earth's surface must have been entirely broken up and changed. Nothing but the bondage of an hypothesis which is not founded upon any sound philosophy could, he thinks, banish from our consideration the high probability of one simple explanation—that in very recent times great changes in the moulding of the earth's surface have occurred over a great part of Europe with sufficient rapidity to cause great destruction of animal life, and during the progress of the submergence to sweep the bodies of the drowned creatures into the fissures and swallow-holes which were opened or enlarged at the same time. If the Uniformitarian hypothesis were true, we ought to find caves and fissures containing remains from the Eocene and Miocene epochs. The accumulation of Pleistocene mammalian remains which forms the Dogger Bank may have been caused by the collection of the bodies in the eddies of a river, or by the sweep of a tidal wave; but the question is, if the first hypothesis is accepted, how came the rivers to be in such roaring flood, and the answer given by the Duke of Argyll is rather more agreeable with the supposition of a sudden irruption of a flood than with the slow and regular deposit of a river. How also can we account for the sudden destruction of the mammoth and its contemporaries, which are known to be preserved in countless thousands in the Tundras of Siberia, from the Gulf of Obi to Behring's

Straits, except by a catastrophe of the kind indicated above. In their case we must assume also that the carcases were frozen almost at the same time as they were engulfed—that there was an inundation, followed directly afterwards by a period of great cold, which has continued ever since. There has been no break in the continuity of physical causation; but the very continuity has apparently produced at intervals some very extensive and very violent changes in the configuration of sea and land. With regard to the remains which are supposed to indicate the remote antiquity of man—the flint implements of palæolithic type found beneath river gravels and fluviatile silts—the evidence is not conclusive; and it is disputed whether the beds have been really slowly deposited, for they are often found full of foreign matter— that is, not belonging to the drainage basin of the river with which they are connected. Thus the Duke of Argyll is enabled to say that many of the palæolithic implements have been found in gravels which cannot be assigned to existing rivers, but may, with a tolerable degree of certainty, be assigned to the same marine submergence which has piled heaps of gravel with dead shells on the top of Moel Trefyn and the hills above Macclesfield —a submergence so brief that time was not afforded for the establishment of molluscan and other forms of marine life. The Duke of Argyll thinks that this view of many of the problems of geology has not been worked out with even tolerable consistency; but now that he has called attention to it, it is not unlikely that some of the advocates of the Uniformitarian hypothesis will reply, and from the contention of rival theorists we may ultimately arrive at the truth.

RELATIONS OF STATIC AND DYNAMIC ELECTRICITY.

By JOHN T. SPRAGUE.

SOME time since I promised to explain a subject which has puzzled a good many, and as to which questions have often been put—viz., the often-quoted statement of Faraday as to the electricity contained in water and ~~in a~~ flash of lightning. That is the text of the present article.

Faraday said that the electricity contained in a grain of water is equal to that in a powerful flash of lightning: some quote him as saying it is equal to that of a severe thunderstorm. Now, we know from chemistry that the potential energy of a grain of water — that due to the combination of hydrogen and oxygen, which combination is broken up by electricity—is ft.-lb. 6,841 ÷ 9 = 760. It seems absurd, therefore, to compare this with the enormous forces exerted by lightning, seeing that it is hardly equal to raising the heat of a pound of water one degree Fahrenheit.

We must remember that when Faraday made this statement he was only beginning the study of electric quantities and relations, our present knowledge of which is largely due to his work. At that time nothing but vague generalities had been attained to, and little was known, or even imagined, as to the nature of electricity. Our present exact system of measurement was undreamed of, and Faraday was therefore unable to perceive that he was comparing together things having no relation such as he was working at; but it is strange that his statements should be constantly quoted as if they contained real truths, and that their true interpretation has not yet been clearly shown. Before attempting this it will be well to bring together the actual statements of Faraday and other workers on the same lines.

Faraday found that to decompose a grain of water required a current for three and three-quarter minutes capable of keeping red hot a platinum wire 1-104th of an inch in diameter. The very vagueness of such a measure at once shows the difficulties under which he laboured: we can express this value definitely as a current, for the time given, of 3·13 ampères; or, better still, as a "quantity" of 704·37 coulombs, the coulomb and ampère representing chemical action equal to ·000158grm. of hydrogen or ·00142 of water. He found that to effect the same decomposition by the machine required 800,000 charges of a Leyden battery of 15 jars, each of 184 square inches of coated surface. Each of these charges, produced by 30 turns of a 50in. plate machine was capable of killing a rat, and was equivalent, chemically, to the action of a platinum and zinc wire, each of 1-18th of an inch in diameter, dipping ⅝ths of an inch into 4oz. of water containing one drop of acid, and developing current for about three seconds. Weber has also calculated that this charge from one grain of water, if placed on a cloud 1,000 metres (3,281ft.) above the earth, would exert an attractive force equal to 1,497 tons. So we have this enormous force and the potential slaughter of nearly a million of rats, originating in water, which we know is only possessed of less than 800 foot-pounds of energy, just about the amount of work a man ought to do in every five minutes of his day's labour.

De la Rive says: "Becquerel succeeded in finding that in order to decompose a gramme (15·43 grains) of water a quantity of electricity was required, equivalent to what would be furnished by 51,586,400 discharges of a battery having one square metre (1·9609yds.) of surface, reduced to 20,063,456 when the charge of the battery is at its maximum. On reducing Faraday's result to the same conditions we find 21,830,451. The difference is very inconsiderable for experiments of this nature." This remark shows how very imperfect was the then existing knowledge. The value of the comparison depends wholly upon the potential given to the charge, not merely on the coated surfaces, and in the actual figures this shows a variation between 51 and 20 millions. He goes on to say, "Adopting the round number of 20,000,000 for 1 gramme, in order to decompose a milligramme (·0154 grain) of water there are required 20,000 discharges of a battery of 1 square metre surface, or an electric pane having a surface of about 5 acres (Faraday's figures give 352 acres). Now, it is this same quantity of electricity that must be produced by the decomposition of this same milligramme of water by chemical means; and if it were accumulated so as to discharge itself instantaneously, it would be capable of producing the effects of a flash of lightning."

Weber established the relation between the statical and dynamical effects of the charge of a Leyden jar by measuring the first with the torsion balance, and the other by means of a galvanometer, to which the charge passed as a current by means of a long column of water which it traversed. His results were as follows:—

"Through each section of a conductor traversed by a current whose force is equal to the electro-magnetic unit there passes, in a second of time a quantity of electricity equal to 155,370 × 10^6 static units, an equal quantity of negative electricity travelling in the opposite direction.

"The quantity of electricity required to decompose 1 milligramme of water amounts to 106⅔ times this quantity (this being the ratio of the electro-chemical to the electro-magnetic units) or 16,573 × 10^9 units of electricity of each kind; to decompose 9 milligrammes, or 1 equivalent, requires of course 9 times this quantity. This quantity of + electricity (9 × 16,573 × 10^9) accumulated on a cloud 1,000 metres above the surface of the earth, would exert an attractive force equal to 226,800 kilogrammes, or 208 tons."

It is further calculated that if all the atoms of hydrogen in 1 milligramme of water in the form of a column of 1 millimetre long were attached to a thread, and all the atoms of oxygen to another, then to effect the decomposition of the water in one second, the two threads would require to be drawn apart with a force of 147,380 kilogrammes, or 145 tons. The thread would need to be tolerably strong, seeing that this immeasurably exceeds the tensile strength of any known material; that is to say, this imaginary force, mathematically demonstrated, is greater than any cohesive force known to exist.

Now let us translate this into modern expressions. We have seen that the dynamic value of 1 grain of water is 704·37 coulombs. What is the corresponding static expression which will replace the 800,000 charges and 325 acres of coated pane? We require a condenser of capacity capable of receiving a charge of 704·37 coulombs, and the mere dimensions of this will depend upon the potential of the charge; starting with the unit 1 volt, and taking the capacity of the usual cable as 3·5 micro-farads per mile, we find that a force of 1 volt (say a Daniell cell) would require 2,465 million miles of cable to receive it, or speaking roughly, enough to wind 1,200 times round the earth and moon, or go twice round the orbit of the earth; that is to say, the earth would take two years in "paying it out."

Let us put it another way: the (imaginary) capacity of the earth is 630 millions of electro-static units, or 700 micro-farads; this quantity (throwing in the odd 4·37 millions) would charge to 1 volt a million such worlds as ours! or, allowing the potential which Messrs. Ayrton and Perry calculated as necessary for their theory of the earth's magnetism—viz., 54 million volts, it would only require 54 grains of water to supply the required electricity, which, however, Prof. Rowland also calculated would result in bursting the earth to pieces.

Leaving all these fantastic unrealities in which some people delight, let us examine the commonsense of the matter. Electricity is nothing but a word in which certain natural phenomena are embodied, and it involves two wholly distinct functions, both of which are commonly called "electricity"; for instance, people talk of the torrents of electricity poured forth in a flash of lightning, and the torrents of electricity streaming out of a dynamo machine, and the idea of "quantity" in these two is wholly different; each belongs to one of the two functions which together constitute electricity. Those two functions are (1), The molecular construction of *matter*—that to which the idea of the "grain of water" is collated, and which we may symbolise as Q, for quantity; (2), the stress put upon those molecules, the "potential" symbolised by E for electromotive force. Static electricity has no existence as a "quantity"; it is simply the evidence of the stress existing in that class of matter which is called dielectric, or which resists the passage of electric current. All the ideas we have been considering are based upon the impossible isolation of Q; the real phenomena always depend upon Q × E. Matter and energy together constitute electricity.

Now, in the case of water the E is a potential of volt 1·5, and what we have to take into account in the case of the grain of water is, therefore, 704 × 1·5 = 1,056, which multiplied by ·7373 gives us a little over the 760ft.-pounds, which we know is the total energy of the grain of water. Let us now consider the case of the lightning flash, the Q of which is this same 704 coulombs, or the grain of water. The E M F of the lightning flash is very uncertain; it is calculated from experiments with De la Rue's 14,000-cell battery, that the E M F of a flash one mile in length is 3,604,000 volts, and this by the same process gives us 1,872 millions of foot-pounds, and enables us to realise why this "grain of water" can produce such great effects when concentrating this amount of energy in some point of high resistance which appropriates great part of it as "work" in possibly one millionth of a second.

But the *current* of such a flash is not, as some say, a very small one, because current is Q ÷ T, related to time, and the ampère means 1 coulomb per second. We have here, then, 704 coulombs, passing in a time variously estimated as one 20,000th to 1 millionth of a second; taking the lowest estimate, we have a current of 14 million ampères, greater than all the dynamos on earth could generate. From this it is pretty clear that no lightning-conductor is ever called upon to carry such a current; either it lowers the potential so gradually that the actual flash when it occurs is reduced to a very small one, or, on the other hand, it only carries a small part of the energy of the discharge, which is largely distributed over surrounding space.

It should be clearly realised that the distinction of static and dynamic electricity is artificial and misleading as usually conceived. *Frictional* electricity differs from that of the battery only in being produced in a circuit of highly resisting substances, and therefore under high potential. But so-called *static* electricity has no existence at all; it is a name which includes either *stresses* set up in dielectrics—that is, actions of energy in an *inductive circuit*, or else of very small currents in a *conductive* circuit of great resistance, all dielectrics having some small conductive capacity.

The static phenomena are exactly parallel with the dynamic. It may be said that there is this difference: that an electric current requires a continual expenditure of energy to maintain it, while the static charge, once produced, may be (theoretically) maintained indefinitely without the expenditure of energy. The theory which says so is a mathematical one, commencing with the favourite formula, "Let us assume." That a charge can be so maintained is an assumption contradicted by every known fact. The fact that no such charge has ever been produced is explained, in order to fit the theory, by the invention of "leakage"; that is to say, there exists no such perfect dielectric as the theory requires for its foundation: all dielectrics are partial conductors, and this means *current*. But even if we imagine such a dielectric, it would involve, not static *electricity*, but energy, stored "potential," as strains upon the molecules of the dielectric; just as we have in the secondary battery, not electricity, but energy, stored potential as chemical forces. Further, no such charge could prove its existence as a charge. When it moves an indicator of any kind, that involves energy expended and current passing. The simple fact is, that the current is infinitesimal and the energy inappreciable. But we have just such currents in dynamic electricity. Experiments have been made as to deposit of minerals, in which the resistance of the depositing cell is so great, that the current would need a century to deposit one grain of metal, and yet that current can indicate itself upon a galvanometer. In such experiments the depositing cell is a static field, a condenser, in which only a small force exists. Its electrodes indicate a static charge, exactly as do the static conductors, and the electrolytic cell and static condenser are exact analogues of each other.

I think these relations are more clearly shown in a tabular form, which contrasts the two circuits and principles, than in any other manner, and therefore I append such a table, which I have prepared for my book

Static	ELECTRICITY	*Dynamic*
Energy *potential*: stored in a field of force, as stress in a dielectric.	means	Energy *kinetic*: acting in a conducting path, along molecular chains.
Inductive	CAPACITY	*Conductive*
Area of dielectric.	varies as	Area of conductor.
Spec. ind. capacity of dielectric.	"	Specific conductivity of material.
Thickness	inversely as	Length
Units of Charge stored under unit Potential.	is measured by	Units of Current transmitted under unit E M F.
The Potential in volts required for unit Charge.	or by	The E M F in Volts required for unit current.
Inductive	RESISTANCE	*Conductive*
Reciprocal of inductive capacity.	is the	Reciprocal of conducting capacity.
CHARGE	ELECTRIC	CURRENT
Potential, in volts.	is as	Electromotive force, in volts.
Resistance.	inversely as	Resistance.
Lines of force under stress.	is related to and dependent on	Lines of equivalent molecules forming chains.
Inversely as the several resistances.	divides among several circuits	Inversely as the several resistances.
	ENERGY, OR WORK.	
Square of charge in unit or equal resistance.	is as	Square of current in unit or equal resistance.
	FORMULÆ.	
Charge $\frac{E}{R} = Q$	Current	$\frac{E}{R} = C$
Potential $Q \times R = E$	Electromotive force	$C \times R = E$
Resistance $\frac{E}{Q} = R$	Resistance	$\frac{E}{C} = R$

NEW METHOD OF MANUFACTURING BICHROMATE OF SODA.

BICHROMATE of soda is, we believe, unknown as a commercial salt, but if it can be produced in a pure state by any process not more expensive than that employed for obtaining the corresponding salt of potassium, there is a wide field of usefulness for it, as it is a more powerful oxidiser than the bichromate of potash, and should be cheaper. Messrs. Potter and Higgin, of Bolton, have recently obtained letters patent for an "improved process of manufacturing bichromate of soda," which is thus described: The chrome ore is furnaced with lime or carbonate of lime and a suitable sodium salt, preferably the sulphate, using in some cases a certain proportion of the recovered sodium sulphate. The furnacing is done in substantially the same manner as in the potassium bichromate manufacture, where lime and sulphate of potash are used. The resulting material is lixiviated with water in the ordinary manner, and the liquor obtained is treated with hydrochloric or other acid, in such quantity as to exactly neutralise it; other acids may be used, but hydrochloric is much preferred to sulphuric or any other. On neutralisation the silica and alumina are precipitated, and carefully removed by settling and filtration. The neutralised and purified liquor is then concentrated in under-fired pans of suitable construction, and, as the boiling solution loses its water, the chloride and residual sulphate of soda contained therein are thrown out in the crystalline form, while the chromates of soda remain in solution. The crystals are removed by mechanical means, either by ordinary hand fishing, or by other means, and after draining are washed with neutralised vat liquor, before concentration. This liquor containing a considerable quantity of these salts already fails to dissolve them, but being far from saturated with chromates takes up nearly all the latter. The washings resulting are then concentrated as above, and practically little or no neutralised liquor will go straight to the pan, but will all previously be used to wash salts. It will thus be seen that the action is an accumulating one, by which gradually all the chromates are left in solution in the pan, and all other salts are obtained in a washed state nearly free from chromates. When sulphuric acid has been used to neutralise the vat liquor, these washed fished salts containing a trace of chromates are then used again, after drying, in place of an equivalent quantity of fresh salt cake. But when hydrochloric acid is used to neutralise the vat liquor, then the washed fished salts, which consist in this case mainly of sodium chloride with traces of chromates, are converted into sulphates by the ordinary salt cake process, and then used again in place of an equivalent quantity of fresh salt cake, thus recovering and utilising the last remaining chromium compounds.

The strong solution remaining in the pan is filtered, or otherwise freed from the last crystals of chloride and sulphate of soda floating in it, and is then boiled down to dryness and the salt perfectly dried (but not fused) in a top-fired mechanical pan, or by other means, care being taken to keep the temperature low and an excess of oxygen always in the gases in contact with the bichrome salt. The bichromate of soda obtained by this process contains monochromate, but as the reactions of the salts are identical this is of no importance. In cases, however, where a pure specimen of bichromate is wanted for a special purpose, the neutralised and purified vat liquor is, after removal of alumina and silica, treated with a further quantity of acid (preferably hydrochloric) in exactly the quantity required to convert the whole of the monochromate salt into bichromate, as calculated from analysis of the vat liquor before treatment with acid, and the process is then conducted as above, but in this case the pans used would have to be of special material, to avoid contaminating the acid liquor, for which purpose lead would probably be the most suitable.

In practice, however, the manufacture of the pure salt is not so advantageous as an impure article composed of about two-thirds of bichromate and one-third monochromate, with a very small but variable quantity of neutral salts of soda, and at this point it has a neutral reaction and the same amount of oxidising power as the potassium salt, and can consequently be substituted for it in whole or in part in equal quantities, weight for weight. The patentees give reasons why no one has hitherto succeeded in manufacturing commercially useful bichromate of soda, but as their process is successful we give it for what it may be worth. They claim the process as a whole, and certain specified operations.

PRACTICAL NOTES ON PLUMBING.—LXXXIV.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from page* 187.)

Equilibrium Ball-Valves.

THERE are various kinds of equilibrium ball valves: some are very simple, whilst others are of a most complicated class, and often without any advantage. For my part, I thoroughly indorse the words which Mr. Muir, the engineer to the New River waterworks, once said to me, when in course of conversation about which kind of ball valves were the best to adopt. His words were: "I like your ball valve for the simple reason that with it you have only one chance of leakage, whereas in most others of this class there are two openings"; meaning that with the class of ball valve, Fig. 401, &c., there is a chance of leakage at B, and also at A J.

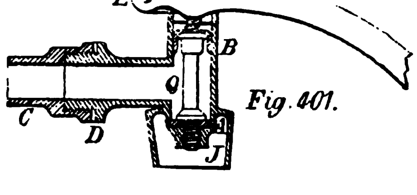

Fig. 401.

The Fig. 401 represents the ball valve known as Lambert's patent, and which has for many years been made public property. It is, on account of its price and simplicity, very extensively used, and consists of a cup leather at B, working within a truly-bored cylinder. On the top cup leather is a slotted guide for guiding the cup leather and spindle, and for keeping the valve perpendicular with the valve-seating, and for actuating the valve and cup leather; it also serves for the rod F to pass through, and to be fulcrumed, as shown at E. The action is as follows:—On depressing the lever F, the cup leather and valve J descends from the seating, when of course the water is allowed to run past the seating Now let the ball float and rise. This will actuate the valve and so bring it up to press against the water, and finally against the seating, and the water will be shut off. At the same time that the water is pressing against the valve so it is against the underside of the cup leather, which tends to push upwards, and by reason of the cup leather and valve with the spindle being so coupled together so that as the water tends to force the valve away, so it does the cup leather, and as the size of the seating is, or should be, of the same bore as the cylinder of the cup leather, so will the force of the water be equalised, and the whole weight of the two be held in equilibrio upon the connecting spindle of the value and cup leather. In this valve as now made there exists a great evil, and one which may be very easily rectified, at least, in the larger sizes. It consists of the usually very narrow space round the sides of the valve and the outlet A of the valve seating. Here the dirt, &c., accumulates, and cannot wash away, but if this space were, at least, ⅜in. to ½in. clear, then this valve would have a better chance to work, and the dirt, &c., to pass away. Caution: When taking this valve out for repairs, &c., be careful not to force the cup leather back with main force, as it will catch in the water way Q, and thereby get its edges cut and spoilt. When it is found to hang, try and push it back with the end of the pliers, &c., or unscrew the valve off the spindle, and take the cup-leather the other way, then, when out, take a sharp-edged reamer, or better, a small ripper (a brassfinisher's lathe tool), and ream away the sharp edges round the edge of the inlet water-way Q; then the cup-leather will freely pass in either direction.

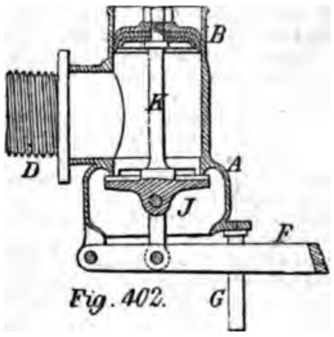

Fig. 402.

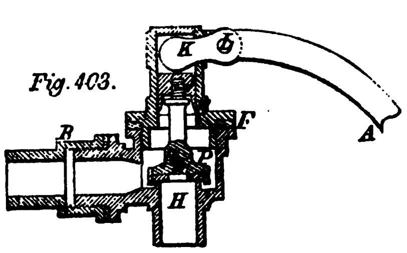
Fig. 402 is the same kind of valve, but worked from below, as at E G.

Ball Valves to Close with the Stream.

For this kind of valve, see Fig. 403. This valve has its seating set inward, and the valve is allowed to work quite clear, and to leave the waterway fully open and free, which is not the case in Figs. 301 and 302; besides this, there is another good feature in this valve. The valve lifting upwards allows any small pieces of dirt and stone to pass freely, and therefore is not so likely to be put out of order by such substances. There is one evil in this ball valve. By reason of its closing with the stream, it is apt to be pulled up too suddenly, and so cause a great concussion in the pipes, as in the hydraulic ram, though this act of inadvertence would not happen with careful men, and, as a rule, this valve works exceedingly well.

Fig. 403.



Movable Tube Seating Equilibrium Valves.

Th's valve, Fig. 404, is made by Guest and *Chrimes, also by Messrs. Stone* and Co., and other well-known brass finishers, and will be readily understood. E is the tube, having a seating formed on its upper edge, and which shuts against the rubber D. Round the side of this sliding tube is fixed a cup leather F, which prevents the water from passing the sides of the tube and valve. The action is as follows:—On lowering the lever I, it being coupled to the tube at L, it takes down the tube when the seating comes below the fixed rubber, and the water is allowed to run down the tube and out at K. Sometimes the valve D is made in such a manner that it is free to move upwards, and can be carried upon the tube seating, which, by reason of its upward movement will prevent the rubber from being cut should the lever be pulled up too high; but on its descent it cannot follow the tube past a certain mark, which is shown by the shoulder R. For repairing this valve unscrew the top C, and take out the valve D, and insert the new rubber *of the same thickness*. This valve, as far as being proof against the effects of dirt, &c., is very good, and may be considered a true equilibrium.

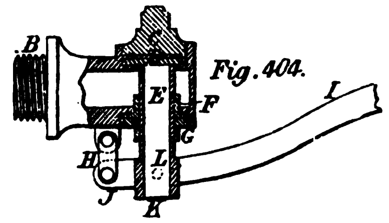


Fig. 404.

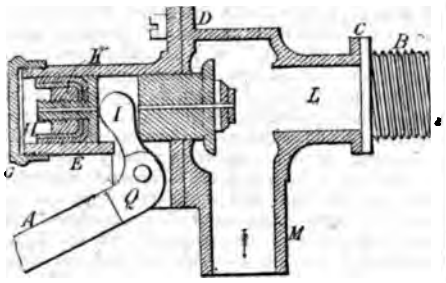
Horizontal Ball Valves.

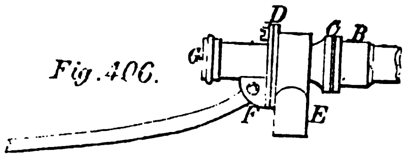
These ball valves *when properly made*, are exceedingly good, and when the valve is made to open its proper width and the body large enough round the outlet of the valve seating L, Fig. 405, the grit, lead shavings, &c, can be washed out, and will fall direct through the outlet. This valve is balanced by the pressure of water being allowed to pass through a small hole drilled up the spindle, and allowed to get at the end as shown at H, Fig. 405, where it is prevented from passing out by the cap G, and from getting between the sides by the cup leather K. To repair this valve, simply unscrew the flange F and re-rubber the valve. The cup leather, *in the best made valves*, can be removed by taking out the small screw Q, and allowing the spindle to fall out.

Fig. 405.



Some makers make the spindle in such a manner that it will not admit of being so easily taken out. When such is the case, a forked screwdriver must be employed to turn the cup leather nut off; then the cup leather can be taken off and the spindle withdrawn, of course providing the lever is unscrewed, &c. Fig. 406 is an elevation of this valve, which will at sight enable my readers at once to select this class of valve.

Fig. 406.



I may say that the varieties of ball valves are legion: some are made to work with cup leathers, some with pistons, and some with diaphragms. But what I have endeavoured to do in this, my work, is to place before my readers those which are universally used, and by all competent judges accepted as being the simplest and the most serviceable for the many different pressures which the plumber has to work against.

My experience, which is close on 30 years practical work under nearly all the different large water companies in England, and some in America, teaches me that of all ball valves in the market there are none to equal those represented at Figs. 405 and 406 *when properly balanced and made*. I write these words in italics knowing it to be a fact, that many makers are to be found making these valves who do not understand their business, nor even the principle on which the valve works.

(*To be continued*)

HOW TO MAKE A CHEAP LATHE.—II.*

The Framework.

NOW, our patterns being at the founder's, we will take advantage of the opportunity thus afforded to make the standards and bed. With reference to the choice of wood for the bed, a word or two will not be out of place here. An iron bed suitable for a lathe of this size would, when cast and planed, cost between two or three pounds—a considerable item. It may, certainly, by a vast expenditure of precious time, be filed up truly, in which case the only outlay incurred is the price of the rough casting and the necessary files. But for the ordinary run of home work, a wooden bed is quite as useful as an iron one, and the lathe I am describing is very much superior to the average specimens of such wood turners' lathes as I have seen. For wood turning alone it is suited admirably, and it is also, if properly made, rigid enough to permit of the use of a slide rest in light metal work.

But if an iron bed should in some cases be deemed more desirable, it might even then be preferable to make a wooden bed in the first place, and at some subsequent period to transfer the poppets to the metal bed, for which they are equally well adapted; the gratification of using the lathe would not be so long delayed, and the filing of the iron bed could proceed at leisure intervals.

In the selection of the most suitable wood, let us choose between oak, beech, or birch for the bed, and birch, pitch pine, or red deal for the standards, taking that which is most easily procurable. Say we fix on red deal quartering for the latter and oak for the former. Two 14ft. lengths of 3in. by 2in. quartering, quite sound, will be required for the standards. The oak, so small in quantity, had better be bought at a carpenter's shop, instead of at a timber yard, in order to secure a bit of old stuff; for oak, if not thoroughly seasoned, will become warped very badly after a few months' exposure of the grain.

For the standards we require two frames like Fig. 10. Prepare four pieces (two for each frame) finished to 3ft. by 3in. by 2in., Fig. 11, A A for the sides. Two pieces, 2ft. by 3in. by 2in., B for the bottom. Four pieces, 1ft. 2¼in. by 3in. by 2in., C C for the cross bars. Mark and cut mortises and tenons to dimensions indicated (Fig. 11).

Shall we presume that all who read this article know exactly how to make mortise and tenon joints? Scarcely so, perhaps. Mortises and tenons, then, are marked with a mortise gauge, that is, a gauge having two cutters instead of one only, as in the ordinary marking gauge, the lower cutter of the two, as well as the head, being capable of adjustment independently of each other. The amout of separation of the two cutters being adjusted to the required thickness of the tenon, the head of the gauge is set in such a position that on being slid along the edge of the wood, the tenon is marked at its proper distance from the face. The same gauge is used for the mortise also.

Here our tenons will be ¾in. thick. and in the centre of the stuff. So the cutters will be set to ¾in. by the screw at the end of the stem, and the face of the head ⅝in. away from the nearest cutter. If we don't possess a mortise gauge we must use a marking gauge instead, and take a little more time over the job. In either case, mark the tenons, and cut down their faces, keeping just a shade outside the lines, with a fine tises on the underside of the back rail, and in the standards. One end only of each diagonal can be fixed at first. Let that be the end attached to the standard. When both diagonals are thus fixed, bring the back rail down on the free ends, and secure with a stout screw, in addition to the glued and mortised joint.

The tool board and rack would only be in the way if we made them now; and as our castings are come home from the founder, we shall prefer to leave the remaining odds and ends of woodwork for the present, and commence fitting up.

Two 14ft. lengths of quartering at 2d. per foot run = 4s. 8d.; two pieces of dry oak—almost a favour to get—say 2s. each, 8s. 8d. Ten shillings, then, will cover the cost of timber, including the three stretcher strips.

THE DIALYTE TELESCOPE.—II.

By W. Bradbury.

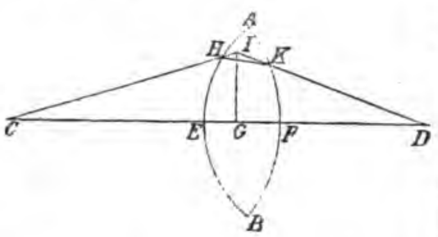
BY the use of formulæ similar to Mr. Beverly's I have computed the following curves for an instrument made with Chance's glass:—

Hard crown object-glass, aperture 4in. clear.
Focus 60in. Equi-convex, each radius 61·2.
Correctors, hard crown and dense flint, aperture 2in. clear.

Focus of each lens, 10in.
Crown lens, biconvex, radii .. 7·7, 15·2
Flint lens, bi-concave, radii .. 15·2, 10·45
Correctors 30in. behind object-glass.

It must be observed that these calculations take into consideration central aberration only; hence it must not be expected that the curves they furnish will be altogether the best. In the dialyte there is evidently a complication of errors, which will probably yield to no formulæ. But one of these imperfections must be noticed—viz., distortion, which may be regarded as a compound species of aberration. Coddington has given formulæ, whereby it may be eliminated, but the process is far too complicated to be reproduced here; however, the main parts may be dealt with in a very simple manner.

Thus supposing we have a single convex lens A B, and the rays from an object at C are converged by it to the point D. Then we say the magnitude of the images are as their distances from the lens—that is, as b is to c, if we call E C and F D, b and c respectively. Now the tangents of the angles H C E and K D F are nearly in the inverse ratio of b to c. They would be so exactly, if the points H and K were equally distant from the axis; but this is not the case. Produce C H and D K to intersect in I, and drop G I square to C D; call angles H C E and K D F, x and y respectively. Then the ratio of the tangents is accurately as G D to G C. That is:—



$$\frac{\tan. x}{\tan. y} = \frac{GD}{GC}$$

Now it is evident that the points G and D are both variable: the first depends on the intersection of the incident and emergent lines; and the second is affected by the spherical aberration. Hence, we must seek so to divide the refraction between the two surfaces, that the joint effect of these two variations may disturb the ratio of the tangents as little as possible. Or, we may say, that ratio of surfaces is the best which gives the ratio of the tangents nearest to $b : c$. So that if

$$\frac{\tan. y}{\tan. x} = \frac{GC}{GD} = \frac{b}{c}\left\{ I + V \right\}$$

we require a lens which shall make the value of V the smallest possible.

In the ordinary object-glass, it is unnecessary to take into account the effect of distortion, *because* the ratio of focal length to aperture is too great to allow eccentric refraction to show any evil effect beyond the ordinary spherical error. But in the dialyte this is otherwise. Even if distortion is not developed by the objective, it must be by the correctors.

With regard to a single lens, Coddington has shown that the best effect is obtained from it by making the surfaces as 9 to 19, or say as 1 to 2; and even with an equi-convex, the factor V is very little increased. Passing on to the separated combination, we cannot do better than follow the same author in the results he has deduced for the Huyghenian eyepiece.

In a combination proportioned as—foci 3 to 1; separation 2—he gives the following values for V with different sets of lenses:—

1st lens, equi-convex; 2nd, convexo-plane, $V = \frac{3}{108}$.
1st „ plano-convex; 2nd, equi-convex, $V = -\frac{9}{108}$.
Both lenses pla.-convex, or convexo-plane, $V = \frac{18}{108}$.

From these it is plain that the first combination gives the least outstanding error; and although the dialyte is not exactly similar to the negative eyepiece, yet there is a great similarity between the two, so that we shall probably not be wrong in assuming that the best arrangement for the former will work well in the latter. The dialyte pair of correctors are generally of equal and opposite foci, which causes their joint effect to be nearly imperceptible. We may consider them as resembling the second lens of the negative eyepiece divided into a positive and a negative part. And evidently if we make the positive part a convexo-plane lens, its counterpart should be a plano-concave, so that their plane sides (or they may have a very shallow curvature) shall come together.

These considerations confirm the correctness of the plan followed by Professor L. Smith.

We must next investigate the proportion of foci necessary for the production of achromatism. Let F and f be respectively the foci of the crown and flint lenses; d, the dispersive power of the crown glass and D that of the flint. Then d/D is the ratio of dispersive powers, generally denoted by δ, and is always less than unity. With the same glass, the amount of dispersion is inversely as the lens' focal length—that is, in a pair of crown lenses, as $d/F : d/F'$. Now if two lenses, crown and flint, achromatise, they must each give the same amount of dispersion in opposite directions; or, we must have $d/F = D/f$: this is generally expressed by saying that the foci must be directly as the repective dispersive powers. If there are several lenses of either kind in contact, the same equation must still be fulfilled, remembering that F and f in that case represent the united powers of each system of lenses. Thus, for two crown and one flint lens we have:—

$$d\left(\frac{1}{F} + \frac{1}{F'}\right) = \frac{D}{f}$$

and suppose F' and f are of equal but opposite foci. Then we get eventually:

$$\frac{F}{f} = \frac{\delta}{1 - \delta}$$

This would give a triple combination something like the dialyte lenses, but requiring the three to be close together.

Next, we will assume that a crown and flint pair are so arranged as to be achromatic when separated by a distance s: to find the proportion of foci necessary. Evidently the effect is the same as if we had a crown lens of the shortened focus $(F - s)$, but with an amount of dispersion equal to that of the whole focus F. Let us find the dispersion due to the reduced focus. Representing it by d', we have:—

$$\frac{1}{F} : \frac{1}{(F - s)} :: d : d'. \text{ or } d' = \frac{F\,d}{(F - s)}.$$

And since this is sufficient to balance the negative action of the flint lens, the following equation is satisfied:—

$$(F - s) : f :: \frac{F\,d}{(F - s)} : D$$

Or, if we substitute δ for d/D, we get—

$$f = \frac{(F - s)^2}{F . \delta}.$$

From this any one value may be found when the other three are known. The value of F is—

$$F = s + \frac{f\delta}{2} \pm \tfrac{1}{2}\sqrt{f\delta\,(4s + f\delta)}.$$

The reduced focus is a mean proportional between the flint and the crown focus multiplied by δ, and if A = acting semi-aperture of crown, a that of flint lens, we have—

$$\frac{F}{f} = \frac{A^2}{a^2} . \delta .$$

Hence, when δ is constant, the foci will vary directly as the squares of the semi-apertures. To apply the formula to a triplet arrangement of two crown and one flint lenses, the second and third in contact, but removed apart from the first, we must substitute $F / (F - s)^2$ for F in the equation for a multiple combination. Then we get—

$$d\left(\frac{F}{(F - s)^2} + \frac{1}{F^1}\right) = \frac{D}{f}$$
$$\text{or } \left(\frac{F}{(F - s)^2} + \frac{1}{F^1}\right) = \frac{1}{f\delta}.$$

And if A and a are the acting semi apertures, the second and third lenses being supposed of equal size—

$$\frac{1}{F} = \frac{a^2}{A^2}\left(\frac{1}{f\delta} - \frac{1}{F^1}\right) \text{ or } F = \frac{A^2}{a^2}\left(\frac{F^1 f\delta}{F^1 - f\delta}\right).$$

If it be a condition that the second and third lenses are equal but opposite in focal lengths, F¹ disappears from the equation, and it becomes—

$$F = \frac{A^2}{a^2} . \frac{f\delta}{1 - \delta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (a)\,8$$

To find F independent of the semi-aperture, we have—

$$F = s + \tfrac{1}{2} . \frac{f\delta}{1 - \delta} \pm \frac{\sqrt{f\delta\,[4s\,(1 - \delta) + f\delta]}}{2\,(1 - \delta)}.*$$

Equation (a) is the ordinary formula for proportioning the foci of the lenses of a dialyte; and though not absolutely correct, as indeed are any of the simple proportions for achromatic foci, yet it gives in an easy manner a near approximation. This is sufficient in an instrument which is designed to furnish within itself the necessary adjustment for elimination of residual errors.

It does not seem probable that anything more than central correction can be obtained from the ratio of focal lengths. Eccentric chromatic refraction will necessarily show itself when the correcting compound lens exerts its effect away from the source of error. A meniscus objective appears better suited for causing less lenticular chromatism than a double convex; but whether an apparent advantage in this way might not be more than counterbalanced by a difficulty in surmounting spheric errors, is a point that can only be decided by practical construction.

Considerable corrective power appears to lie in the form or disposition of the lenses of the eyepiece. Both Mr. Wray and Professor Smith allude to the obtrusiveness of eccentric chromatism; the former says this was corrected by a peculiar form of eyepiece; the latter gets rid of it by rearranging the positions of the eyepiece lenses. We are not told in what the peculiarity of the eyepiece consisted; but the fact that it can be overcome by a particular construction shows that the imperfection is not so serious as many might anticipate. Professor Smith says, "It is necessary to separate the lenses of the eyepiece considerably, to insure correction throughout the whole field."

This is a very simple way of improving the achromatism, and one which anyone can adopt with very little trouble. It is not easy to see why an increase of separation should have a corrective action on the marginal chromatism; but in the passage of coloured rays through an arrangement of small lenses, many minute changes are induced which can only be judged of by their final effect. The negative eyepiece is chromatically undercorrect, which is obvious from the fact that the field lens would disperse the white ray into red, and blue rays, the former behind the latter; and in this position they are unsuitable for transmission to the eyelens. Hence, it would seem old universities, that they are acting in harmony with examples afforded by classic times, and in obedience to present national necessities. There is, however, one thing about all these competitions which does not produce unmixed satisfaction, and that is that all cannot win. There must be those who are first and those who are second or third and those who are last, and naturally enough the losers feel more or less disappointed. But all who try to win and fail are nevertheless gainers. Though they do not gain all they desired or expected, they gain something. The poet says, and says truly—' 'Tis better to have loved and lost, than never to have loved at all.' A dozen boys may run or jump, and though only one may win, all strengthen their muscles and develop their frames. So it is with the candidates for the Cambridge and Oxford Local Examinations. A few get prizes; a few others get certificates or honourable mention; but all get the reward granted to honourable endeavour. I would therefore say to the successful 'be not too elated,' and to the unsuccessful 'be not cast down.' The first school song I ever heard, or at all events the first I remember, had this refrain—'if at first you don't succeed, try, try, try again.' If you have not succeeded to the measure of your expectations you may succeed better next year or the year following; but, whether you win prizes or lose them, you will be better to the end of your lives for the trial. I cannot conclude these few observations without again referring to the benefit of universal education. Education is essential to the individual citizen and the State. It is essential on account of the position we occupy, the advantages we inherit, and the national and international duties we have undertaken. There is and there will be an increasing demand for educated men and women to keep our industries going, and to maintain our institutions and our national life. And I regard these local examinations as amongst the necessary means to develop the mind and character of our people, and I trust that they will meet with abundant success and thereby increase the educational wealth of the country, and at the same time shed an additional lustre on those ancient seats of learning—the Universities of Oxford and Cambridge."

---

* It may be observed that both in this and a preceding similar formula, since s is the amount of separation, $\frac{f\delta}{2}$ and $\frac{f\delta}{2(1 - \delta)}$ = half the focus of a crown which would produce achromatism in contact with the flint; the quantity under the vinculum which remains to make up the value of F, will approach to the value of $\frac{f\delta}{2}$ and $\frac{f\delta}{2(1 - \delta)}$ as s diminishes, and if $s = o$, then $F = \frac{f\delta}{1 - \delta}$ as before shown.

THE TRANSMISSION OF ENERGY.

III.*

By Prof. Osborne Reynolds, M.A., F.R.S.

(*Concluded from p.* 191.)

SO far I have spoken only of the conveyance of power by means of coal, corn, or in one or other of the several forms of packed energy. To-night I come to consider the transmission of power by what are more distinctly mechanical methods, and by currents along pipes and conductors. These are the means by which power is almost always distributed, *i.e.*, transmitted from the acting agent, be it horse, water-wheel, or steam-engine, to its operation, whatever it may be. In most cases the distance of such transmission is so short as to be the subject of small consideration in determining the means to be employed. That is to say, the means are chosen rather by their adaptability to receive and render up the power than by the efficiency with which they transmit it. Thus, if we take an ordinary mill, the shaft which receives the power from the engine is generally driven at that speed which is best adapted to receive the power from the engine, and deliver it to the machinery in the mill, without considering whether a much smaller shaft might be used if it were caused to run at a much higher speed. Thus, in a mill driven by an engine of two or three hundred horse-power, the shaft which receives the power will generally be 5in or 6in. in diameter, whereas it would be possible to use a shaft of 2in diameter if the efficiency of the shaft were the only consideration.

My object is to show the limits within which the use of each means is confined, however fit it may be for its purpose. Taking first the mechanical means, which are shafts and ropes, we find that the possible limits to both these means are absolutely defined by the strength of material. The amount of power any piece of material will transmit by motion against resistance, is simply the mean product of the stress or force acting in the direction of motion on the section, multiplied by the velocity, so that, if the stress is uniform over the section, the work is the product of the area and intensity of stress and the velocity.

In a revolving shaft, nither the stress nor the velocity are uniform over the section, both varying uniformly from nothing in the middle to their greatest value on the outside; so that their mean product is exactly half the product of the greatest values. The greatest power per square unit of section a shaft can transmit is half the product of the greatest stress into the velocity at the outside of *the shaft.*

Taking, then, the greatest safe working stress for steel at 15,000lb. on the square inch; taking what is the greatest practical velocity at the surface, 10ft. per second (the speed of railway journals); the work transmitted is 75,000 foot-pounds per second per square inch of section—135 h.p.; so that we should have to have a shaft of upwards of 7 sq. in. in section to transmit 1,000 h.p., that is, a shaft of over 3in. diameter. The friction between such a shaft and lubricated bearings is well-known, ·04; so that, calculating the weight of the shaft 24lb. per foot, we have power spent in friction about 52,000 foot-pounds per mile, that is one-tenth the total power the shaft will transmit. That is, if we put 1,000 h.p. into a 3in. shaft, making 500 revolutions per minute, we ought, at the end of a mile, to be able to take 900 h.p. out of it. If we had to go farther, the size of the shaft might be diminished so that in the next mile we should again lose a tenth, and if we repeat this process seven times, we shall, at the end of seven miles, have left about half the original power put in.

It would be thought, perhaps, that a 3in. shaft is very small to transmit so large a force: this is because the speed of 500 revolutions per minute is inconveniently high for purposes of employing the power; but if it were merely a question of transmission, it would be about the best speed. This, then, shows the limit of the capacity of shafts as transmitters of work.

Turning now to steel ropes, these have a great advantage over shafts, for the stress on the section will be uniform, the velocity will be uniform, and may be at least ten to fifteen times as great as with shafts—say 100ft. per second; the rope is carried on friction pulleys, which may be at distances of 500ft. or 600ft., so that the coefficient of friction will not be more than ·015, instead of ·04. Taking all this into account, and turning to actual results, the work transmitted per inch would be 1,500,000 foot-pounds per second; or that a ¾in. rope is all that is necessary to transmit 1,000 h.p. in one direction: this would make the loss per mile only 1-50th. But in practice, rope has to be worked backwards and forwards, and the tension in the backward portion of the rope must be half the tension in the forward portion. This reduces the performance from 1-60th to 1-20th, which would cause half the work to be lost in 10 miles. If we use a bigger rope, and run at lower speed, then the coefficient of friction would be reduced to 0·1, and the distance extend to 15 miles.

Experience with ropes is large, and they have been found, without question, to have been the most efficient mechanical means of transmitting power to long distances, but their use is subject to drawbacks. The ropes wear somewhat rapidly, as do also the pulleys on which they run, and this circumstance is very much against their use in any permanent work. Nevertheless, they are used for working mines, steep inclines, and steam ploughs; while at Schaffhausen they have been used for transmitting power to considerable distances.

Turning to the transmission of power along pipes, we find the conditions somewhat modified. The formula for the amount of power transmitted by water is the same, namely, the product of the area of section into the velocity. But the resistance obeys different laws. In the case of shafts and ropes, we have seen that the distance is subject to an absolute limit.

In the case of fluid in pipes this is not so. No matter how long a pipe may be, if there is no leakage, water would flow along the pipe until the level of its surface were the same at both ends. But the rate of flow would diminish with the length and diameter of the pipe. Thus we can transmit power through a perfectly tight pipe, however small, and however long; but when we come to consider the gross power that can be transmitted through a given pipe, with a given per-centage of loss, the question is different. Given the size and strength of the pipe, the gross amount of power, and the percentage of loss, and the limits are fixed. Thus, taking a 12in. pipe capable of standing 1,400lb. on the square inch, the loss in transmitting 1,000 h.p. would be about 5 per cent. per mile, at first increasing—as the pressure fell to 700lb.—to 10 per cent. We should thus have lost half the power in about seven miles. We cannot say that seven miles is the absolute limit, for with a 24in. pipe which would cost four times as much per mile, we could transmit the same power thirty times as far with the same loss. The cost of laying a 12in. pipe for seven miles, however, would probably be as much as even 1,000 h.p. would stand; while a 24in. pipe for 200 miles would be out of all proportion. Then there is the consideration of leakage, which, although very small for short lengths, is larger for greater lengths.

Seven miles is at present an outside economical limit of hydraulic transmission, even for such a large amount of power: but with air the case is different. This flows so much easier than water, that the cost of transmitting the same power through the same distance, with the same loss, would be about 12 per cent., or, at the same cost per mile, the air may be transmitted 100 times as far with the same loss. The total cost, however, would thus be 100 times as great, which would exceed the economical limit; but not only theory but practice has shown that power may be economically transmitted five times as far by air as by water—something like thirty miles. But on comparing these two means, one circumstance must not be lost sight of, and that is, that getting the power into the pipe in the form of compressed air, will cost twice as much as getting it in in the form of water. This is a great advantage for water where the distance is short; but where the distance is long, the greater efficiency of air more than compensates for this initial loss.

Like water, air can only be transmitted economically where the quantity is large, the friction being proportionately greater in small pipes than in large, varying as the four-fifths power of the diameter. This is a great drawback, both as regards hydraulic and compressed air transmission. It does not affect ropes and shafts in the same way, but even in these cases considerations of durability prevent these means being used efficiently for the transmission of small quantities of power to considerable distances, so that, with the possibility already mentioned, there remains an opening for any means that will enable power to be transmitted efficiently in small quantities, and such a means we have in the flow of electricity along wires or conductors. In considering electricity, we may well start with the questions—1. Will electricity enable us to transmit power in large quantities more efficiently than the foregoing means? 2. Will it enable us to transmit small quantities? These questions may be more definitely answered than they could a few weeks ago. Thanks to the experiments of M. Deprez, who appears to have been the only one, out of all those who are advocating the use of electricity, who has had the courage to try and see what can be done, we can now say with certainty that a current of electricity, equivalent to 5 h.p., may be sent along a telegraph wire 1-6 of an inch in diameter, some ten miles long (there and back) with an expenditure of 29 per cent. of the power, because this has already been done. In order to do this, it would seem that M. Deprez has perfected his apparatus so as to have nearly reached the possible limit. Compared with wire rope, this means falls short in actual efficiency, as Messrs. Hems send 500 h.p. along a ¾in. rope. To carry this amount, as in the experiment of Deprez, one hundred telegraph wires would be required; these wound into a rope would make it more than 1·4in. in diameter, four times the weight of Mr. Hems's rope. With the moving rope the loss per mile is only 1·4 per cent., while with the electricity it was nearly 6; so that, as regards weight of conductor and efficiency, the electric transmission is far inferior to the flying rope. Nor is this all. With the flying belt, Mr. Hems found the loss at the ends, in getting the power into and out of the rope, 2½ per cent.; whereas, in M. Deprez's experiment, 30 per cent. was lost in the electric machinery alone, which is very small as such machinery goes. But this is not all. No account is here taken of the loss of power in the transmission to and from the electric machinery—a matter which is, I believe, very much under-estimated.

The machines made revolutions at 1,000 and 700, much too high for direct connection with either a steam-engine or any mechanical operator; the power, then, had at each end to be transmitted through gearing, or a system of belts. And supposing this alteration of speed to have been five or six at each end, experience tells us that a loss of at least 15 per cent. must ensue. This loss was indeed apparent, for the dynamometer was connected with the machine with a belt, which showed a loss from this one belt alone of 20 per cent. Taking the whole result, it does not appear that more than 15 or 20 per cent. of the work done by the steam-engine could have been applied to any mechanical operation at the other end of the line, as against 90 per cent., which might have been realised with wire rope transmission. To set off against this, electricity has the enormous advantage in the conductor being fixed, and in the fact that it is likely to be, if anything, less costly and more efficient for small quantities of power than for large. These advantages will certainly insure a very large use for electricity in the distribution of power, particularly for high speed machinery.

There is yet another means of communicating and distributing energy now coming rapidly into vogue. This is by the transmission of coal gas along pipes. The distances, often many miles, through which the gas is often transmitted before reaching the engine, are such that, with any other means of distributing power, would considerably enhance the cost of the power. But in the case of gas, it does not appear that these distances are at all a matter of consideration. This may be at once explained. It takes about ten cubic feet of gas to develop 1,000,000 foot-pounds in a gas-engine, whereas of air compressed in the ordinary way it would require something like 140 cubic feet to yield the same power. Hence the comparative cost of transmission is the cost of transmitting ten cubic feet of gas against that of 140 cubic feet of compressed air, and these would be about as one to tion to the subject, and remarks that the quantity of catechu to be used necessarily varies according to the properties of the feed-water. He considers, however, that the placing of the catechu on the plate immediately over the fire is neither suitable nor requisite. His experience in removing incrustations already formed extends mostly to cases where the thickness was ¼in. to ⅜in., and by a carefully following out of his receipt, he maintains that the incrustation soon becomes detached and floats in the water in pieces about the size of a half-crown.

---

* *Abstracted from the Cantor Lectures, delivered before the Society of Arts.*

The catechu at first makes the water of a deep red colour—as may be noticed by the gauge glass—and if this shade is not produced a further quantity of catechu must be added. In a few days the dissolving of the incrustation will have been complete. At this time—or in any case before the water has changed from deep red to bright red—the boiler is put out of action and is cleansed from the incrustation, now lying in free pieces, as well as from dust, &c., and is filled again as usual with water. This cleaning out of the boiler some days after the first addition of the catechu is absolutely necessary, for as soon as the catechu is saturated with the incrustation the sinking of the floating pieces causes the recommencement of incrustation in various parts of the boiler. It is therefore suggested to postpone the adding of catechu until eight or ten days before the cleansing of the boiler, care being taken that a sufficient quantity of catechu be added during that period.

According to Herr Hiller's theory, the introduction of a quantity of catechu when the boiler is being filled again is not advisable, as the consequent thickening of the water is apt to cause stoppage of taps, &c. He considers the catechu ought to be added to the feed-water when it is hot. Some pounds of catechu should be placed in a strong drill bag, which should be fastened in such a way as to be covered by the feed-water, the catechu being thus dissolved. If the sack is empty before the water is of a deep red colour, more catechu should be added, the bag being cleaned out first. When the required deep red tinge is attained, the addition of catechu ceases, but is resumed if the water loses that shade, or else the consequences may be serious. Should it be desired to give up the use of catechu, it should not be broken off at once, but should be continued until the next boiler-cleaning takes place, and then ceased.

There are some descriptions of water which, though not containing the substances which usually form incrustations, have other kinds of impurities. Against these catechu is of no effect.

The cleaning of boilers where catechu is used has to be more frequent, though less troublesome, than when such is not the case, on account of the increasing substance thickening the water. The saving of the boiler itself is considered, however, to make up for this circumstance, and for the relative high cost of the substance used. A powder has, it is remarked, been for some time in use in which catechu is employed in union with other chemical substances.—*The Engineer*.

[The right to prepare and sell the catechu referred to is said to be the subject matter of letters patent granted in 1874 in the United Kingdom, which patent is still in force.—Ed.]

USEFUL AND SCIENTIFIC NOTES.

White Fillings for Teeth.—There are several white fillings in use by dental surgeons which contain neither mercury nor silver. They are made by mixing oxide of zinc with impalpable glass-powder in small proportion; and just before using, when the cavity of the tooth is prepared, a small quantity of deliquesced chloride of zinc is placed on a glass slab, and enough powder added to make a thick paste, mixed rapidly. It "sets" very quickly, and forms a good temporary stopping. It is slightly irritating to the "nerve" of a tooth, and should not be inserted directly into a cavity in which caries has far advanced without placing a little solution of guttapercha in chloroform over the region of the pulp. A less irritating filling is made by mixing the same powder of oxide of zinc with pyrophosphoric acid; this is a more permanent white stopping.

A VINEYARD proprietor near Nimes having had several complaints made to him about his wines, requested M. Barthélemy, Professor of the Faculty of Sciences at Toulouse, to analyse them for him. In some of them a rather large proportion of arsenic was found, larger than the trace sometimes found in certain red wines. The wine from one barrel tested contained no arsenic at all, and in this instance the cask containing the wine was a new one; it had not been previously used. The other barrels had been cleaned after use with "drogue," which, in point of fact, is diluted sulphuric acid, and the sulphuric acid of the central districts of France has of late years contained so much arsenic that M. Barthélemy has sometimes used it to obtain *a supply of that material.*

SCIENTIFIC NEWS.

THE famous red star which M. Trouvelot saw for a moment near the sun during the total eclipse of May 6th last is now recognised as, without doubt, Alpha Arietis—at least, Prof. Krüger, of the *Astronomische Nachrichten*, says that he has a communication from Prof. Holden which practically settles the question, and the intra-Mercurial planet is once more undiscovered.

Dr. Palisa's small planet 226, discovered at Vienna on July 19, 1882, has been named Weringia.

The anniversary meeting of the Royal Society will be held as usual on St. Andrew's Day, Nov. 30, when the following names will be submitted for election as officers and council:—President, Prof. T. H. Huxley, LL.D.; Treasurer, J. Evans, D.C.L., LL.D.; Secretaries, Prof. G. G. Stokes, M.A., D.C.L., LL.D.; Prof. M. Foster, M.A., M.D.; Foreign Secretary, Prof. A. W. Williamson, LL.D.; other members of the Council—Capt. W. Abney, R.E., Prof. W. G. Adams, M.A., F.C.P.S.; the Duke of Argyll, K.T., D.C.L., J. G. Baker, F.L.S., T. L. Brunton, M.D., Sc.D., W. H. M. Christie, Astronomer Royal, W. De la Rue, M.A., D.C.L., Sir F. J. O. Evans, K.C.B., Prof. G. C. Foster, B.A., F. Galton, M.A., F.G.S., J. W. L. Glaisher, M.A., Sir W. W. Gull, M.D., H. Müller, Ph.D., Prof. J. Prestwich, M.A., F.G.S., Prof. O. Reynolds, M.A., O. Salvin, M.A., F.L.S.

The death is announced of Prof. P. T. Riess, the well-known physicist. He was the first Jew admitted into the Prussian Academy of Sciences, being chosen in 1842.

The death is also announced of M. Louis Bréguet, the famous horologist of Paris. He was a distinguished mechanician and electrician, and contributed many important papers to the Bureau des Longitudes. He was born Dec. 22, 1804.

The telegraph wire to the summit of Ben Nevis has been completed; and as Mr. Omond will by the time this reaches our readers have settled himself in his post, those who wish can have telegraphic messages as to the state of the weather at the highest point in Great Britain.

At a quarterly meeting of the Institution of Mechanical Engineers, held last week at Birmingham, an interesting paper by Mr. E. A. Cowper was read, in which the author described the inventions of James Watt and his models preserved at Handsworth and South Kensington. Mr. Cowper gives a list of 34 models which he describes, and points out the improvements which have followed on the inventions of Watt. This paper, when published, will be useful to many, for as there is no explanation appended to the models, it is necessary to carefully examine them in order to read their meaning.

The Institute of Civil Engineers have arranged for a series of lectures on Heat and its Mechanical Applications during six alternate Thursday evenings. The lecture on Nov. 15 will be "The General Theory of Thermodynamics," by Prof. Reynolds, F.R.S. On Dec. 6 "The Generation of Steam and the Thermodynamic Principles Involved," by Mr. Anderson. On Jan. 17, 1884, "The Steam Engine," by Mr. E. A. Cowper. On Feb. 24, "Gas and Caloric Engines," by Prof. Fleeming Jenkin, F.R.S. On March 20, "Compressed Air and other Refrigerating Machinery," by Mr. A. C. Kirk, and on April 3rd "Heat Action and Explosives," by Capt. A. Noble, F.R.S.

In opening the class of engineering in Edinburgh last week, Prof. Fleeming Jenkin delivered a lecture on Telpherage, in the course of which he said it would provide the cheapest mode of inland conveyance for small quantities of goods, and might enable explorers to reach the North Pole. We will give an account of the system shortly.

The electric light was, last week, employed with much satisfaction and success in the operating room of the Royal Ophthalmic Hospital, Moorfields. The "light" was a platinum wire incandescent burner in a metal case, with a lens in front and a reflector behind it. The battery was a four-celled bichromate. The "light" was affixed to a movable stand, which could be carried about and held in any desired position by an assistant.

According to experiments made by Professor Pulny, of the Ecole Polytechnique of Vienna, incandescent lamps fed by alternating current machines, have a longer life than those fed by direct currents. It has been known for some time that with direct currents there is a transference of carbon to the negative side of the filament, and if the direction is changed at regular but comparatively long intervals, the top of the filament increases in size. With alternating currents it is found that the filament preserves its form and thickness for a very long time, but slowly becomes more slender at the bend.

A series of ten lectures on the diseases of field and garden crops, will be delivered by Mr. W. G. Smith, F.L.S., before the Institute of Agriculture, at South Kensington (British Museum), during next week. The lectures will be fully illustrated.

One of Mr. Webb's compound locomotives recently took a train of thirteen coaches from Euston to Carlisle, ascending the Shap Fell inclines without assistance. The weather was "greasy," the time 7h. 20m., less 32m. for stops at stations. A run of 300 miles at that speed is not a bad performance for a "complicated" machine.

The "diffusion pulp" from the beet sugar factories has been largely used on the Continent as a food for cows. According to MM. Andouard and Dezounay, it does not deserve its reputation as a milk-producing food. Their experiments, however, were made with pulp which had been preserved in a silo. Given to a cow in quantities of 60lb. and then 120lb. a day, there was an immediate augmentation of 32 per cent. in the yield of milk; the richness in casein and mineral salts did not appear to be affected, the proportion of butter was increased 12½, and of sugar 23½ per cent.; but children refused the milk on account of its flavour, and the experimenters doubt whether good-flavoured butter could be made from it.

We regret to record the death on Oct. 26, at Southsea, of the Rev. Nathaniel Stedman Godfrey, S.C.L., F.R.A.S., for twenty-five years vicar of St. Bartholomew's, Southsea, and for many years an esteemed contributor to these pages, aged 66. We have also to record the death of another contributor, Captain James Steel, late quartermaster in the Royal Engineers, which took place at his residence, Glenalvon-villa, the Avenue, Southampton, on Monday week. Captain Steel joined the Royal Sappers and Miners in September, 1839, and on account of his great taste for the investigation of scientific questions, combined with mathematical abilities of no mean order, he was promoted by the late General Sir Charles Pasley, R.E., then commandant of the Royal Engineers' establishment at Chatham. Having passed through the junior grades, this worthy regimental non-commissioned officer was promoted to sergeant-major, on the 6th October, 1854, and performed the duties so as to earn the respect of both officers and men, until the 24th of October, 1863, when he was commissioned as quartermaster. Quartermaster Steel retired from the Royal Engineers on half-pay in November, 1873, and was appointed manager of the Ordnance Map Depot in London, an appointment which he held with much credit, until he resigned it about six years ago. In addition to Captain Steel's scientific attainments, he was an ardent musician and a proficient on the violin.

The Otto Engine and Dowson Gas.—We understand that Messrs. Crossley Brothers have recently made a further test of the fuel consumption with the Dowson gas at their new works at Openshaw, and that the following is the result:—During 17 days there was an average of 90 (indicated) horse-power, and 8 tons of coal were used, the fuel consumption being as low as 1·3lb., per indicated horse-power per hour, although the power was produced by several engines.

ACCORDING to a communication made to the London section of the Society of Chemical Industry, by Mr. W. Weldon, F.R.S., it does not seem that we are much nearer to cheap aluminium than we have been for a long time. A short time since it was announced that a new method of production had been invented and was in use; but Mr. Weldon says this invention only relates to the production of anhydrous alumina from potash alum, and if the method of obtaining this were 50 per cent. cheaper than that of M. Pechiney, of Salindres, it would only cheapen aluminium by 5 per cent.

taking into account the p.m. of A deduced from meridian observations at Dorpat and Poulkova, he finds the movement of B rectilinear, and due to the p.m. of A. He remarks, however, that on this hypothesis it is difficult to understand how, unless the small star be variable, it should have been missed in 1857 and 1858, as the distance then would be considerably larger than in 1872, when the measures were made without any trouble; for, according to his formulæ, the minimum distance was reached in 1871·3, and the stars ought then to begin to separate.

M. Perrotin has recently measured this curious object with the 15in. equatorial by MM. Henry at Nice: he gives 198·9°: 2·39″: 1883·6 (4 nights). Strange to say, he sees a fainter star, 11·3 mag., with *exactly* the same position angle, the distance being only 1·44″. If this star really exists, Σ. 2400 is one of the most remarkable triples known. Perrotin suggests that some of O. Σ.'s observations may refer to this new star, and not to Σ.'s companion. O. Σ.'s observations, when he failed to see or only suspected Σ.'s *comes*, were made with a power of 858 on the 15in. refractor. It is to be hoped that this interesting object will not be neglected in future.

Oct. 31st. **H. S.**

β DELPHINI, δ EQUULEI.

[22014.]—Since writing my last letter (21988) I have had two opportunities of measuring β Delphini. They were nights on which there was a great deal of fog, and the definition was exceptionally good—the finest I have had this year. But in a short time the fog thickened so much as entirely to cover up the sky and put an end to work.

The measurements were as follows:—

β Delphini. R.A. 20·31. Mags. 4·3, 5·7.
P = 193·0°. D = 0·3″ (est.) Ep. 1880·826.
P = 192·0°. D = 0·3″ (est.) Ep. 1880·829.

In a star of such difficulty, however, there may well be an error of 10° in the angle; but I believe it to be not far off the mark.

I tried δ Equulei the same night; but could not be sure that it was double.

A CHEAP ADAPTED PYROLOGICAL HAND-BLOWER.

[22015.]—Accustomed as I am now to see our native English ingenuity and talent employed in adapting instruments and apparatus, well known and cheaply sold in connection with other and more ordinary uses, to the purposes of blowpipe analysis, it has not yet been my lot to come across such a simple and ingenious adaptation as this by Mr. J. T. Letcher, of Truro, Cornwall.

It is, in few words, the conversion of one of those white, vulcanite, children's air-balls, about the diameter of one's closed fist, sold in toyshops for 3d. or 4d. each, into a *blowpipe hand-blower* (!), and a very efficient one Mr. Letcher has made of it.

Although, of course, such a blower would not be expected to possess the power of leather bellows, the return of the elastic ball to a spherical shape after squeezing (which creates the atmospheric indraught) being by no means so vigorous as the outwards force of a contained steel spring, or the muscular pulling open of hand (housemaid's) leather bellows, and consequently the pressure of indrawn air and then of expelled air being proportionately less; still, for ordinary purposes of blowpipe analysis—as e.g., the sublimation of volatile metals on aluminium plate, &c.,—this cheap and most ingenious little hand-blower is really first-class.

The valves are placed in two small turned pieces of boxwood inserted into the poles of the little elastic air-globe, and an elastic air-reservoir, covered by a hair net, is situated about halfway in a piece of vulcanised rubber tubing leading to the telescopic stand for the jet and nozzle, which are moved up, down, or sideways on a kind of universal joint, this stand being also, I believe, an invention of Mr. Letcher.

That gentleman has also sent me a most ingenious telescopic-stand holder for platinum wire, &c., and for Al plate on a pinch, though the grasp of the geometrical pen is scarcely long enough for that; but I have doubled this length by boring another hole for the screw nearly at the base of the pen "arm."

Mr. Letcher has also been so good as to send me a most beautifully-finished air-reservoir blowpipe, with platinum jet (Fig. 3, "Easy Lessons, &c.," Vol. XXXVII. p. 163, "E. M."), which, with his other apparatus, I shall have the pleasure and pride of showing in France, Italy, Switzerland, and Germany, on my sojourn there shortly, as specimens of the work of an English "Bergmechanikus," as Plattner calls Lingke ("Probirkunst," &c., p. 32).

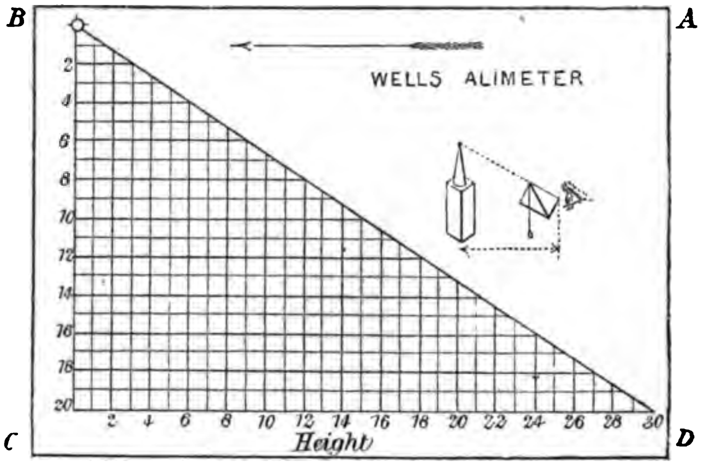
W. A. Ross.

AN INSTRUMENT FOR ROUGH ESTIMATION OF HEIGHT OF BUILDINGS, &c.

[22016.]—I have lately seen an ingenious application of the properties of similar triangles, which seems worthy of a place in your paper.

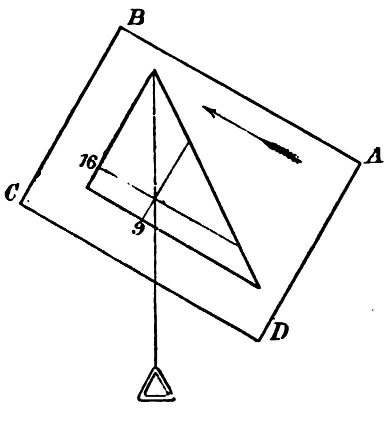
If Fig. 1 is cut out and pasted on cardboard, it will answer for measuring heights up to 30 yards. Make a fine hole exactly at the corner of the triangle near B, and pass a silk thread through it. Fasten with a knot behind, and attach a light weight, such as a wire ring, at about 4in. from the hole, at the other end of thread. This is to act as a plumb line.

Fig. 1.



To use it to measure a house, for instance:—Stand at a convenient distance, say, 16 yards from it, and look along the top edge A B at the point of which you wish to ascertain the height. The silk thread will now hang as in Fig. 2.

Fig. 2.



Look along the line on B C marked 16 yards, and the point at which the plumb line cuts it indicates the height of the top of the building measured from the level of your eye. Add to this the distance from your eye to the ground, say, 5ft. 6in.

Thus the height of the building, as indicated in Fig. 2, is 9 yards, or 27ft. Adding 5ft. 6in., gives 32ft. 6in. as the total height.

In measuring the horizontal distance (in this case assumed to be 16 yards) from the building to the observer, a point vertically beneath that to be "sighted" must be taken to measure from. Instead of reading the divisions as yards, they may be read as feet.

It is best to stand at a distance about equal to the height to be measured. For this purpose, B C should be made as long as C D; but space forbids my making it so in the figure.

I have been told that it was invented by a Mr. Wells, a gardener under Sir J. Paxton.

Glatton.

RAILWAY SPEEDS.

[22017.]—With reference to the letter of your correspondent "St. Aubyn's" (letter 21970, p. 175), asking for details as to the journey of "three hours exactly" between Leeds and King's-cross, by the Duke of Edinburgh's special, I inclose you an extract from a note received by me this morning from Mr. Cockshott, superintendent of the line for the Great Northern. Mr. Cockshott says:—

"We have not at any time run a train from Leeds to King's-cross in three hours. H.R.H. the Duke of Edinburgh has not travelled on our line from Leeds to King's-cross for a considerable time."

The origin of this extravagant report consists in the fact that on June 24th, 1882, the Prince of *Wales* was conveyed from *Bradford* to King's-cross (193 miles) in 3h. 48m., including a stoppage of 5 minutes at Grantham (as I was informed at the time in a letter from Mr. Cockshott).

At the meeting of the British Association in Southampton during the last week of August, 1882, Mr. John Fowler, doubtless alluding to the above run, stated that "a few months ago the Duke of Edinburgh was taken from Leeds to London, a distance of 186¾ miles, in exactly three hours."

The wish, however, must have been father to the thought, for according to the superintendent of the line himself, such a run never did take place. When such a thing does occur, it will no doubt be on the Great Northern.

In the mean time, I think that however interesting these "parade" runs may be, it is of much more practical importance to know what is the ordinary average of the speed attained, as a matter of course, every day of the year by our express trains.

In a few weeks I hope to have published a little pamphlet containing details of speed, gradients, &c., for all the express lines in the kingdom.

Cambridge, Oct. 31. **E. Foxwell.**

THE AUTOMATIC VACUUM BRAKE.

[22018.]—May I draw the attention of your readers to another danger of the automatic vacuum brake in use on the Midland Railway. A fortnight ago, two men were fined at Leicester for leaving a train in motion. From the statements of passengers in the train, and also of people on the platform, it appears that the brake leaked off, after the train had come to a stop. This allowed the buffer-springs to recoil, and move the carriages, and three persons were thrown down in leaving the train. At a previous station a passenger had been thrown down in exactly the same manner. Surely some strong measures should be taken to compel the company to remedy this state of affairs. Not only are trains constantly running past danger signals, and into buffer stops; but here is a case of passengers being thrown down owing to the use of a dangerous appliance, which allows the power to leak away when it is urgently required. The drivers are punished for jerking the trains. This is most unjust, as it is not their fault. Some months ago, inspectors were sent round to inquire into these cases of "jerking" the trains. When the drivers asked to be shown how to remedy this, the answer was something to this effect: "You must use your own judgment; I have not come here to show you how it is to be done, but to tell you that it has to be done." No answer could show more clearly that those who ought to know do not know how to use this appliance—an appliance supposed to be for the safety of passengers and servants.

This jerk is due—firstly, to the more powerful steam brake stopping the engine (to which it is fitted) more quickly than the train, which causes the impetus of the train to compress the buffer springs; and secondly, to the leaking off of the brake on the carriages, allowing the buffer springs to rebound.

This compression of the buffer springs shows the want of power of the vacuum brake. Couplings are often broken owing to the use of a powerful steam brake on the engine in conjunction with a weak vacuum brake on the carriages. On July 13, the 11.10 a.m. train Leeds to Bradford (engine 158), was stopped by the application of the brake by the guard. Since the steam brake cannot be applied by the guard, the motion of the engine was not arrested, and the tender coupling was broken. On Oct. 10, a coupling was again broken on the 6.22 p.m. Leeds to Skipton, at Armley, owing to the rebound of the carriages. On Oct. 25, 1.30 p.m., Leeds to Morecambe, coupling broken at Saltaire, from same cause—3 mins. delay.

Another source of danger has lately come under my notice. Engine "waste" has by some means entered the hosepipe and stopped it up. On Friday, September 28th, the 9.30 a.m. Bradford to Skipton ran past Frizinghall station owing to this cause, *although the vacuum gauge on the engine showed 20in., thus indicating that all was right.* On Saturday, September 29th, 7.30 a.m. Bradford to Ingleton ran past Manningham from the same cause, the gauge showing 20in. On the same day, the 11.20 a.m. Bradford to Keighley ran past Manningham from same cause. The remarkable point is, that in all these cases the gauge showed the drivers that the brake was in perfect working order, and yet when the brake was wanted there was none.

The ejectors can also prove a danger to the drivers. On June 29th, the 12.33 p.m. Keighley to Bradford was delayed 10 minutes at Shipley. The nut of the spindle attached to the ejector handle blew off inside, allowing the ejector handle to come completely out. The steam from the boiler issued through the hole, and the driver had a very narrow escape from being scalded. The train was in motion at the time (having just started), but the brakes were *not* applied automatically. Cases have also occurred in which drivers have been burnt by the flames issuing from the fire owing to the use of the large ejectors.

I think the majority of your readers will agree with me in saying that this brake is a most dangerous appliance, and ought not to be allowed to be used any longer. **Meteor.**

THE ACCIDENTS AT RETFORD AND BRINNINGTON JUNCTION, AND CONTINUOUS BRAKES.

[22019.]—On the 24th of August a collision occurred at Retford, on the Manchester, Sheffield, and Lincolnshire Railway, between a Great Northern passenger train and part of a coal train.

Major Marindin reports: "Great responsibility is incurred by the Company in leaving a passenger line of such importance running through a busy goods yards without the ordinary safety appliances of interlocked points and signals, and without the protection of block-working, which would have prevented the accident in this case."

The Great Northern passenger train was fitted with Smith's vacuum brake, and in the Board of Trade return the Company states that it *can* be applied by the guards; in actual practice it seems that in the present case the guard had no control over this brake. The engine-driver does not appear to have been aware that the line was blocked until too late; but the guard saw the home signal at danger when probably 500 yards away from it, and Major Marindin states: "If he had had the power of applying the continuous brake, which is a most essential condition for a proper brake, he would probably have been able to stop the train *and avert the collision.*"

Colonel Rich has presented his report upon the double collision which occurred on the 12th September near Brinnington junction on the Cheshire Lines (Joint) Railway.

An excursion train, from Doncaster to Liverpool and Chester, broke loose when running between Bredbury and Brinnington Junctions (near Stockport), and the leading portion of the train was twice run into by the rear portion (fourteen passengers being injured). The line is on an incline of 1 in 63 and 1 in 80.

The passenger train consisted of two engines and tenders, and nineteen vehicles, all fitted with Smith's vacuum brake, but the vacuum brake-pipe was not extended to the front of the second engine. The train was stopped at Bredbury by signals and the brake was in good order; but immediately after passing the starting signal the driver of the second engine observed that the indicator on his vacuum-gauge showed that the brake was out of order. It is a well-known fact that the vacuum brake is slow in action, and therefore causes severe [illegible] worked upon a long train; and from where the broken drawbar was pick[illegible] be no doubt that it was broken wh[illegible] checked at the Bredbury signal.

Colonel Rich reports: "If the [illegible] had been of an automatic kind, the [illegible] probably, have been prevented, applying itself to the rear portion of the train as soon as the brake-pipe was broken."

The general report upon the accidents which occurred during the year 1882 has recently been published, and contains a long list of cases in which accidents might have been avoided by efficient brakes, and also details of several which were caused by the failure or unsatisfactory working of vacuum brakes.

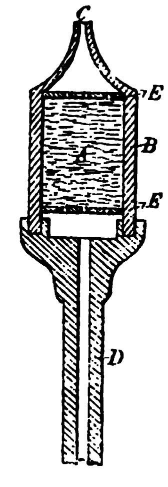
Mr. Calcraft states that the reports show "that no system of working, however complete in itself, can be considered satisfactory or as fully providing for safety which does not comprise the fitting of passenger trains with continuous brakes upon the conditions indicated by the Board of Trade." It must be remembered that the conditions above referred to were laid down more than six years ago, yet we still find the brake question in the present very unsatisfactory state. It is perfectly clear that certain companies never will adopt good brakes until compelled to do so. Under these circumstances it is clearly the duty of Parliament and the Board of Trade to protect the lives of the passengers by enforcing the adoption of safety appliances.

Clement E. Stretton.

Saxe-Coburg-street, Leicester, Nov. 3.

LANTERN MATTERS.

[22020.]—Having received so many valuable hints from "ours," I hasten to give what I believe will be of use to *all* who use the lantern. My troubles began in slide painting in making a sufficiently fine outline; and this is how I overcame this difficulty, and hit upon a plan at once as good, if not better, than that given by Mr. Dallinger some time since of drawing on ground glass with a pencil:—I first hunted up an old round table; this I painted a dead black colour, smoothing it off with sandpaper and filling up all cracks; then another coat of black, with plenty of turps in and a few pinches of vermilion to take off any tendency to blue in the paint. When thoroughly hardened, you have a circular blackboard, upon which you may sketch your intended outline. With a white chalk crayon, work as many fine outlines as you think proper. I then from this took a negative with an instantograph, using the 3¼in. by 3¼in. prepared "lantern dry plates" of Lancaster, giving about five seconds in dull weather, and developed until the black table began to show the merest trace of darkening; then I worked off and fixed and dried. I then had a most beautiful outline of the subject I wished, and done in *one fourth* the time it would have taken me to draw on the glass direct, and far better, and shows beautifully on the screen. Any amount of detail can be quickly done on the round black board, with the positive assurance that it will show well when magnified.



A. Asbestos fibre chamber.
B. Brass tube.
C. Nipple.
D. Pipe from dissolver to gas bag.
E. Perforated brass to contain the asbestos in place.

While thinking over the various lights in use, I remembered being told, at a certain lecture at which I was present, that only one gasbag was used, and in that bag were two gases mixed in their explosive proportions, and yet the audience were not blown to "smithereens." I unfortunately did not learn what kind of burner was used, and beg [illegible] our experts whether a burner could [illegible] this purpose (gases mixed in [illegible] as follows:—From [illegible] and the light [illegible] devised of [illegible] experts, and so always enjoy our 450-candle power light with no danger. And if this is feasible, let us by all means know size required for chamber and size of nipple hole, as well as number of feet required in one gasbag to hold both gases for, say, *one hour's* consumption.

March. **James Green.**

COLOURING LANTERN PHOTOGRAPHS.

[22021.]—Perhaps other amateurs besides myself have been discouraged at the difficulty of colouring smoothly the skies of lantern photographs. Having failed in getting results to please myself by dabbing, stroking, and many other dodges, I have now succeeded in getting perfect gradation of tone by pouring on a filtered solution of colour, previously ground up with "medium," in an agate mortar. Pour it on very dark at the top of the picture and flow it down to the horizon, then back again slowly, and allow it to drain off at the edge; when the proper depth is attained, blotting off the drainings from the edge; when dry, the outline of the horizon is easily obtained sharp by rubbing off the paint which has run over the border with a fine paper stump. Should any dust settle in spite of all precaution, I make my clouds at the faulty part, thus getting rid of specks. This may be, after all, a well-known dodge; if so, I apologise for intruding it in "ours."

Clapton. **Gerard Smith, M.R.C.S.**

GRINDING AND POLISHING GLASS SPECULA.

[22022.]—I would here call attention to a little error that has escaped my notice. In my last letter, Vol. XXXVII., p. 600, line 23 from bottom, "shadow" should be "shadows." As to Fig. 1 on the same page, though reduced in size from the one I sent, it is plenty large enough to use a scale upon to make the triangles by for any sized speculum. As to Fig. 2, the wood engraver has omitted to represent the pitch at the corners of the triangles seen in section, which pitch I refer to in p. 601, as shown in Fig. 2.

I now go on from where I left off in my last letter. I there supposed the amateur had his speculum rough ground, and fixed in the machine ready to begin with the elutriated emery. I may here observe that "elutriated" is a much better term than "washed," washing being only the process of removing the mud and dirt from the used emery. I forgot to mention that for rough grinding, 60 hole emery is the best size up to 8in. diam., above that, 40 hole is best, 60 and 40 hole meaning respectively emery that has been passed through sieves with 60 and 40 holes to the inch (in length). I must now tell the amateur how to get his elutriated emeries, and how to use them. As my object is not to go over again what others have explained before in our columns for years, I would refer the amateur to what I believe to be the best description of truing and smoothing, and an excellent mode of elutriating his emery in our obliging and always practical friend "Prismatique's" letters, Vol. XXXIV., pages 187 and 304. I believe almost everyone who practises the work will have his own little modifications of the general mode of doing it, and, of course, everyone thinks his modification is the best. I will, therefore, give some general observations and practical hints on this part of the subject. The amateur who has worked out the hollow of his speculum, and edged it, will, if he has carefully collected all the emery with a sponge into one vessel of water into which he keeps washing his sponge, have enough worked emery to collect all his six sizes of elutriated emery form, this number being enough for his purpose. If he lets the emery settle for three hours or more, and then pours off the water down to the emery, he will have what is technically called "sludge," and it is from this sludge that the trade gets all its grades of truing and smoothing emeries—they never buy it. But as some amateurs may not be able to get enough from their first sludge, "Prismatique" has kindly told me that I may here tell them that they can get 1lb. of what is called "washed" emery for 4s., from Medway's, Lloyd's-row, St. John's-street-road, London. From this emery the amateur can get all the grades he wants as "Prismatique" directs in his letters before referred to. Now, as there is very little wanted, I think the amateur may try to get all he wants from his own sludge, which, by the way, will continually accumulate with each speculum he makes, as in the trade. Now, one important thing in elutriating emery is to have plenty of water, especially for the amateur, when his sludge has accumulated, and there is another source of error to those who have plenty of sludge. It is the accumulation of mud with the emery, which will prevent the emery from going down in the time given for each grade. This mud is the ground glass and the metal of which the tool is made, and very fine emery. It is highly important, then, that the amateur commence the elutriations with com[illegible]tively clean sludge; to clean his sludge he [illegible] have plenty of water. I may almost say the more the better. I will give him what I consider the least safe limit for him—those used to it may use less. A teacupful of sludge, when dried, will weigh about 7oz., and will still about fill the cup. I have tried this experiment on purpose to have a handy means of judging for the amateur. Of course, to anyone who has practised for years, he can guess near enough; in fact, he gets to do all without much thought, and without any measuring; but I find, when I attempt to describe a process, simple as it may be to me, it does not do to say to an amateur, "put a little of this and plenty of that together, mix them for a short time, and then let them stand for a long time before pouring." I have to suppose the amateur is only learning, and has no experience to lead him to understand what a "little of this and plenty of that, &c.," means, as to quantity or time. I, therefore, have to descend to details that, to those who are farther advanced, may seem trivial and quite self-evident. I must confess that to write these letters is far more trouble than to do the whole thing. Well I have just said a teacupful of sludge weighs about 7oz.; now two teacupfuls of sludge, or say 1lb. of dry emery to each gallon of water, will be enough for washing the mud from the sludge, more water would do no harm, would be better in fact. Now for the washing: I will give my way: the amateur must have a sieve of 60 meshes to the inch, it must be brass, so as not to rust; he must pass his sludge through this. It is useful to press the sieve half way into the water below, so as to open the holes and half fill the sieve, then tap the sieve and let the sludge run through, what will be left on the sieve will have to be thrown away as of no value; of course, I have supposed he has roughed out with 60-hole emery, as I am by supposition dealing with a 6in. speculum. If he roughed out with 40-hole emery he must pass what is left through a 40-hole sieve, and thus save the unbroken down emery that would not pass through the 60-hole sieve; then throw what remains away, which will be bits of sponge and bits of glass and dirt of all kinds. Now for getting rid of the mud: the amateur must stir up all the sludge that has passed through the 60-hole sieve in plenty of water, not less than a gallon for every two teacupfuls of sludge, or say 1lb of dry emery, let it stand for 3 hours, then pour off all the water down to the emery at the bottom, but not to pour any of the emery away. This will carry off a lot of dirty, yellowish-brown mud. Repeat this, filling up with clean water three or four times, or until, as "Prismatique" says, the sludge, when stirred up, is of a chocolate colour. I always let stand three hours; and "Prismatique" corroborates this, and says: "Three hours will settle the finest emery when standing; but if the sides of the vessel be tapped the whole of the time, so as to cause a series of wavelets on the surface, the mud may be drawn off the finest emery in an hour." "Prismatique" further warns that great care must be taken, or perhaps much of the finest emery may be poured away and lost. This I proved to my sorrow once by letting stand only one hour (without tapping all the time), and I lost nearly all my No. 6 emery. I think, therefore, the amateur had better be on the safe side, and let stand three hours in plenty of water, and pour away.

I will now suppose the sludge is tolerably clean from mud. The amateur has now to divide his sludge into six grades in the following way:—He must have not less than one gallon of water to every pound of emery (those who are accustomed to the work may use less, but I recommend this as a safe proportion for an amateur); he must first get out the 60-hole emery, as this is altogether too coarse for truing. This I do by stirring up the sludge in the water, but not with a rotary motion, and tapping the sides of the vessel for three seconds; then quickly, though steadily, pouring off right down to the 60-hole emery, which will be seen to be at the bottom, with a little more, not quite so coarse, emery. All this I collect and put with the 60-hole emery for roughing purposes again. I repeat this into the first vessel (cleaned) back again, after which I find my sludge is clean from the coarse emery. We must now commence the dividing of the sludge into the 6-grades. I give below the times of subsidence used by Dr. Draper, "Prismatique," and myself; the times I use are a modification of what I believe the late Andrew Ross recommended:—

	Seconds.			Minutes.			
Dr. Draper..	3	20	60	3	10	30	60
Prismatique..	3	10	30	2		5	15
H. A. W. ..	3	10	35	2¼	7	20	60

It will be observed that each series begins with 3 seconds; this I take is really to get the coarse emery out. "Prismatique's" No. 6 is deposited in 15m., because of the tapping all the time, which helps to throw down the fine emery, and so takes a shorter time, so that there is not much difference between my No. 6 and "Prismatique's" No. 6, mine being only a little finer; his No. 4 is what is left of the bought fine or "washed" emery. It will be observed that the time for any particular emery is about three times the previous time used, and my series is a modification of the late Andrew Ross, merely bringing the series of times into a closer approximation to this law between the two extremes, 3s. and 60m., though in actual practice I find we need not be so particular, so that we are near the proper time. I will now describe how I have practically carried out the elutriation in a way that will be suitable and easy for the amateur to follow. Let him take four vessels which I will call jars No. 1, 2, 3, and waste jar, put the water containing the washed emery into No. 1 jar, stir up and let stand 10sec., then pour half into No 2 jar, fill up No. 1 with clean water, stir up and let stand 10 sec.; pour half into No. 2 jar, stir up No. 1 and pour all into No. 3; this is No. 1 emery. Now with the sponge wipe out No. 1 jar and clean sponge in waste jar, which should be three-quarters full of water, thus clean the sponge and wipe out No. 1 jar several times to make sure that it is free from all No. 1 emery. Now stir up No. 2 jar and let stand 30sec. and pour half into No. 1 jar, now carefully and slowly, so as not to shake up the emery, pour the water out of No. 3 jar into No. 2 jar nearly down to the emery, but not letting any of the emery come over; now pour all the No. 1 emery into a basin to finally settle, putting a bit of paper with 1 on it in the basin to show it is No. 1 emery, clean out No. 3 jar into waste jar, clean the sponge well out and put it on a clean place, and never let it get to the bottom of the waste jar, or it may pick up some course emery and convey it to some of the finer emeries further on. Now fill up No. 2 jar with water and stir, let stand 30sec. and pour half into No. 1 jar. What is left in No. 2 jar is No. 2 emery; stir up and pour all this into No. 3 jar to settle while the next emery is being obtained, clean out No. 2 jar into waste jar. Now stir up No. 1 jar, and here I may observe the hand is best for this with the sleeve turned up, we can then feel that the emery is stirred from the bottom, let stand 2 min., pour half into No. 2 jar. Now, pour off the water in No. 3 jar nearly down to the emery into No. 1 jar, there having been plenty of time for all No. 2 emery to settle during the getting of the first lot of No. 3 emery; and No. 3 jar should always be kept quiet from one emery to another. Fill up No. 1 jar with water, but so as to allow the hand to go in and yet not make it run over; this is always what is meant by filling up. Put the emery in No. 3 jar into a basin for final settling, put a bit of paper in with 2 on it—this is of course No. 2 emery. Now stir up No. 1 jar and let stand 2 min., pour half into No. 2 jar. What is left in No. 1 jar contains No. 3 emery; pour all this into No. 3 jar to settle; clean out No. 1 jar into waste jar, what settles in this waste jar must not be thrown away, it is only waste for the present elutriation; it must be kept for the next. This jar may be the vessel into which the emery is washed from the roughing, and No. 1 emery wets; this will be understood further on. We have now half the emeries, and all the amateur has to do is to repeat the process, only altering the time; the water that is left containing fine emery that will not settle in the one hour had better be allowed to stand 3 hours, and then poured off down to the emery, and this emery kept, so that if the amateur has made any mistake, he will not have lost his fine emery. The emeries in the basins may be allowed to stand for several hours, or till the next day, when the water may be poured off close down to the emery, the emery then can be put into covered vessels ready for use.

The amateur is now ready to begin the grinding of his speculum in the machine—and to prevent scratches, which I have noticed is a general fault in amateur work, I use three jars for washing the emeries off the speculum and tool into after each wet. I keep a separate sponge in each. On the outside of the first jar to be used, I have painted with Brunswick black "R, 1." This means that I wash into this jar with its own sponge, the roughing and No. 1 emery after each wet, so that the coarse emery never gets beyond this jar to the finer emeries; on the second jar to be used there is "2, 3, 4," meaning that I wash these emeries off the speculum and tool after each wet into this jar, with, of course, its own sponge; these emeries may be called the truing emeries for convenience; thus, the particles of the comparatively coarse No. 2 emery never get carried by the sponge into the fine smoothing emeries 5 and 6; on the third jar to be used for the smoothing emeries there is "5, 6," meaning that into this jar is washed these emeries after each wet, by its own sponge—the sponges are kept always in their respective jars, except when in use, when they are kept on the inverted lid of their respective jars. Why the amateur is apt to get scratches is, because he washes his, perhaps, single sponge, into a small vessel that allows the coarse emery to be stirred up each time the sponge is washed, and so some is carried in the sponge to the speculum; and again, using one sponge, some of the coarse emery gets entangled from the beginning in its fibres, and gets set free by the repeated washings of the sponge during the various wets, right down to the finest emery. Now in the trade a very large pan, or even a tub, containing many bucketfuls of water is used to wash the emeries in off the work and tool; this allows the emery to settle below the influence of the surface disturbance caused by the successive washings of the sponge, added to this practice gives a dexterity to avoid sources of error; it is, therefore, better for the amateur to take too many precautions than too few, though it be at the cost of being laughed at by those in the trade.

As I have explained before, it is important to get nearly all the mud from the sludge before beginning the elutriation; otherwise the emeries will not go down well. Now one of the great sources of the finest mud is the two last emeries, for these, after using with a plain tool—*i.e.* an ungrooved tool—become so fine as to be little or nothing but mud. Of course, where grooved tools are used, a lot of emery gets into the grooves and does not get ground down. I should recommend the amateur to use plain tools for though I believe it is impossible to get so near an approach to a spherical surface with plain tools to begin the polishing with, as with properly facetted tools, yet on account of other advantages attendant upon the use of plain tools, and most of all that we must depend finally upon the polishing to get a true figure, I recommend the amateur to save himself the trouble of grooving his tool, and to use plain tools, which if he does, he can afford to throw away his used smoothing emeries, and save a lot of mud getting into the sludge he gets his emeries from. I am indebted for this practical hint of throwing away the two last emeries after use to our obliging and eminently practical friend, "Prismatique," and I have the correctness of the hint confirmed in my notes, for I find I had tried this experiment. I collected the used emery of each number into a separate basin of water during the grinding up of a speculum; I let the emery settle and then examined under the microscope the average size of the emery grains of each number of emery, and I found that each used emery had been reduced two grades: thus, for instance, No. 2 emery, when used, had been reduced to the average size of the grains of No. 4 unused emery: No. 3 emery when used to the size of No. 5 unused, and so on; so it follows that No. 4, the last of the truing emeries, as I call them, and the last I collect when used in my second vessel marked "2, 3, 4," would be reduced to the size of No. 6 unused emery; therefore it is important to keep this emery; but No. 5 emery when used would be reduced to what No. 7 emery would be if we used such a number; but as we do not, we had better throw it away, for it has become practically mud, so No. 6 emery, when used, would become No. 8, which would only act as still finer mud, and impede the going down of other useful emeries; and so it follows these practical hints of our true friend "Prismatique" can be proved to be theoretically correct. There is another hint that he gives that I can bear testimony to: he says, "The great need is to have purity to a great degree, although absolutely *pure* emery is not so good to smooth with as that procured from sludge." Another piece of interesting information I am indebted to our ever-obliging friend for; I obtained it in this way. "Prismatique" very generously sent me a specimen of his elutriated emeries to compare with mine in their use, as I wanted to be able to tell the amateur how to get the very best, taking all things into consideration. Well, I tried them, and found that they cut better and longer than mine of the same fineness. This led me to examine them under the microscope and compare them with mine, when the mystery was all revealed. "Prismatique's" emery for each size was wonderfully regular in the size of its grains, and comparatively very clean from mud, while mine was composed of different sizes of grains to a large extent, for each size of emery, and contained a considerable amount of mud, which under the microscope is very easily distinguished, when the emery is mixed with water and put between two pieces of glass; I used the animalcula cage. Of course I was anxious to know how "Prismatique" got his so regular in size and clean. He very kindly explained that in the trade there is the extra precaution taken of what is called "cleansing" each number of emery, and that it is done in the following way: Each number of emery is mixed with water and well stirred, and allowed to stand till the main body of the emery is down, when the suspended smaller particles and the mud are poured off into the tub or pan in which the sludge is collected. We can easily understand that, when all the sizes are together, that the larger particles will carry down much of the smaller emery and some remaining mud; but when each number is put into its own water alone, it is free from the mass of the smaller sizes and their mud; the second elutriation or "cleansing," as it is called, is carried out under more favourable circumstances than the first elutriation; which accounts for the more favourable result. But "Prismatique" warns that great care must be taken with the fine emeries, and allow time enough for them to go down, or they will be poured away. I think the amateur had better not risk "cleansing" his emeries, and instead, take an extra wet or two of each emery, for I found that it took four or even five wets sometimes, of my emery of a particular size, to do as much as three wets of "Prismatique's."

And now as to the use of the emeries. I do not think I can say much more than "Prismatique" has said in his two letters in our columns I have referred to before. The quantity of emery to be used will perhaps be the most difficult to get at to the beginner; it takes more for the coarser emeries than the finer for each wet; the rule being to use no more than can be kept between the speculum and tool during the grinding, and water enough added to make it into a paste, not thin enough to run down the sides of the speculum during the grinding, and in thus squeezing out, to allow the tool to come in contact with the speculum and drag;—for the finer emeries about the size of half a pea; for the coarser emeries three or four times as much.

Addenbrook Villa, Love-lane, Stourbridge.

TO "F.R.A.S." AND "PRISMATIQUE."—OPTICAL AND LANTERN TRANSPARENCIES.

[22023.]—I trust "F.R.A.S." will not consider my note on "Shadow v. Mirage" a piece of impertinence; it was written on the day his remark appeared, and why it appears now I cannot say; but I intended the word "screw" to be screen, and also, I fancy I wrote "reflection" in the diagram

I do assure "Prismatique" that I had no intention of making a bullseye in the way he supposes; but my shaft, though barbless, has not altogether gone astray, since it has drawn another letter. Regarding him as I do in the light of an unbreakable bank of practical information, I shall draw on him as long as he will honour the draft, and lest he quote the Hydrostatic Paradox of Controversy and leave me in contempt, let me add that I do not write as one having authority, nor to see myself in print, much less to triumph in argument; but simply to elicit facts.

He says "figuring to surfaces other than spherical has always been resorted to." Now I know that the grinding of lenses to curves other than spherical was attempted before the days of Dollond and Hall; moreover, I never supposed that, except in the earliest days of achromatism, the marrying process was adopted for "best" productions, and not then for larger lenses, seeing that the expense of a large stock of glass would have forbidden it. I supposed one or other curve was reground again and again till it suited, and if, while the ratio of focal lengths was correctly chosen, the radii for curing spherical aberration were wrong, a worker could only produce decent results by curves other than spherical, to obtain which he would find it necessary to have a considerable "take" in one direction or the other on the polisher.

Dollond, we know, did not select the correct curves to cure spherical aberration, so that his final curves must have been other than spherical. Tulley had not a complete theory to work from, and perhaps the same may be said of his work; but what I want to know is, did Dollond *deliberately* choose these spherical radii with the intention of producing curves (ultimately) other than spherical, or did he not rather, when he altered a curve, believe he only had altered its radius or produced a more correct sphere? The "take" might even have been recommended as a means of producing a correct spherical curve. "Prismatique" himself says their practice was to smooth and repolish till a good result was obtained, and suppose the curves then to be spherical, and emphasises this by saying that the old artists did not worry about what the final curves were, so long as a good glass was the result; from which I should have inferred that when on testing they found a curve wanted a "take" at the edge, they supposed the radius wanted shortening. Gundlach, too, assumes the use of spherical curves, or rather mentions no other.

If opticians based their work on the theory, some one of them must have discovered the flaw in the theory. Who was he, then? Or do opticians only use their own curves based on practical experience?

We have the history of the theory and its development pretty complete; when shall we get that of the practice? It seems never to have been written, but has to be gleaned from the traditions of the shop, accessible only to men like "Prismatique," or inferred from the works of old masters. If "Prismatique" and "O. V." would undertake the work, what a book they would make!

Speculum making has fared better than o.g. grinding, chiefly because it has been in the hands of amateurs. From Newton downwards, all the workers of note, save Short alone, have freely given us their discoveries. What a list, putting great and small together: Newton, Hadley, Mudge, Herschel, Rosse, Lassell, Key, Purkiss, Wassell, Blacklock, Tydeman, Bell, "Optical Bricklayer," "Dicturus," and a hundred others. None withholds aught, save With, and he has promised to add his story. We cannot hope to add Mr. Calver's name at present; but it is to be hoped and expected that he will not let his process die with him, as Short and (must I add?) Dollond, Tulley, and the o.g. makers.

Practice and theory are, naturally, jealous of their honours; but I don't think "Prismatique" is fair on Newton, whose *experiments* (*not theory*) misled him; and, after all, if we except Hall, of Essex, of whom we know little (an amateur too), it was not Dollond, but Euler, a pure theorist, who first called in question Newton's results on *theoretical* grounds, and so started Dollond on the right track.

Theory, of course, must have some facts to work with, and an accumulation of facts is of value to test and sometimes suggest a theory; but I fancy theory more often improves the practice than *vice versâ*. However, that is not worth arguing about. The two should be combined, as in the brotherhood of "O. V." with our good friend "Prismatique."

Is there a good process for obtaining lantern transparencies direct? I know the nitric acid one, and it is not successful in my hands. I sometimes draw my picture with white chalk or paint on a black ground (autotype tissue), and photograph that; but though a wrinkle worth knowing, it is not altogether satisfactory, save for maps, when the method, using a blackboard, or slate and chalk, is good. The mountains (usually a difficulty) come out capitally, and are easily stumped by a finger tip. In ordinary cases, a paintbrush and ink, followed immediately by blotting-paper, produce good results.

Bow.

HEATING BOILER FEED WATER.

[22024.]—The interesting description of Engert's steam boiler, in the E. M., points out the value of heating the feed water as a means of preventing incrustation; but according to Calvert and Thwaite, the boiling of the feed water has also a tendency to prevent the internal corrosion of the boiler plates; in fact, the latter authority recommends the addition to boilers of a separate vessel, in which the feed water is to be heated up to 200° Fahrenheit, in order, not only to produce calcareous deposition, but to drive off the air always contained in unboiled water.

J. L. Tomlinson.

PREPARING HARD WOOD FOR TURNING.

[22025.]—I found the following so useful in preparing pieces of very hard wood for turning, that I send it to you in hopes you may find a place for it in your journal. As I had a number of such pieces, from 4in. to 5in. in diameter, which had to be squared at each end, I got some iron rings of ¼in. thickness, which I turned up, inside and out. I bored holes in each of $\frac{7}{16}$in. and put a pinching-screw into each, then put a large face-plate and centre-point on lathe. Having put a squared slot into the face-plate, so that I could move the pin to take in the 4in. ring, I centred the wood and rounded it with the axe at one end, and put in a suitable ring, then put it between the centres. This enabled me to turn up the end square, and by changing ends, the opposite one also, which I could not do by any other means.

Forester.

A "PATENT" FILE.

[22026.]—In reply to "L. B. B." (letter 21995, p. 196), circular files are in use in most engineering shops in one form or another. The simplest and best circular file for general work is an emery wheel; but where the filings themselves are valuable, it is quite common to use a disc of steel cut as an ordinary file. The crankshafts of locomotives are cut out of solid forgings by what are really circular files; the only difference being that the teeth are separate to admit of being taken out and sharpened. If your correspondent will go to any decent toolshop, he, no doubt, will see plenty of circular files if he will ask for circular cutters; these will never replace hand files, as the work has to be held to the cutter, which must, of necessity, be a fixture. No doubt if "L. B. B." wanted to file off the end of a bolt on a locomotive, he would find it "some" easier to do it with a hand file than to hold up the locomotive to a fixed circular file or emery wheel.

Thomas Fletcher.

ELECTRIC ELEMENTS.

[22027.]—"Voltameter" altogether ignores the argument about zero. It, however, points to a mistake in the theory of electricity being two incomprehensibilities; what they are is not stated in the letter 21875. Gordon says that the same law of potentials will not hold for both static and voltaic electricity. Now what authorities has "Voltameter" to support his views? Gordon does not, and Maxwell says that either the two-fluid or one-fluid theory may be used to explain electrical phenomena.

Maxwell certainly concludes that electricity is one of the factors of energy, and that potential is the other, but this is an error which he falls into because he takes no account in the experiments mentioned ("Maxwell's Electricity, 1873," Vol. I. p. 36, &c.) that the electricity is caused by mechanical force in the friction and subsequent separation of two bodies, and afterwards by the force required to place the electrified bodies in various positions with regard to conductors, by which the effects of induction are produced. The force required is very little, and cannot be readily perceived. It is, however, absolutely required to produce the static electrical form of energy, and this force may be observed in much greater strength in the case of inductive electric machines such as the Wimshurst.

It is, therefore, the difference between two potentials—that is one of the factors of energy, and the quantity of electricity movable that is the other.

Maxwell is, however, an authority in my favour, as he compares potential to temperature, and in the case of fluids to pressure; but he fails to perceive that the electricity does not exist in the conductors, and only in the dielectrics they are in contact with, so he is driven to conclude electricity is out of the ordinary law of energy because he treats it as existing in the conductors. More modern authorities have perceived this error, and Planté concludes from his numerous experiments that electricity is propagated by mere mechanical vibration. This is in unison with the known effects of heat, light, and sound. I consider it is sufficiently proved that electricity is a vibration of matter, as no other form of motion could produce mechanical force; but there are many who will not acknowledge it to be correct till further evidence is obtained. In the mean time, the vibratory theory gives a perfect explanation of the voltaic battery, and with regard to Mr. Crookes' experiments, it must be observed that the electric, mechanical, or heat energy is propelled directly from the negative pole, just the same as light and heat in the case of the radiometer.

J. Sutcliffe.

LECLANCHE BATTERY.

[22028.]—Rev. J. J. M. Perry makes mention in letter 21988, p. 192, of a special form of Leclanché battery supplied to him by Mawson and Swan, and he says "of which, I believe, Mr. Payne is the inventor." I desire to correct the error into which Mr. Perry has fallen, as I am *not* the inventor of the battery.

It was originally introduced for telegraphic purposes, and finding that it was well adapted for the particular work of which Mr. Perry speaks, I have recommended it to many persons who, like myself, have used it with pleasure and success. It is a very convenient form of battery for lighting the miniature Swan lamps used by microscopists, astronomers, surgeons, and dentists.

Some persons have attempted to use the ordinary Leclanche attached to their house bells, and failing to obtain the desired result, have said that it was not possible to do that which I asserted: hence my reason for requesting Mr. Perry (when recommending the battery to his friends) to be careful to specify that it was not the ordinary form.

J. B. Payne.

THE VOSS ELECTRICAL MACHINE.

[22029.]—In the interesting description of this machine given by Mr. Frederick Cowle there are one or two points upon which I should much like to be enlightened.

1. How can he, in his fourth paragraph, recommend that the side bearing the thin glass should be kept as near as possible to the revolving disc, whereas it is generally directed that the papered side of the indicator—in this case glazed with thin glass—*should not face* the disc?

What is the supposed action of the thin glass? My small machine of 12½in. diameter has none, and yet works fairly well. Does it increase the length of spark, which, as far as I can see, in the Voss machine never exceeds one-third of that given by a Holtz of the same size? Any contrivance to lengthen the spark would render the Voss machine nearly perfect, constituting, as it does, an almost unfailing source of electricity in any condition of the atmosphere.

2. In making his condenser, how does Mr. Cowle attach the copper-wire loop to the tinfoil coating? His description is not quite clear, and leads to the supposition that he cements the outside plates of the condenser by strips of guttapercha to the central plate in the same manner as is recommended for the thin glass over the inductor. If so, the thickness of the wire loop would, of course, prevent the plates from adhering at one end, and I should think the weight of the whole would very soon draw the wire out from between the plates and lacerate the delicate tinfoil.

Could Mr. Cowle say what ought to be the size of a condenser for my machine? Revolving disc 12½in., inductors on a circular disc.

3. Does Mr. Cowle mount his absorbing combs (Germ. "Einsauger") on the glass pillars where the Leyden jars usually stand, or nearer the revolving disc, and has he a contrivance for making them advance to or recede from the disc at pleasure?

I presume that each comb is separate, and not connected by a bar of ebonite as in my machine, which is one of the cheap simple construction.

The discharging bar, with its combs and brushes is, I suppose, fastened to the axle of the disc; and I should be glad if any one would explain precisely how this part of the apparatus acts. It must be of greater importance than merely to discharge the disc, as it is absolutely essential to the working of the Voss machine, which gives nothing whatever without it, whereas in the Holtz machine it merely increases the effect and lengthens the spark, and, indeed, its introduction was comparatively recent. The whole action of the Voss machine is to me very far from clearly intelligible, and altogether different from that of the electrophorus; whilst the constant change of polarity which occurs in mine at almost every discharge, is to my mind most difficult to account for, notwithstanding Mr. Sprague's elaborate attempt at explaining it in a former number of the "E. M."

If we clearly understood it, we should be able to prevent it altogether; and this would enable us at once to accumulate a far higher degree of tension on the poles, and consequently lengthen the spark.

My machine with 12½in. disc will never, under the most favourable circumstances, give more than two inches with Leyden jars attached, while on substituting the Holtz discs I at once obtain a good clear six inches.

Would it not be possible to design a double machine—a small Voss to supply a constant charge to the inductor of a large Holtz machine, which itself would produce very powerful effects – the two discs to be revolved by the same handle. We might then have a Voss machine with a disc of six inches supplying electricity to a Holtz with one of 36, by which means we should always be able to obtain a spark of 16 or 18 inches in length, as the normal length of the Holtz spark may, I believe, be reckoned at nearly half the diameter of the disc.

Were this possible, we might have, at a comparatively low cost, a machine capable of producing the most formidable effects.

Ethel Constance May.

HOW TO MOUNT FOR THE MICROSCOPE. II.—PRELIMINARY EXAMINATION OF OBJECTS.

[22030.]—I NOW proceed to give some hints on the selection of objects and the preliminary examination of them.

Classification of Objects.—As to what to mount: almost anything may be mounted, so long as you get it not with man's handiwork on it, but bearing only that of nature—clean, small, and either almost transparent, or with a natural surface capable of being viewed by reflected light. The objects for mounting may, accordingly, be either inorganic (elementary bodies, salts and other chemical compounds, ores, rocks, etc.) or organic; and the inorganic specimens may, if thought appropriate, be distinguished by a brownish, vegetable by a green, and animal by a pink label. The inorganic will be intended either as examples of crystallisation, or to subserve other purposes; and the organic will be intended as specimens of tissues, of organs, or illustrative parts of organs, or of entire animals or plants, or characteristic parts of them. This may serve as a rough classification of objects, which will help to mark off the ground we have to travel.

Necessity of Preliminary Examination: Crystals.—Among the most beautiful purely inorganic objects are crystals, which, when fairly transparent, may be tried with the polariscope; but before attempting to mount either crystals or anything else, it is necessary to make oneself familiar with their behaviour when unmounted. The crystalline form is assumed by an immense multitude of bodies (which are for that reason called crystalloids) when they are deposited from solution, or from the liquid or gaseous state. The usual way of causing them to crystallise is to dry a solution—generally a watery solution—containing them. Let the reader, then, before attempting to mount any crystals, dissolve small quantities of various crystalloids in water, place a drop or two of the solutions on slides, allow them to dry, either with or without the aid of heat, and examine them without and with the polariscope, both when dry and when in the act of crystallising and drying. In this way he will see twenty specimens where, if he confined himself to mounting, he would see only one; and any chemist whom he knows will give him for a penny or two a few grains each of a number of soluble salts, especially if the chemist knows he is working at the microscope and is likely to be a customer. Chloride of sodium (common salt), alum (potassio-aluminium sulphate), ferrocyanide of potassium, nitre (potassium nitrate), lump sugar, Epsom salts (magnesium sulphate), and the three kinds of so called vitriol—white vitriol or sulphate of zinc, green vitriol or sulphate of iron, *and blue vitriol* or sulphate of copper, afford easily *obtainable and not very difficult examples. They at the same time illustrate the six systems or fundamental types of crystallisation.*

The Monometric System—Salt and Alum.—Alum and common salt exemplify the first, the cubical, regular, isometric, tessular, or monometric system, of which the original form is the cube, whence octahedra arise. To understand this, take a square of soft soap, or cut a small square out of a larger one. If exactly cut, it will be a cube; that is, its six sides will be equal squares, at right angles to each other, and it will correspond in shape to a cubical crystal. Now make a dot exactly in the centre of each of the six sides, and thrust, or imagine that there is a thrust, a needle from each dot through the centre of the piece of soap to the dot opposite it. The parts of the three needles which do not project beyond the surface of the soap will then answer to what are called the three axes of the crystal—three lines drawn through its centre in the direction of its length, breadth, and thickness or depth. These three needles, lines, or axes, will in the above example be (1) at right angles to each other, and, (2) of equal length; which are the characteristics of the monometric system. The edges or corners may now be flat bevelled, giving a variety of secondary forms: and, in particular, if each of the eight corners is bevelled at a right angle to a line drawn to it from the centre, till the new corners meet at the ends of the axes, a regular octahedron, a figure with eight equal triangular sides, will be produced. Common salt crystallises in cubes and alum in octadedra, in which salt may also be made to crystallise by being previously dissolved in a solution of fresh urine. It is not, however, to be supposed that monometric crystals are always simple cubes, or octahedra. The two forms may be combined; edges or solid angles may be shaved off, giving additional faces. Some faces may be larger than others, because they have been more freely exposed to the solution, or two or more crystals may grow together or interlock (twin crystals). The upper half of an octahedron, for example, may grow on the top of a cube, or you may get a half-cube or octahedron. Analogous phenomena present themselves in the other systems, so that I must content myself with describing the forms from which the others are produced by shaving or flat bevelling, or, in other words, by arrest of growth at certain parts of the crystal.

The Dimetric System—Yellow Prussiate of Potash.—The dimetric, quadratic, square prismatic, or pyramidal system—in which the axes are still at right angles, but one of them, *longer* or *shorter* than the other two—is exemplified by potassium ferrocyanide or yellow prussiate of potash, a commercially important salt, which the reader will find indispensable if ever he injects the vessels of animals with prussian blue. To understand this system, take a new, unsharpened, and circular lead pencil. It is a cylinder. Cut the sides till flat surfaces are produced, and you have what is commonly called a prism—a hexagonal prism if six sides are left, a triangular one if there are three, and so on. The primary form of the square prismatic system is a square or quadrate prism, which is, in effect, a cube prolonged into a square column—i.e., into a column of which the cross section is a square. Again, the ends of the pencil, or of part of it cut off, may be sharpened, not round, but so as to leave each end with four equal triangular sides, like half of such an octahedron as was described above, and differing from it only in being, as it were, pulled out or pressed in. Or the two forms may be combined, a piece of the prism being left in the middle; or the two ends may be cut off at right angles to the length of the pencil, which may, finally, be bevelled in various ways.

The Hexagonal System: Potassic Nitrate.—This system differs from the dimetric only in that the pencil must have six equal sides instead of four; or, in other words, there are three equal secondary axes in the same plane, and having an angle of 60° to each other, and a primary axis at right angles to that plane, and longer or shorter than the secondary axes. Such crystals, when in their simplest form, look like hexagons as seen from above, and like couples of triangles placed base to base when lying on their sides. Snow-crystals are of this shape; and potassium sulphate, which, however, really belongs to the trimetric system, often crystallises in a form quite indistinguishable from the hexagonal; as also nitre usually does. Such a figure as that described has 12 equal sides (if a prism is not inserted between its two ends). If, then, six of these sides grow, and the other six abort, a rhombohedron, a figure bounded by six rhombi, may result. From the frequent occurrence of such figures (soda nitre, or nitrate of sodium, belongs to the hexagonal system, and crystallises in rhombohedra, which closely approach to cubes); the hexagonal is also called the rhombohedral system. A rhombus is a straight-sided, four-sided figure, in which the sides are of equal length; but the angles are not right angles. Other more complex figures may also result from bevelling. Thus, if the hexagon has its sides doubled by bevelling, what is called a "scalenohedron" may appear.

The Trimetric System: Sulphate of Zinc.—Where, as in salt and alum, the three axes are equal, it is sufficient to measure one; hence it is that the first system is called monometric. The second and third are both dimetric; that is, two must be measured. But in the complicated forms of the third system it is difficult to recognise the axes. In this fourth plan of crystallisation, as in the others, the axes are aclinic (α not, κλινη a bend), that is, do not slant or bend towards each other—i.e., and do not leave a greater angle one way than another. But they are all of different lengths, so that to measure the crystal, the three must be measured. For this reason it is called the trimetric system, and it has also received the names of rhombic, prismatic, right prismatic, orthotypic, and isoclinic. These names I give simply because a reader might find one of them used in one book and another in another, and might not know them to be equivalent. The simplest form of a trimetric crystal is a couple of right four-sided pyramids joined by their bases, and having their opposite, but not their adjoining, sides equal. A right pyramid, prism, cone, cylinder, &c., is one planted perpendicularly on its base like a new pencil, and not sloping to one side like the top of a hop kiln. A four-sided prism may be interposed between the pyramids. Sulphate of zinc crystallises in this way in the cold, and so does sulphate of magnesia crystallising from a cool solution. This is also, as has been said, the veritable crystalline shape of nitre and sulphate of potassium, the hexagonal form noticed above being produced by bevelling, which may be seen in different stages on different crystals. In consequence of bevelling, rhombic and rhomboidal faces, faces with only two opposite sides equal, or quite irregular, are frequently met with.

The Monoclinic System—Sugar.—These crystals, of which sugar affords an example, are usually easily recognised by being sloped, and sloped in one direction only; for while, as in those which are denominated trimetric *par excellence*, the three axes are unequal, one of them is at right angles to the other two, but these are not at right angles to each other. The sulphates of iron, sodium, magnesium, when first boiled down and then left to finish crystallising at rather more than blood heat, and zinc crystallised at about the same temperature, afford other examples of monoclinic crystals, of which the last two are especially interesting, because the sulphates of magnesium and zinc also crystallise, as we have seen, according to the trimetric method. The reason of the difference is that when crystallised cold they contain seven, and when crystallised warm retain only six molecules of water.

The Triclinic System.—Sulphate of Copper.—In this system, all the *three* axes *incline* or bend, none of them being at right angles, or, in equivalent words, perpendicular to any of the others. Sulphate of copper, which is also interesting because it is dichroic, affords an excellent example. A dichroic crystal is one which shows of one colour when the light is transmitted through it in one direction, and of another when it is transmitted in another. Such crystals as chloride of potassium, which is monometric, may seem to polarise without a polariscope, and when they polarise the dichroism adds to the richness of the effect.

I do not give the above as a full or complete account of crystallisation. I have endeavoured merely to explain the general features of the six crystalline systems without technicality, and to illustrate each by an example of a common substance soluble in water, incapable of doing mischief unless the reader eats it, and easily examined microscopically. The examples are set at the heads of the paragraphs. I have just been going through them again to make sure of them. For the material of the theoretical part of the paragraphs I have used the article crystallography in "Watts' Dictionary of Chemistry."

Many crystalloids, like sulphate of zinc or of magnesia, crystallise in two (or more) different ways. They are then said to be dimorphic or polymorphic. But, independently of this, no user of a microscope must omit to notice—

Different crystalline forms assumed by the same body.—Any crystalloid, polymorphic or not, can be made to assume the following forms, which are modifications of the first, to which the preceding sixfold division refers.

First, the shape or shapes given in books of chemistry and classified above. To see this, take a little of the substance, and add water to it till the whole is dissolved, obtaining as strong a solution as possible. Place a drop or two of this in the centre of a slip of glass, or, still better, of a shallow gold-size, or a deeper, cell. As the drop begins to dry, crystals will form perhaps round the edge. They may be taken away, or placed near the middle, with a fine glass rod, and in the same way two crystals which by growing are going to touch may be separated. Crystals form best from a somewhat turbid solution, since the particles which cause the turbidity give the crystals something to start from. Notice the beginning of the crystallisation—for the crystals may be seen forming if the stage is not tilted so as to cause the liquid to run. At first will be perceived a minute mass with no definite crystalline form. Watch it with the highest power you can use; and the crystallising liquid will be seen filled with much smaller specks, which dissolve in the neighbourhood of the mass, evidently passing to it in a dissolved state through the liquid, for the mass concomitantly increases in volume. The crystals will be irregularly developed if all their sides are not equally free to receive these additions; do not, therefore, allow the liquid to become very shallow in order to obtain larger crystals, since, for ordinary microscopical purposes, it is of no use to have a crystal so large that the whole of it cannot be brought into focus at once. Dry up the liquid with blotting paper when the tops of the crystals get near the surface—white thick blotting paper is the best, and a torn edge absorbs better than a cut one, and try tilting the slide or cell in different directions, so as to make the liquid run this way and that, and roll the crystals so as to prevent the face next the glass from being stunted. For sugar, use a thick drop of syrup on a bare slide; for alum, allow a few drops of a hot saturated solution to begin evaporating on the hot hob in a deep cell.

Secondly, if a more dilute solution—say five per cent.—be used, or a thinner drop be laid on the slide and allowed to dry without any of it being removed by blotting paper or otherwise, modified and flattened forms, joined together, will appear. These may be obviously what they always are in reality, flattened and joined modifications of the original crystalline shape, as with a not very thin drop of solution of acetate or sulphate of copper, as with sulphate of zinc and magnesia, they may be traceries like those seen on the windows in frosty weather. But the original shape always reveals itself; the traceries of monometric, and consequently rectangular salt or alum, are rectangular, and those of clinic, or non-rectangular sulphate of copper, are oblique. Or they may be butterfly-like, as in sugar, since the crystals spread out in the direction in which there is the most plentiful supply of material. On account of alternations in the richness or poorness of the fluid (the surface of which may often be observed to form ridges before crystallisation commences), or because of aggregation of the crystalline particles in layers or in minute oval, leaf-like, or other masses, markings will often be seen in the crystal as it advances.

Thirdly, if a still thinner layer is secured—e.g., by tilting the slide on one side so as to make the drop run, and especially if the drying of the solution is accelerated by warming the slide over a spirit lamp, the above phenomena will be mingled with or replaced by others still more beautiful. If the crystalloid is one which to crystallise will absorb water from the air—a trial will determine whether this is the case or not—the slip may be allowed entirely to dry over the lamp; a mere film of moisture may otherwise be left, or the slide may be breathed on after being dried. At first nothing particular will be seen; but, presently, scales, shells, or shafts of crystallisation will appear, starting from centres (which may be made artificially in some cases by touching the slide for an instant with a fine capillary tube containing water, and in others by touching it with a heated needle), and radiating till they meet others from other centres, so as sometimes to form roughly hexagonal or six-sided figures. Viewed with a high power (through a covering glass), this arrangement seems to me to consist of innumerable little crystals pointing to the centre, and placed end to end like little magnets. Try sulphate of copper, tartaric acid, citric acid, and sugar (separately). Irregularities in cooling or drying may produce twisted, curved, or wave-like or fluted forms, especially if they dry warm. The addition of a *little* gum to the solution improves them in many cases; if somewhat more is added, they tend to become hairy or woolly. At first they may be quite smooth and fine from edge to edge; but secondary aggregations are apt to form within them, producing a broken appearance, with, it may be, a look of curling, like that of leaves as they wither. Sometimes circles form, with concentric markings, either in or external to the scales spoken of above. If breathed on, only the general figure of the original circle is left; but new markings appear round its circumference, the whole having the appearance of one of those crystals of carbonate of lime in gum or silica of which so much has been written, and being due to the same cause —crystallisation under difficulties.

Fourthly, new forms (which, as in the other cases, are, I suppose, only modifications of the primary one) present themselves on dissolving the crystalloid in gum of the consistence, say, of olive oil.

And fifthly, if the slide is overheated or allowed to dry too rapidly, there is no time for regular crystallisation to take place. Shapeless, or almost shapeless, crystalline masses are formed; the water of crystallisation is driven off, and a powder is left, or the crystalloid itself is decomposed.

Francis Grant.

AN INEXPENSIVE BELL BATTERY

[22031.]—Prescott describes a [illegible] battery where bichromate of pot[illegible] acid take the place of nitric [illegible] battery. The solution is mad[illegible] bichromate of potash in 5lb. of hot water, and when cold, adding strong sulphuric acid. The zinc is placed in the outer jar containing a saturated solution of common salt, which is made by adding salt until the water can dissolve no more. Five of these cells give a fair current to a small lamp, but the porous pots are soon ruined—sometimes the bottom coming completely off.

But to make a cheap battery of this description for bells, the elements must be reversed. In the outer jar should be a large surface of carbon in bichromate solution (adding a few drops of sulphuric acid), the lumps of graphite packed closely round the porous pot. Inside the porous pot a strip of zinc is placed in a solution of salt. Two of these cells coupled for intensity will be sufficient to ring any ordinary bell. If you do not wish to spoil the porous pots, place just enough salt to acidulate the water—say half a teaspoonful to each. The bichromate will last a long while; but the saline solution in the porous pot should be changed once in 6 weeks or two months. To keep a couple of porous pots in clean water in reserve would be as well, as all the impurities would soak out in the mean time. A couple of these cells can easily be made up by experimental electricians for next to nothing in cost, as many have most of the materials required at hand.

Reading, Oct. 30. **S. E. Kelf.**

CONCERNING LOCOMOTIVE ENGINES.

[22032.]—According to Mr. A. Luis, page 295, the resistance per ton of a train is given by the formula

$$R = 12 + \frac{v^2}{114}$$

where v is the velocity of the train in miles per hour. Taking this as correct, the total resistance of a train weighing W tons (which I suppose includes the weight of the engine) will be

$$\frac{1368W + Wv^2}{114} \text{ lb.}$$

The train moves over $88v$ feet per minute, so the amount of work done in that time is

$$\frac{120284Wv + 88Wv^3}{114}$$

and the horse power $= \dfrac{(120284 + 88v^2)\,Wv}{3762000}$.

I would like some particulars as to number of strokes per minute made by different classes of locomotives. I note the expression given by Mr. Stretton on page 182, for the tractive force of engines, and am rather surprised that the factor $\frac{\pi}{4}$ is not involved, as regards the area of piston. There is nothing in the formula to indicate the rate at which the engine can move while exerting the said tractive force. How is this rate calculated?

Quayside, Newcastle. **W. John Grey.**

DOUBLETS FOR MICROSCOPE.

[22033.]—It has long been well known that by using two convex lenses in the place of a single one we may obtain a less amount of spherical aberration than by using a lens of the same power as the pair. It has even been said that we may reduce the aberration to 0. Thus Dr. Parkinson ("Optics," p. 124, Vol. III., Ed. 3) gives two examples in which this is said to take place; but as he gives us no demonstration, or even any explanation of how such a thing can happen, we are left to receive it on faith; and perhaps after all it is not very much to ask us to believe it on the word of so great an authority as Sir J. Herschel, from whom the examples are taken. I regret to find, however, that the formula which has been used to obtain the conclusions given below, gives results which are utterly at variance with the idea that the lenses are aplanatic, and therefore I would not have ventured to write upon the subject had it not been that the formula above spoken of will bear the strictest testing by a method which appears to be quite unexceptionable. One of the simplest forms, then, that can be proposed is when the doublet consists of two equal plano-convex lenses, having the curved side of one of them touching the flat side of the other, and the flat side of the pair turned towards the eye. The spherical aberration of a ray falling upon the pair will thus be reduced to five-fourteenths of that of the same ray falling upon the equivalent single lens of the same form.

We may [illegible] still further reduction by substi[illegible] and a meniscus whose [illegible] aber[illegible] contact [illegible] first with one side and then with the other, towards the object, and I have often fancied that there is not only a difference in distinctness, but also a sensible, though small, difference in the amount of colouring, owing to the fact that the spherical aberration is greater for blue than for red rays, causing what Mr. Bradbury happily names "spherico-chromatism."

If, now, for one of the convex lenses we substitute a concave one, we may reduce the spherical aberration to any extent we please. Thus, suppose one lens is a double convex, with radii in proportion of 5 : 6, the more curved surface being outward and toward the object, and the other a plano-concave, with flat side outward, and having a focal length twice that of the other; the spherical aberration will be reduced to less than a hundredth part of the first lens, and if, besides this, we make the concave of flint glass, we should get a pair which should be passably free from aberration of both kinds, though in the latter case the spherical aberration will not be so well corrected as with common glass. **W. G. P.**

LEGAL REPLIES.

[22034.]—Telegraph Wires (52146).—The querist has confused the Statute of Limitations, which now gives 12 years instead of 20 as to real property, with the Prescription Act that deals with the acquisition of easements. I do not think any user—at all events, under 20 years—can give the Post-Office authorities such an easement over the land of the querist as would prevent him at least raising the wires. I should advise him to object to the wires at once, and require an acknowledgement from the authorities that they are on his land by his leave, in which case the 20 years' user would not give any right.

Poor-Law—Wife's Maintenance (52150).—I think the order made by the magistrate would remain valid until rescinded. But if it became necessary to enforce it by distress, the magistrate might require it to be shown that the wife was still in need of support to the same extent as when the order was first made.

Sale of Spirits—Fraud (52162).—This raises several rather curious questions. It is, I think, quite clear that if a wife obtains wine or spirits under guise of grocery, and without her husband's knowledge or authority, he cannot be made liable for their price. In the same way, I think what he has been deluded into paying by this sham he could recover back again from the grocer as money obtained by fraud. But it is not so easy to see how the case could be made a criminal one. There is no such vague crime as "fraud." A false pretence must include a false pretence of an existing fact, made with the intention of defrauding, and which does defraud, the person in question. The fraud is certainly gross, and in every way to be condemned; but I do not think that it would support a criminal conviction. **Fred. Wetherfield.**

2, Gresham-buildings, Guildhall, E.C.

Errata.—The Eye of the Flea, p. 196.—The engraver has reversed the drawing and not the letters. Transpose A and B and shift *d* and *c* to the proper focal points.—T. P.

Errata.—Study of Pyrology.—Several errors have, unfortunately, slipped into Col. Ross's letter on p. 193. In middle col., 14th line from bottom, read "primordial progression"; in 3rd col., 27th line, read "unproved"; p. 194, 25th line, read "separates in large"; 35th line, read "rationalistic tree"; 42nd line, read "rising"; 46th line, omit "how."

Incandescent Lamps.—Would it be surprising to many readers to learn that incandescent electric lamps were used forty years ago to illuminate a mine? We are so accustomed to be led away by the rapid progress of the last few years as to forget the work of pioneers. Carbon in a vacuum was used in the lamps above referred to; but of course the vacuum was not so high as that at present used, because the apparatus for obtaining it was not so perfect.—*Electrician.*

South American Timber.—Some investigations by M. Thanneur show that South America is rich in woods for engineering purposes. The yandubay is exceedingly hard and durable; the couroupay is also very hard and rich in tannin. The quebracho is, however, more interesting than any, and grows abundantly in the forests of La Plata and Brazil. It resembles oak in the trunk, and is used for railway sleepers, telegraph poles, piles, and so on. It is heavier than water, its specific [illegible] varying between 1·203 and 1·333. The [illegible] first is reddish like mahogany; but grows [illegible] time. Being rich in tannin, it is em[illegible] leather in Brazil, and has [illegible] for that purpose into [illegible] one-third of powdered [illegible] of ordinary tan gives

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51064.]—**Soldering.**—I am sorry if I mistook what B. T. Lewis said; but he must not suppose that though on occasion I have used oil or grease, that I approve of them, or would at all recommend the use of them. As "A., Liverpool," refers to tin, I must say a few words on one or two things in his letter. I particularly referred to soft-soldering brass, silver, and tin. Now, in soldering these, a flux is not used—only something which will evaporate at about the same temperature as the solder melts, and so keep the metals from oxidising. Some people use one thing, some another; but I have never found anything so good as muriate of ammonia, as it used to be called, or the old name, sal-ammoniac. I don't think it does quite so well for iron unless, while the soft solder melts, it is rubbed about with a bit of charcoal. It wants no cleaning off, like rosin. For hard-soldering a flux is required to make the spelter melt more easily, and so borax is used, which not only does this, but spreads a covering from the air over the metal to be brazed. "A." is quite right when he says all grease should be avoided.—Edwd. Thos. Scott.

[51607.]—**Dissolving Human Hair (U.Q.)**—I don't think this querist will ever obtain what he desires. Even supposing that the potassic hydrate could be entirely removed without leaving anything in its place, which would practically be extremely difficult, not to say impossible (evaporation being out of the question), the hair ought to be precipitated in the form of powder (!)—R. A. R. Bennett.

[51619.]—**Specific Gravity.**—I am very grateful to Mr. Alfred H. Allen and to "N. C. R." for their kind replies; but if Mr. Allen will allow me to trouble him once more, I should like to ask the reason for employing the constant 38·5, and the method by which it is obtained, as this knowledge may perhaps enable me to discover that which I am in search of—viz., a rule for the determination of the quantity of any simple substance from the sp. gr. of its solution by means of different equations. —J. R.

[51698.]—**Yeast.**—I see various replies have been given to "E. R. D." and others about yeast; I venture to add one to the number. Some years ago we made bread at home, and were often troubled to get yeast—of course, brewer's yeast—which often made the bread bitter. I got a recipe for artificial yeast, which we found to do well; but it must be kept in a jar, not a bottle. Hops, ¼oz., boil for 20 minutes and strain; rub fine 1lb. of potatoes, mix with the liquor, and set to boil; mix with it a ¾lb. of flour made into a paste with cold water, cool, and add ½ pint of yeast mixed with 2oz. dried flour. In using let the water be warmer than usual. One pint is sufficient for 12 or 14lb. of flour. We also used the old leaven, which does very well, and gives no bitter taste. I am surprised it is not used more.—Edwd. Thos. Scott.

[51768.]—**Joy's Valve Gear.**—If "Historian, J.A.H." will forward me particulars of size of his engine, and a skeleton tracing of it, I will inform him the royalty on it according to size, and will furnish him with 3in. scale drawing of valve gear, which is included in the royalty.—David Joy, 8, Victoria Chambers, Westminster, London.

[51792.]—**Cancer in the Mouth.**—"St. Bart.'s" mentions in his communication that he has seen 300 cases of cancer in the lower lip. May I inquire did every one of these smoke, or had they been smokers up to the time of the appearance of the cancer? Also, did any of the men smoke cigars only, or pipes only? If pipes only, were they meerschaum or amber tipped, or was the common clay used? I ask this to gain information whether or not it was caused by the adhesiveness of the clay pipe, or whether it is due to the irritation of any pipe.—T. R. Allinson, L.R C.P., &c.

[51807.]—**Tinning Bright Iron.**—"Gotha" should find an answer to his query on p. 346, last volume. Gore, "The Art of Electro-Metallurgy," gives several processes, or rather solutions, some of which are worked in Birmingham, but I believe the best is that now used by the company established by Mr. Elmore.—Nun. Dor.

[51814.]—**Mahogany Stain.**—"D. W. W." should say what wood his furniture is made of, and the kind of stain used. Is he prepared to rub off the polish and restain? If so, he will find recipes in back volumes.—Nun. Dor.

[51821.]—**Window Fernery.**—If you want your plants green in winter, you will require to heat your fernery—anything that you can keep up, but not less than 45°. There is nothing better for a case in a room than the filmy ferns, of which there are many beautiful kinds, and which love the atmospheric conditions they there find. Prominent amongst these is the Killarney fern, the most easily managed as well as one of the most beautiful. Then there are Club Mosses (Selaginellas), which are most suitable, notably, S. opoda, Mertensi, denticulata, hortensis, and cæsia; these are just at home in a case, and present a very fresh and attractive appearance. The soil should consist of good peat in lumps about the size of a walnut, ejecting all dusty particles, and mixing with it plenty of silver sand and some small pieces of charcoal. In this the plants are to be planted, and they will need but little water if the case is to remain closed, merely opening it for an hour or so in the morning.—G. J.

[51831.] — **Electric Gas Lighter.** — The "battery" is, no doubt, a chloride of silver cell, and information will be found about the identical (I suspect, for querist does not explain) thing on p. 391, No. 927. Directions for making chloride of silver batteries on p. 73, No. 913.—Nun. Dor.

[51832.]—**Damp Shop.**—Ventilation is the best thing; but something depends on the cause of the smell. If it proceeds from dry-rot, it is doubtful whether much can be done without pulling up the floor and putting in new joists, &c., taking care then to secure free ventilation underneath, and, if possible, a concrete or asphalte coat over the ground. —Nun. Dor.

[51834.]—**Soap and Soda.**—I would suggest the use of the microscope.—C. T.

[51850.]—**Canoe or Small Sail Boat.**—The plan of emptying a boat of water by it own motion involves the use of a valve, which is so arranged that it will let water out of the boat but not allow any to enter. As the boat is forced through the water the valve opens and the water in the boat escapes. Some life-boats are fitted with these self-emptying valves. A mere pipe with a tap or plug cannot be relied upon.—Nun. Dor.

[51899.]—**Medical Coil.**—When I placed the coil in the tube I could feel no difference. Taking the E.M.F. of a bichromate of potash cell as 100, the E.M.F. of a chloride of silver cell is about 60. In the chloride of silver cell there is a silver plate which has chloride of silver melted on each side. A zinc plate is clamped on each side; between each plate there is a pad of blotting-paper, which is saturated with chloride of zinc. Gaiffe's cell is made like this.—Watt.

[51899.]—**Medical Coil.**—The latter part of this paragraph (page 201) has been misprinted (or miswritten). It should read:—"With no free liquid, but sodden blotting-paper—i.e., blotting-paper saturated with the solution used. Is this of sufficient power for the purpose?" I have read (in the English Mechanic, I believe) that a condenser makes very little difference in the shocking power of a coil, but a great difference in the length of spark obtainable. Will somebody please explain this? It passeth my understanding.—Thor.

[51905.]—**Tool Cabinet.**—I have laid down a simple plan for keeping tools together. Fig. 1 can be extended to any extent. It is composed of a length of deal, nailed on to a wider piece, with partitions between. This is for holding chisels, gouges, bradawls, screwdrivers, gimlets. I have mine nailed to a dry wall, within easy distance of bench, in workshop. Fig. 2 will hold the planes and other things. In putting away the bits, fit a piece of wood into the space allotted for them; bore holes through, and square up the holes with a chisel. Then put the shanks of bits in the holes; this leaves them sticking up without touching. This piece can be taken out when wanted; select the bit, then put back in place. Always make a practice of keeping a tool in one place, so that when wanted you will know where to find it.—A. Best.

Fig. 1.

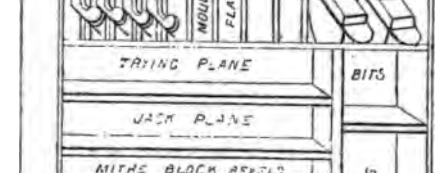

Fig. 2.

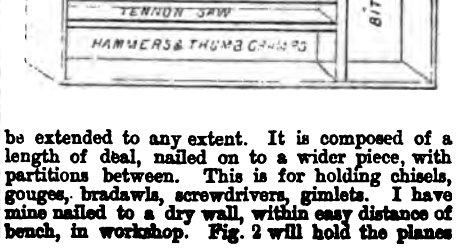
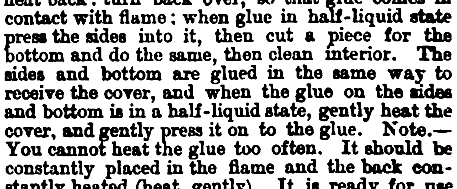


[51935.]—**Law of Copyright.**—The proprietors of the magazine, having paid A. for the article, it becomes their property; and if they choose and see fit to enter it at Stationers' Hall as copyright, *they* would have the right of action as against the other proprietors for infringement of copyright.—J. Russell Pridham.

[51944.]—**Coppered Wire.**—I think "Ressorp, F.C.S." and "A Practical Chemist" are rather hard upon S. Austel, as they took no notice of the answer of "Chemicus," who made exactly the same mistake on p. 320 last volume. It is a great pity that these misleading names are given to so many substances. There is no reason why sulphate of copper should not be called "bluestone"; but why call sulphate of iron "copperas" for no reason whatever? I think myself that there is copper sulphate *and* copper sulphate. If it is not pure it does not produce nearly such good results. The more acid the solution is made, and the longer the articles are immersed, the more the copper adheres to them. I don't quite see how anything covered with copper itself in the metallic state can look otherwise than "coppery." The copper could be deposited on the wire by electricity, but it would be a vast deal more trouble. The wire must be perfectly clean and bright.—R. A. R. Bennett.

[51944.]—**Coppered Wire.**—"Practical Chemist's" reply to this query on p. 201, leaves something unsaid: it omits the process recommended by your correspondent. It is easy for any-one to criticise: what is wanted is information. As a matter of fact Mr. Bennett's reply is perfectly correct, and is quite efficient for giving a slight film of copper to iron articles. Gore gives several recipes, the simplest of which is Roseleur's, for iron wire, equal parts sulphate of copper and sulphuric acid to 100 parts of water. If the wire is properly cleaned and after immersion is run through a draw-plate, the film of copper will be very adherent. Dr. Puscher's method is 10 parts sulphate of copper, 5 sal-ammoniac, and 150 water. The articles are to be subsequently heated over a charcoal fire, to drive off and waste the ammoniacal salt. Another preparation is hydrochloric acid 1, water 3; a few drops only of a solution of sulphate of copper are to be added from time to time. Where a stout coat of copper is required, such as for cylinders of calico-printing machines, the battery must be used.—Nun. Dor.

[51949.]—**Zoophyte Troughs.** — **Materials.**—Back, plate glass 3in. by 2in.; sides and bottom, slips of glass ¼in. wide, ⅛ or 1/16 (or ¼ if liked) thick; covers, thin glass 2in. by 1¼in.; marine glue (soluble), obtained from any tool-maker, about 1s. per lb.; spirit lamp (mounting table recommended), dissecting needles. Directions.—Place the cover on the back in the middle touching the bottom, mark round its sides and bottom thus: take the cover off, heat the back. Take a small piece of glue (size of pea or smaller) on end of needle, heat in flame until it lights, then place on glass on line, so on until line is covered with glue ¼in. thick; heat back over flame, and with finger damp (not wet) press the glue until it sticks on the back well. Take two strips of glass, length of sides of cover, again heat back; turn back over, so that glue comes in contact with flame; when glue in half-liquid state press the sides into it, then cut a piece for the bottom and do the same, then clean interior. The sides and bottom are glued in the same way to receive the cover, and when the glue on the sides and bottom is in a half-liquid state, gently heat the cover, and gently press it on to the glue. Note.—You cannot heat the glue too often. It should be constantly placed in the flame and the back constantly heated (heat gently). It is ready for use immediately. I first wrote out the above three years ago, and can add nothing to it, save that I have always found the troughs give entire satisfaction.—John Alex. Ollard, F.R.M.S., Enfield.



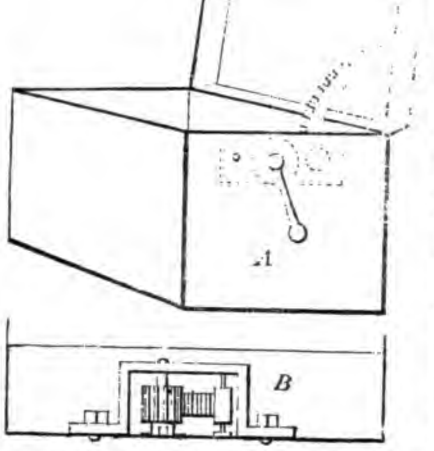
[51961.]—**Cleaning Object-Glasses.**—I am very much obliged to "F. R. A. S." for noticing my query to Mr. Lancaster and "Prismatique."

There is another point in connection with objectives that I should like to submit to him. Some three years ago, upon the recommendation of Mr. Lancaster through these columns, I had the lenses of a small o.g. cemented together with Canada balsam. The improvement was unmistakable, both as regards light and definition. Now, I am aware that that process is not applicable to anything above 3in. in diameter on account of the unequal expansion and contraction of the two glasses, which if cemented together would subject them to a severe strain. But why not employ some permanently fluid body, such as castor oil, to connect the two lenses? A simple experiment with two pieces of plate-glass will convince anyone of the advantages of optically connecting the two surfaces by a drop of castor-oil spread between the two plates. They then look like one solid glass, and when put upon a sheet of white paper their transparency is very marked. Now, before making a similar experiment with my 3¼ o.g. I should like to know whether anything of the sort has been tried, and if not, whether the experiment is likely to injure the glass. The success already alluded to, on a small scale, leads me to hope for an improvement in light, if not in definition.—ACHROMATIC.

[51991.]—**Star Magnitudes.**—The magnitudes in Proctor's atlases are taken from the British Association Catalogue in the majority of instances; but in respect to a number of the brighter stars they are taken from Sir John Herschel's "Photometric" table. Upon the latter scale all the magnitudes are lowered by about half a magnitude. The following are the estimates of various authorities for these stars. Sir John Herschel's measures are from the "vulgar" column of the table referred to. α Andromedæ: Sir J. H. 2·54; Heis, 2·0; Baxendell, 2·36; Piazzi, 1; Argelander, 2·0; Flammarion, 2·0; Sir W. Herschel, 2·1. α Coronæ: Sir J. H., 2·69; Heis, 2·0; Bax., 2·65; Arg., 2·0; this star is possibly slightly variable. α Ophiuchi: Sir J. H., 2·63; Heis, 2·0; Sir W. H., 2·0; Arg., 2·0; Flam., 2·0. α Capricorni: Heis, α^1 4·0, α^2 3·0. γ Ursæ Majoris: Sir J. H., 2·71; Heis, 2·3; Arg., 2·3; Pickering (mean), 2·45; Flam., 2·7; Seidel, 2·6; Wollff, 2·5; Groombridge, 2·3. ζ Ursæ Majoris: Heis, 3·7; Arg., 3·3; Seidel, 3·6; Wollff, 3·6; Pickering (mean), 3·45; Flam., 3·7; Groom., 3. My own most recent estimates are—α And., 2·0; α Cor., 2·5; α Oph., 2·0; γ Urs. Maj., 2·4; ζ Urs. Maj., 3·6.—S. MAITLAND BAIRD GEMMILL.

[52002.]—**New Inman Steamer.**—The *City of Chicago* is 430ft. long, 45ft. beam, 33ft. 6in. deep, and of 5,600 tons gross. She has eight water-tight compartments, four masts, four decks, and a bridge deck 188ft. long. The saloon is forward of the machinery. The engines have one h.p. cylinder 56in. dia., with piston valves, and two l.p. cylinders 80in. dia., all having a stroke of 5ft. There are four double-ended and two single-ended boilers, working at 90lb. The ship was built by C. Connell and Co.; engined by J. and G. Thomson, and did 15 knots on her trial trip.—LONDON RIVER.

[52021.]—**Raising Lid of Iron Box.**—I would suggest a quadrant rack and pinion working within, and at one end of box actuated by means of a socket lever handle fitting on end of pinion spindle. This arrangement would, of course, entail patterns of rack, pinion, and a small bracket, the latter to carry pinion, and a small friction-roller to keep rack up to its work. The weight of lid would govern strength of rack and pinion, which would look more sightly if they were in gunmetal. It would be better, perhaps, if the pinion could be covered in by means of a case or shield, with an opening for the rack to descend through.—W.R.H.



A, end elevation, showing position of rack, pinion, friction-wheel, and handle; the latter removable, and fitting on end of pinion spindle, which should be squared. B, plan of bracket, showing pinion, rack, and friction-roller.

[52031.]—**Dynamo.**—It may please "L. O. V." to know that I have seen the same size machine as his light five 15 c.p. Swan lamps to their full power. I am sure it is a far more serious fault than a small variation of R. between A. and F.M. It is mere guesswork to find the fault without seeing the machine. Let him proceed as follows:—Disconnect the F.M. wires from the brushes, and connect them with a bichromate or other strong cell; the F.M. ought now to be strongly magnetised. The armature ought now, when the brushes are connected, to give a strong current. If it does not, you may conclude the fault is in the A. alone. Test the A. for insulation, also F.M. If the pole pieces are fastened down on an iron bedplate, it would quite account for the failure. The halves of commutator ought both to be insulated from axle, as this lessens the chance of a short circuit.—W. H. E., Coventry.

[52031.]—**Dynamo.**—If the insulations are perfect, and connections good to each half of the commutator, there is no reason why machine should not work. If the magnets are connected together at the base, it is very important that it should be a perfect fit, as magnetic continuity is very easily severed; the surfaces should be planed or scraped. If you want to use an incandescent lamp, it is better to connect the wires as for a shunt circuit, so that a portion only of current traverses the magnets. To do this, connect one wire to first brush, then round both limbs of magnet to second brush; then take a wire from each brush to lamp. You will then see that the current has two ways open to it, and to a certain extent will regulate the power of magnets. The brushes must be perfectly insulated from machine, and from one another. If the resistance of outside circuit was made equal to R on F.M., half the current would traverse each.—NO SIG.

[52034.]—**G.N.R. Engines.**—644 (Doncaster, 1880), 6-coupled goods, single frames, 5ft. 1in. wheels, cylinders 17½in. by 26in.; 678 (Doncaster, 1882), 6-coupled shunting saddle tank, wheels 4ft. 6in., cylinders 17½in. by 26in.; 30, 4-coupled (leading and driving) mixed traffic engine, 5ft. 6in. wheels, cylinders 17½in. by 24in.; 598, same class, by Kitson, 1876; 101A and 102A are a mistake, probably meant for 201A and 202A. These are single-wheel Jenny Lind engines, by E. B. Wilson and Co., of Leeds. They have 6ft. wheels, and had cylinders 16in. by 20in. They have been rebuilt, and possibly the cylinders are now 17in. dia. They have inside frames to driving, and outside to trailing and leading wheels. There was another of this class (No. 222), but it has been broken up. No. 102A is a 4-coupled (leading and driving) goods engine, double frames, built by Hawthorn.—METEOR.

[52041.]—**Brush Dynamo.**—Connect your A. up as a Pacinotti ring armature. Screw six straight bars on commutator, and connect inside end of No. 1 coil and outside end of No. 2 coil to No. 1 bar; inside end of No. 2 coil and outside end of No. 3 coil to No 2 bar, and so on all round. The R. of A. will now be equal to 3lb. of No. 16 wire. The R. of F.M. should be altered so as to equal the R. of A. The central boss is all right if it is insulated from the coils themselves.—W. H. E., Coventry.

[52046 AND 52047.]—**M.R. Engines.**—The new express engines which have lately come out from Derby (Nos. 1657—1659) have 6ft. 9in. wheels and 18in. by 26in. cylinders. They are similar to 1562—1581 class (1882-3), but I hear that the bogie has a slightly shorter wheel base. 1602—1608 are new goods engines by Beyer, Peacock, and Co.; 5ft. 2in. wheels, cylinders 17½in. by 26in.—of same class as 1582—1601. They are fitted with steam brakes. The 10 shunting tanks turned out are, I understand, similar to 1420 class: wheels 4ft. 6in., cylinders 18in. by 24in. Their Nos. are 201, 202, 210, 211, 212, 218, 219, 1397, 1398, and 1399. The last five are fitted with vacuum brake for passenger traffic. I have not dimensions of the new four-wheeled shunting saddle tanks 1322–1326. I understand they are for dock work. A new class of Midland express engines, with 7ft. wheels and cylinders 19in. by 26in., and Joy's valve gear, are being built. They will be one of the most powerful classes of express engines in existence.—METEOR.

[52055.]—**L. and. Y. Locos.**—Dimensions of both 111 and 669 classes have been given in back vols. A sketch of 669 class has also been given.—METEOR.

[52066.]—**Brazing.**—A fan driven at a high pressure may, if the air-passages are large enough, do moderate work in brazing if well managed. A fan driven by hand is about useless. The power of a blowpipe depends on the pressure of the air supplied, and with a hand fan the pressure is practically nothing. For quick brazing, a pressure of about 1lb. on square inch is necessary for the air supply. The fan made by "Cyclist" probably does not supply air under a pressure of half an ounce on the square inch; hence his failure.—THOS. FLETCHER.

[52075.]—**Legal.**—I am of opinion that the executors would be right under the circumstances in paying the legacy to the married woman, without the husband's receipt; as she is under the protection of the law, and not of her husband.—J. RUSSELL PRIDHAM.

[52077.]—**Machine Drawing.**—Have you tried drawing a machine from measurements taken by yourself: if not, I should advise you to, as this would get you into the way of drawing from rough sketches.—J. O. BRETTELL.

[52077.]—**Machine Drawing.**—Has "Engineering Student" simply been copying his drawings line for line? If he has, I should advise him to draw them to different scales; but presuming that he has been drawing to different scales, and failed to get the requisite practice, he would do well to adopt a plan which I found of immense benefit in preparing for exam. last May; let him take some machine with which he is familiar, make his own sketches and measurements, and from them make a drawing. He will find it the best practice he can have.—WEST BROMWICH.

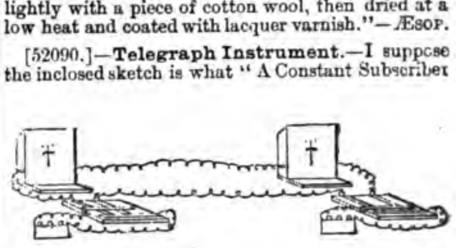
[52083.]—**Punching Machine.**—The area sheared by the punch is 3·1416 by diameter of hole in inches by thickness of plate in inches. The resistance to shearing is 3·1416 by diameter of hole by thickness of plate by shearing strength of plate. Or, as given in my work—advertised in these pages—multiply the circumference of the hole in inches by the thickness of the plate in inches, and by the shearing strength of the plate, in tons per square inch, for the power required. Thus, assuming the resistance of the steel plate to be 30 tons per square inch, we have, for the power required to punch a 2in. hole in a 2in. steel plate, the following: 6·2832 × 2 × 30 = 376·992 tons.—S. NICHOLLS.

[52084.]—**Building Society.**—The building society has not power to go outside its rules, and if there is nothing in the copy of the rules furnished to the members, stating their right to impose or enforce continued subscriptions, then they are not entitled to do so.—J. RUSSELL PRIDHAM.

[52085.]—**Building Society.**—You don't say how many shares you hold. I presume by your query that you only hold one share. You would obviously have to continue your payments of £3 with interest and expenses for 20 years before the property would be clear of the mortgage. It is uncertain how long it would be before the shares were worth £60; it all depends on the value of the land.—J. RUSSELL PRIDHAM.

[52089.]—**Frosting Tin Tubes.**—A very good way for producing a crystalline appearance upon articles made of tinplate is the following, taken from "Workshop Receipts":—"Place the article, slightly heated, over a tub of water, and rub its surface with a liquor composed of 4 parts of aquafortis and 2 of distilled water, holding 1 part of common salt, or salammoniac in solution. When the crystalline spangles are sufficiently developed, the article must be immersed in water, and washed lightly with a piece of cotton wool, then dried at a low heat and coated with lacquer varnish."—ÆSOP.

[52090.]—**Telegraph Instrument.**—I suppose the inclosed sketch is what "A Constant Subscriber and Reader" wants; it explains itself. I also inclose sketch of a switch arrangement of mine for including call bells in the same circuit. When A presses a key of transmitter, both bells ring; and when B answers, he turns his switch off of D on to E, A doing the same to his switch. After the message is sent, the switches are ret —A. LAUNDY.



[52087.]—**Pressure on Crank** determine as follows:—Areas of cy by pound pressure will equal poun pin; then area of high-pressure by steam-pressure of 62lb. at one-fourth of stroke as stated, 268·8 × 62 = 16,665·6lb. But as the stroke is only half of low-pressure one, hence half of its leverage, or half of its pressure, 16,665·6 ÷ 2 = 8,332·8, or 3 tons 14cwt. and 55lb. Then area of low-pressure cylinder will be 490·875 × 18lb. pressure = 8,835·75lb., or 3 tons 18cwt. and 99lb. By the action of the two pistons you will have a pressure of 7 tons 13cwt. and 32lb. on your crank-pin. Assuming that your crank-pin is 6in. diameter and 8in. long, there will be a pressure of 357·6lb. per square inch on pin. In the calculation of the above I am taking the low-pressure piston and air pump to form something like a balance for high-pressure piston and connecting rod, and, consequently, the transmitting power at nil. If "H. N." will get one of Reed's "Engineer's Hand Books," he will find a lot of useful information on pressure on crank-pin—in fact, everything attached to a steam engine.—FIRER, Dewsbury.

[52095.]—**Telescopes.**—"Achromatic" will find a list of some of the largest telescopes in the world, refractors and reflectors, in Prof. Newcomb's "Popular Astronomy," published by Macmillan and Co.—C. R. T.

[52103.]—**Engines.**—Thanks to "Engineer, Dewsbury," and "Labor Omnia Vincit" for answering my query. Would either of the two gentlemen help me a little further? I have always been given to understand that the number of expansions in a cylinder is obtained by dividing the length of stroke by the point of cut-off; by doing so in the above query, I can only get four expansions, and, adding two expansions for the steam passing from the high-pressure cylinder into the low-pressure cylinder, that will be six expansions. Any further information will be thankfully received by—YOUNG ENGINEMAN.

[52103.]—**Engine.**—Supposing there is no loss between the engine and the boiler, the steam will enter the high-pressure cylinder at 75lb. gross (this is the pressure at point of cut-off) and is cut off at half stroke; the final gross pressure will be 37½lb. This steam has now to exhaust into the low-pressure cylinder, and to fill half of it. Now as the low-pressure is four times the high-pressure, one half of the low-pressure one will be twice that of the high-pressure one. Hence, to fill this space, the steam must expand into twice its volume, and so become half of its pressure, or 18¾ gross. This is the back pressure in high-pressure cylinder. Next the 18¾lb. of steam in low-pressure cylinder is cut off at half stroke also, and expands through the other half of the cylinder; hence, its final gross pressure will be 9⅜lb. and vacuum by gauge as stated = 13lb., there will be 2lb. back pressure. The initial effective pressure for high-pressure cylinder will be 60 − 3¾ = 56¼. The final or terminal effective pressure will be 37½ − 18¾ = 18¾. The initial effective pressure for low-pressure cylinder will be 18¾ − 2 = 16¾; final effective 9⅜ − 2 = 7⅜. So if we divide the initial effective by the terminable effective, we shall get the number of expansions, 56¼ ÷ 7⅜ = 7·6 expansions, so you will have to cut off steam in single-cylinder engine at one-eighth of stroke nearly to get the same number of expansions as in compound engines. I should like to ask "Engineer, Dewsbury," how far the low-pressure piston will have traversed, while the high-pressure piston remains stationary to increase its volume twice, and thus become half of its pressure.—FIRER, Dewsbury.

[52108.]—**Integral.**—The given equation—

$$\frac{d^2u}{dx^2} = \frac{u}{d^2}$$

Multiplying by $2du$—

$$\frac{2du\,d^2u}{dx^2} = \frac{2udu}{d^2}$$

Integrating—

$$\frac{du^2}{dx^2} = \frac{u^2}{a^2} + c.$$

Extracting and arranging—

$$\frac{dx}{a} = \frac{du}{\sqrt{u^2 + a^2c}}$$

Integrating—

$$\frac{x}{a} = \log.\, c_1 (u + \sqrt{u^2 + a^2c})$$

Whence—

$$e^{\frac{x}{a}} = c_1 (u + \sqrt{u^2 + a^2c})$$

Resolving this equation—

$$u = \frac{1}{2c_1} e^{\frac{x}{a}} - \frac{a^2cc_1}{2} e^{-\frac{x}{a}}$$

Which is an expression of the reputed form—

$$u = Ae^{\frac{x}{a}} - Be^{-\frac{x}{a}}$$

—S. STOKES.

[52107.]—**Toning Bath.**—According to the usual computation of 1gr. AuCl to a sheet of paper, the toning bath you purchased should have contained 3gr. AuCl. It must not be supposed, however, that a toning bath can be used down to the last grain without strengthening; if you managed four or five sheets it did not do amiss. From half an hour to an hour is a good average time for toning, a much shorter time not being desirable; for not only is there much greater danger of "mealiness," but the coating of gold is much more superficial, and consequently not so permanent.—W. ROBINSON, JUNR.

[52114.]—**Painting on Glass.**—Take good clear resin—any quantity; melt it in an iron pot; when melted entirely, let it cool a little, and before it begins to harden pour oil of turpentine sufficient to keep it liquid when cold. In order to paint with it, let it be used with colours ground with oil, such as are commonly sold in colour shops.—A. W. NICHOLLS, Birmingham.

[52116.]—**Legal.**—(1) You are not liable for the rates and taxes, &c., left unpaid by the tenant from whom you purchased the business; only for trade liabilities which you took over when you bought the business. (2) If a lodger does not pay his rent, give him notice to quit; and if he has any goods distrain on them—you cannot detain them, as you have only a lien upon them for your rent. If you sell, and anything remains after paying your expenses, you are bound to return it.—J. RUSSELL PRIDHAM.

[52117.]—**Legal.**—The duty of an executor or executrix is to settle the estate of a testator according to the directions given in his will. The executrix has the power to realise the estate, and to pay all debts, claims, and demands due by the testator before the residue of the estate comes to L. It is the custom to advertise that claims will be paid by the executor or executrix, if sent in by a given time; after which time the executor proceeds to distribute the assets among the persons whose accounts have been verified. When this has been done, the rest will belong to L. and her family.—J. RUSSELL PRIDHAM.

[52119.]—**Misshapen Chest.**—"T. T.'s" son is evidently suffering from what is known as pigeon breast; that is, the ribs meet together sharply in front, and form the projection he names. It points to rickets in childhood as a rule, and now, I am afraid, cannot be remedied. Let him put his son to a less laborious employment, or even to one where he uses his brain rather than his muscles.—T. R. ALLINSON, L.R.C.P.

[52127.]—**Platinum.**—The following substances act injuriously on Pt crucibles. Metals: Alkalies, sulphides, chlorine, and phosphorus; also, lead chloride, and silver chloride, and bromide. Sulphur at a high temperature would quickly ruin a Pt crucible. The above are all I know of; probably there are many other substances to be cautious of.—METEORITE.

[52127.]—**Platinum Crucibles.**—This query has been answered lately (p. 45, present volume). The substances which must not be heated on platinum are: caustic alkalies and barium hydrate; cyanides, chlorates, nitrates; substances likely to give off chlorine or sulphur; easily reducible metallic salts or corresponding metals—e.g., silver, tin, or lead. From the fact that substances giving off sulphur are not to be heated, I presume that sulphur is detrimental to platinum.—R. A. R. BENNETT.

[52130.]—**Water Rate.**—By the 15 and 16 Vic. cap. 158, the company has the power to charge you the extra rate if they deem it necessary, and you will have to pay.—J. RUSSELL PRIDHAM.

[52134.]—**Cabinet-Making**—To "G. W. J."—The way to make a mahogany wardrobe will appear in a short time.—J. P.

[52138.]—**Copying Negatives for Lantern Transparencies.**—See last volume, p. 182.—W. ROBINSON, JUNR.

[52138.]—**Lantern Slides.**—I have lately been printing from quarter-plate negatives in gelatine, and can therefore give the information required. It is, in the first place, most important to get a suitable make of gelatine plates, as the greater part in the market are quite useless for lantern slides, although suitable for negative work. It is only recently (after trying many kinds without success) that I have come across a make which gives without trouble the requisite density of shadows and clearness of high lights. This is the Albert plate, sold by Elliott, Jewin-street, London. Exposure.—Place the plate in contact with the negative in an ordinary printing frame, and expose about one second to weak daylight (a couple of yards from a window), or about 20 seconds 3ft. from a paraffin lamp. Development.—Pyro gives a rich reddish brown tone, very effective in a lantern. I will not give formula, as everyone who has dryplate negatives to copy is accustomed to some particular formula, and had better adhere to it. I use the "Berkley" solution of pyro (with sulphite of soda). It is essential to use the smallest amount of ammonia that will bring out details, and a few more drops of dilute ammonia can be added to the developer afterwards to get density. Ferrous oxalate developer.—This gives blacker tones, but is not always so well under control as pyro. To 1oz. of a saturated solution of oxalate of potash add a ¼oz. of saturated solution of protosulphate of iron and four minims of a ten per cent. solution bromide of potassium. If unable to get sufficient density, intensify as follows:—After fixing in hypo. and thoroughly washing, soak for about an hour in a saturated solution of bichloride of mercury (which dissolves much easier with the addition of a little chloride of ammonia), wash well, and redevelop with ferrous oxalate, as described above. This gives black tones. It is, I think, the best of the mercury intensifiers; but I prefer to do without it, as the shadows are opaque and dead. I have presumed, in these instructions, that the inquirer has some knowledge of developing gelatine plates. The great point in lantern-slide making is exactness of exposure; over exposure is the general fault, and is fatal to brilliancy. If it be desired to use the wet collodion process, full particulars are given on p. 182 of the last volume. For copying quarter-plates, the camera must have a range of at least double the focus of the lens used.—A. WATKINS.

[52141.]—**L. and S.W. Engines.**—"W. B. P." will find a pretty full description of Gooch's locomotives in Bourne's "Catechism of the Steam Engine." I give a few of the principal dimensions of the "Snake," one of those made by him for the above line. Diameter of cylinders, 14½in.; length of stroke, 21in.; diameter of driving wheels, 6ft. 6½in.; diameter of leading and trailing wheels, 4ft. ½in.; total wheel base, 12ft. 8½in.; No. of tubes (181), out. diam, 1⅝in.; length of barrel of boiler, 10ft.; diameter of barrel of boiler, 3ft. 7½in.; fire-grate area, 12·4 sq. ft. Total weight: leading wheels, 8 tons; driving wheels, 6 tons; Trailing wheels, 19 tons. It has outside cylinders.—L. B.

[52142.]—**Resistance Coils.**—"Volt" cannot make his coils accurate unless he has a standard coil to balance his own against, as you cannot get two pieces of wire alike.—WATT.

[52143.]—**Chemical, &c.**

Undried Air. mm.

Height of barometer .... = 746·9

Level of mercury in trough.... = 565·9

True level of mercury in eudiometer = 317·3 + 0·4 = 317·7

∴ Column of mercury in eudiometer............ = 248·2

∴ Pressure on air in eudiometer .... = 498·7

$$\therefore \text{Its volume at } 0^\circ\text{C. and } 760\text{mm.} = \frac{292{\cdot}7 \times 498{\cdot}7 \times 273}{760 \times 293{\cdot}2} = 178{\cdot}8$$

Dried Air. mm.

Height of barometer .... = 747·4

Level of mercury in trough .. = 565·9

True level of mercury in eudiometer = 310·7 + 0·4 = 311·1

∴ Length of column of mercury in eudiometer.... = 254·8

∴ Pressure on air in eudiometer................ = 492·6

$$\therefore \text{Its volume at } 0^\circ\text{C. and } 760\text{ mm.} = \frac{286 \times 492{\cdot}6 \times 273}{760 \times 293{\cdot}2} = 172{\cdot}6$$

∴ Vol. aqueous vapour = 178·8 − 172·6 = 6·2

$$= \frac{6{\cdot}2 \times 100}{178{\cdot}8} = 3{\cdot}467 \text{ per cent.}$$

Question.—Let x° = the point on the scale of Celsius. Then the corresponding point on Fahrenheit scale will be $\frac{9}{5}x + 32$.

∴ $x + \frac{9}{5}x + 32$.

From which we get $\frac{4}{5}x = -32$

and $x = -40^\circ$ on either scale.

—SPENCER COLLYNS.

[52144.]—**Gun Query.**—If you get the gun on the muscle of the arm it is sure to punish you. When placing gun to shoulder, can you reach trigger easily? If not, I would have a bit cut off stock, which would not interfere with balance of gun, and any gunmaker would do it for half a crown. If "H." lessens the charge of powder or shot, he will not be able to kill anything at a respectable distance.—W. A. L.

[52144.]—**Gun Query.**—I think if "H." were to take a little off the toe of the gun (the lower end of stock) so that it did not hook under his arm so much, he would find it an improvement, or have one of Silver's anti-recoil heel-plates: he would then not need the toe so long, as the friction of the india-rubber will prevent the stock from rising too high. "H." must remember that the shorter he has the stock the longer, proportionately, he must have the toe for that reason.—SWALLOW.

[52144.]—**Gun Query.**—If you had the stock shortened it would undoubtedly be to your advantage, as, from reading your query, I should say that the stock is too long. The effect of shortening would be that the gun could be brought up with greater freedom and less effort, and also, it would lessen recoil. The heelplate should be bevelled $\frac{1}{10}$in. lower on the arm side, and 1oz. or more of lead put into end of stock, to restore the balance.

Any further information will be given, if required, by advertising address.—W. J. Mears.

[52144.]—**Gun Query.**—I have not the least doubt but that the inconvenience felt by "H." is owing to the stock of his gun being too long. When the gun is put up to the shoulder the heel of the stock catches under the armpit, and so rests against the arm instead of against the shoulder. I have had this experience myself, and know the discomfort of it. I believe that if the stock were shortened half an inch or so, it would come up all right, and I do not think that the balance of the gun would be affected. In using a gun it is well to get into a habit of throwing it forward to the full extent of the arms, and then bringing it back against the shoulder. By this means the stock is certain to get into its right place, and the forward action of the gun in the direction of the object most materially assists the aim.—K. W.

[52144.]—**Gun Query.**—I say emphatically:—1. Do not lengthen or shorten your stock. 2. Do not lessen your charge of powder. 3. And certainly do not pad your stock or your shoulder. In all probability the reason why you get the gunstock "upon the muscle of the arm below the shoulder" is because your shoulder is padded and is too full and convex, and also because you hold your right arm down to your side, and stand with your feet too close together. Get your left foot well out, raise your right arm at right angles to your side, throwing the elbow as far up and as far out as you can possibly stretch it, and you will never again bruise the "muscle of the arm below the shoulder," and you will find the action much freer and easier than the old one. I was trained to this position by a crack shot, and have always found it far preferable to the one usually seen in print. The left hand is the fulcrum of the gun, and should be almost its entire support, and the right hand in the position I have indicated can easily be used to press the stock inwards and keep it on the shoulder. The action of swinging the gun round to right and left is very free in this position, and is the business of the left arm. I assume, of course, that "H.'s" gun is a good one, and his cartridges are properly filled.—R. Pearce.

[52146.]—**Telegraph Wires.**—My advice to "Blackburn" is, that he should state the circumstances under which he is placed to the Post-Office authorities, and come to some arrangement with them. My own opinion of the subject is that they have not the right of user, and if it prevents you from using your property to advantage, by reason of the wires, I have no doubt they would have them so placed as not to interfere with you.—J. Russell Pridham.

[52150.]—**Poor-Law.**—If after the magistrate's order on the man to pay the weekly allowance, he has neglected or failed to do so, the wife had better go into the workhouse again, and leave the guardians to do the rest.—J. Russell Pridham.

[52152.]—**Brush Dynamo Machine.**—It is not necessary to insulate the ring from the boss. The important point is to thoroughly insulate the wire from ring, and this is easily tested with a battery. I presume "Williams" knows that the commutator in Brush dynamo is necessarily different from other kinds on account of the peculiar method of connecting coils. There should be a pair of semicircular rings divided from one another by about ⅛in., and insulated from spindle for each pair of coils on rings, and placed in relation to them so that brushes collect the currents when the coils reach the position of best action. There are usually eight coils, and magnets embrace three of them at a time. If "Williams" has made an ordinary commutator or collector, I should advise him to try connecting the coils in series as in Gramme's ring.—Light.

[52156.]—**Photographic.**—Owing to abnormal reduction of silver, which may arise from various causes—e.g., too new a collodion, too little acid in bath or developer, some organic impurity in either of the latter, or leaving developer or re-developer too long on the plate. The discolouration of cyanide is owing to your not having washed the plates sufficiently after development. It is no detriment so long as the plate is cleared within a reasonable time. It is foolish to throw fixing solutions away, as they contain a good deal of silver, which can be easily recovered by the addition of potassium sulphide. The addition of a little gelatine dissolved in acetic acid, to the ordinary iron developer, will give increased density; but in such cases as you speak of it is generally necessary to resort to mercurial intensification.—W. Robinson, June.

[52156.]—**Photographic.**—For a long time I experienced the same trouble with dry plates as you describe as happening to you with wet plates, and was quite at a loss to remedy it. The deposit was like yours, a sort of white powder, with a yellow tinge, which settled on the plate during developing. It was possible to remove it with a piece of wool; but that generally scratched the film. I was using a developer composed of solutions of oxalate of potash and protosulphate of iron, which were mixed at the time of using. At last I found that the deposit was caused by there being too much of the protosulphate of iron in the developer; accordingly, for the future, I reduced the quantity, the result being perfect absence of this defect. I should say that the cause of your failure was the same as mine—that is, if you use an iron developer, which is supposed to answer better than any other kind with Mawson's collodion. I infinitely prefer to use hyposulphite of soda instead of cyanide of potassium, to fix with, as it is far less poisonous, and quite as effective.—Machina.

[52160.]—**Battery.**—Daniell's battery is generally used for electric clocks. Some wrap their zincs in calico, others use the ordinary Daniell. About fourteen cells, I should say, in your case.—Watt.

[52160.]—**Battery.**—I was very much astonished when I beheld "Salopian's" query. I had no idea that any battery would work so long. Will "Sigma" or other reader tell me whether this battery will work electromotors, &c.? Does it work for six weeks without replenishing? At present, I am using a Daniell's 3-cell battery, but it only works the motor for an hour at a time. I don't suspend any copper sulphate crystals in a muslin bag, but simply put them at the bottom of the jar. It is absolutely necessary to keep the solution concentrated by suspending the copper sulphate near the surface of the solution? How many Walker's cells equal three Daniell's?—R. A. R. Bennett.

[52162.]—**Legal.**—The husband has no power to prosecute the grocer, as he entered the item in the bill as sugar at the request of the wife. The fraud, if any, is against the wife.—J. Russell Pridham.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last, R. A. R. Bennett has replied to 51607.

Artificial Production of Minerals.—Bourgeois has succeeded in producing wollastonite artificially by the direct fusion of the proper proportions of lime and silicic acid at a bright red heat, and allowing the fused mace to cool in the furnace very slowly. Distinct crystals and crystalline masses were obtained, which corresponded entirely in form, though not in optical properties, with the natural mineral. The same investigator also succeeded in producing an artificial melonite by fusion at a bright red heat of lime, magnesia, aluminia, and silicic acid in the proportions corresponding to the composition of the natural mineral. De Schulten has produced an artificial analcime by heating to 350° Fah., in a hermetically sealed copper vessel, for 18 hours, a solution containing the proper proportions of sodium silicate and sodium aluminate to constitute the mineral, with the addition of some lime water to aid the crystallisation of the resulting analcime. The resulting crystals exhibited the well-known trapezohedra form characteristic of this mineral—the dodecahedron and combination of these two simple forms. The chemical constitution and the optical behaviour of the artificial compound corresponded perfectly with those of the natural mineral.

QUERIES.

[52166.]—**Engine Power.**—Will any of your readers kindly tell me the h.p. of my engine with the following dimensions? Length of stroke, 16in., piston making 72 strokes per minute, diameter of cylinder 13½in., pressure of steam, 50lb. (as indicated by boiler gauge) cut-off at ½?—also when the steam is cut off at ⅜, ⅝, and when it is cut off altogether.—O. C., Bradford.

[52167.]—**Time Keeping.**—Would some of your worthy correspondents kindly give me a simple plan of correctly checking men's time in a small engineering shop? I enter the time each man commences work, but they often dispute my account, and I have to pay time I feel certain they are not on the ground. Llewellin's checking machines are too expensive. I should like to be able to make some simple contrivance. A little help will be esteemed.—Good Time.

[52168.]—**Royal National Tricycle.**—Will any of our readers give description, with sketch if possible, of the double driving gear as fitted to above machine?—viz., Lawson's friction cone clutch, with special reference to its automatic action by the steering handle.—G. S.

[52169.]—**Atomic Weights.**—Is it possible to obtain a really reliable table of elements with their atomic weights? In relabelling my bottles lately, I have experienced some considerable difficulty in adding the combining weights, owing to the various figures given in different works for the same metal. Uranium, for instance, is given as 60, 120, 240 and 59·4. Cerium is also given as 47, 92 and 138. Pray, which is the most correct? Of course, I am aware of the differences in the new and old notation, where the mysterious doubling of some of the numbers occur; but that does not explain the discrepancies referred to.—Experimenter.

[52170.]—**Midnight Sun.**—Would "F.R.A.S.," or any other reader, give the form to enable me to calculate the height of the sun above the horizon at midnight on 21 June and 21 July, say at N. Cape, lat. 71° 10′ 20″ N.?—C. R. T.

[52171.]—**Legal.**—A father, on the marriage of his daughter, settled a certain sum upon her, and handed over to her trustees a further sum to be invested for the mutual benefit of himself and his daughter, the interest thereon, in the first instance, to be paid by the trustees to the daughter towards her allowance during her father's lifetime, and the balance (if any) to be paid by her to her father. There is no allusion to the payment of income-tax, but the bank stop the full income-tax out of interest. Should not the daughter pay to her father the full balance, less only the income-tax on the balance?—in other words, should not the daughter pay her own share of the income-tax? Would Mr. Wetherfield kindly decide the point for—Fairplay.

[52172.]—**Timing of Transits.**—My transit instrument has three wires. The equatorial interval between the preceding and central wires is 2 seconds less than that between the central and the following wire. Now I want to know (1) Is not such a discrepancy as this indicative of careless or bad work on the maker's part? (2) In view of this unequal spacing of the wires, would it not be better to take star transits over the central wire alone, and not take the mean time of the three wires? (3) In order to get instrument into meridian, which is better, the method of high and low stars, or the Pole star at one of its transits?—Clock Star.

[52173.]—**Reading the Circles of an Equatorial.**—The hour circle of my equatorial is 7ft. from the floor, while the declination circle is over half a foot higher. This makes it exceedingly inconvenient, as it necessitates the jumping up on high stools or chairs to read them, while it is impossible, holding a lamp in one hand when thus perched aloft, to properly work the clamp and slow-motion screws. Would some one who has had experience tell me whether there are any drawbacks to the system of reading the circles from the eye end of the telescope by tubes and prisms? Mr. Grubb applied this method in a very ingenious way to the great Vienna refractor. I have seen telescopes as small as 6in. aperture fitted with reading tube for the declination circle, but not for the right ascension one. I presume it could be done however.—Clock Star.

[52174.]—**Slide Valve.**—I have just completed a small power horizontal engine, 2⅝in. bore, 4¼in. stroke. I tried it with steam, with a pressure of 50 pounds to the inch, and the piston would not move, but the steam came rushing out of the exhaust. Knowing it was some fault with the valve, I lengthened the rod, bringing the valve down to the bottom about ⅛in., and had the satisfaction of seeing it work excepting that too much steam escapes through the exhaust. The steam does not leave the exhaust in a series of puffs at each stroke, but comes out in one continuous stream. I have allowed about 1-16in. lead, the exhaust is ⅜in., and the two ports 5-16in. The steam enters the slide-valve case directly behind the valve, so as to keep it close to the cylinder face. Will some kind friend inform me where I am in error?—also should the valve be nearly as wide as the slide-valve case, and is there any better way of keeping the valve close to cylinder face?—One who is Perplexed.

[52175.]—**Perspective of an Interior.**—I have done an ideal drawing of an Oriental interior, but cannot get the perspective of the ceiling correct; and as no book on perspective that I have seen deals with the case, I think an explanatory sketch would be useful to others besides myself. For convenience I will make dimensions in describing. I wish to draw a room 30ft. long and 15ft. wide, one end being northwards and the other towards the south; the walls are 10ft. high, and above them is a semicircular ceiling, the pitch of which would be 7ft. 6in., and the height of the room in the centre 17ft. 6in. The ceiling does not form a "tunnel," but is quadricircular from the end wall, and this is the tough point. Now, I want to make a sketch of the room, as it appears to me when I stand at the south-west corner at a point, say, 5ft. from the south and west walls. The ceiling is ornamented by a pattern of cross bars drawn diamond-wise; this I also wish to depict, and make the joins the pattern in the corner correctly. I do not know if position of the line of sight is conditional or empiri but if the latter, I will place it at 5ft. above the floo the north wall. I do not understand algebra, and, therefore, cannot give purely comparative data. I should be greatly obliged if some one would give the rules to work out a sketch of the roof.—Murano.

[52176.]—**Light for Oxy-Hydrogen Microscope.**—Two weeks ago, I addressed a query respecting the limelight. As I am writing this from the Antipodes, it will be some weeks yet before I shall see any replies that may be kindly made to my questions. In the mean time, I have had an opportunity of reading a little work on the magic lantern by Mr. Chadwick, which contains a great deal of valuable information on the subject. My jet as mentioned in my previous communication, is one for burning "mixed gases" from one bag, and this kind of burner is mentioned by Mr. Chadwick ("Magic Lantern Manual," p. 51) as very dangerous; but I fail to see that it is more dangerous than using the gases in separate bags, for, from a paragraph a little further on, Mr. C. says that sometimes, from unequal pressure, the gases do become mixed, and accidents occur. On page 53 of the same book, there is the description of a safety valve invented by the author, and said to have been put to severe tests and never to have failed. I have no doubt amongst the many readers of the "E. M.," there are some who have had experience in burning the mixed gases and using the valve in question. Will they kindly give me the result of their experience in this matter? The valve is called the back-pressure valve, and appears admirably suited for the purpose; and should it be as efficient as stated, I cannot see why it would not be quite safe, with ordinary care, to use the gases mixed, instead of the trouble and expense of two bags.—Tasman.

[52177.]—**Outer Walls of Houses.**—Would any of your readers, connected with the building trade, kindly inform me what is the necessary thickness of outer-walls of dwelling-houses (in proportion to the height) as laid down by recent legislation for the Metropolitan district?—Leo.

[52178.]—**Combustion Without Flame.**—I remember reading that Mr. Fletcher, of Warrington, performed an experiment in a lecture, in which a jet of ignited gas was directed on some metal, and when this got hot the gas was momentarily turned off and on again, when, although there was no longer any flame, the heat increased until the metal was melted. Will Mr. Fletcher, or anyone who knows the details, give a description which will enable me to repeat this remarkable phenomenon?—Glatton.

[52179.]—**Slide-Rule Formulæ—their Construction.**—What are the broad principles on which these are constructed?—Constants for formulæ involving simple proportion I can manage; but how is the setting determined when quantities vary as the squares or roots of others, as in the following examples. I should be glad to see the successive steps which decide that the constant should be on A line, the plunger speed on B, the cub. feet on C, and the diameter of pump on D. Knowing this, of course, the constant 183 is soon found by trial. The formulæ is for pumps.

A 183
B. Ft. per min.

C Cub. ft. per minute
D Dia. of pump in inches

Glatton.

[52180.]—**Electro-Magnets.**—Would it be possible for one battery, or accumulator, to actuate a series of 70 electro-magnets in circuit, so that all would sustain the same weight? I should require them to lift about 600lb. through ½in.; but by a long lever, I could, I suppose, make a pull of 30lb. through ⅛in. do this, so about 30lb. will be the actual weight lifted. Could the current from the accumulator be regulated so as to produce any required weight of pull against an opposing spring from 0 up to maximum?—E. C. P.

[52181.]—**Balance Gear of Omnicycle.**—Could any of readers explain to me the balance gear of this machine, and how it works? I have one, but cannot understand its mechanism.—John Alex Ollard, Enfield.

[52182.]—**Coloured Inks for Bone Work.**—Will one of your numerous readers give me instructions to make any coloured ink to use with an indiarubber stamp for printing on bone, and that will not discolour or wash out? To use either on a pad or as a jelly, and also one to use with steel dies?—Bone.

[52183.]—**Legal—Settlement of Real Estate on Wife.**—I am about to leave home, probably never to return, and am possessed of a little real estate which I am anxious to settle on my wife for her life, and after her to my children, if possible in such a way that should I, which is improbable, enter into business, and say, get into debt, that it may not be affected in any way to her loss. Would it be any more certain to her if I gave it entirely to trustees, without power to sell, hypothecate, or mortgage, and for them to pay her the proceeds, such as rent, &c.? I am now entirely free of debt, and in addition to taking with me some capital for myself, would leave her with some spare cash. The trustees would be her brothers.—Schluyttdaskin.

[52184.]—**Altitudes.**—I should be very much obliged if some one would complete accurately the following altitudes:—

Upper Alt.	Ther.	Air Station	Lower Alt.	Air Station	Ther.
29·546	68·1	69·1	30·142	73·9	71·1
29·575	66·2	66·3	30·109	70·7	67·3

Latitude 50° N.—Rosicrucian.

[52185.]—**Sunspots.**—Would some one among your astronomical correspondents be kind enough to inform me as to the exact time at which the present period of solar disturbance attained its actual maximum?—I mean the decimals which will be entered in future tables as maximum of 1883.—S. M. B. G.

[52186.]—**Saturn.**—How am I to identify any satellites I may chance to see with a 3½in.? What is the smallest aperture which will show the crape-ring at all?—and the smallest which will show it properly?—*Antares.*

[52187.]—**To "F.R.A.S."**—I would be much obliged to you if you would inform me what bearing, if any, Mr. Stone's recent researches upon the length of the terrestrial day have upon Prof. G. H. Darwin's theory of Tidal Evolution of the Moon?—Selene.

[52188.]—**Lubricating Oil for Lathes.**—Which is the best?—I find sperm oil gums up. I have been recommended neats-foot oil, to which is added five per cent. caustic lime, and exposed to the air and light for a fortnight, and then filtered. Have any of "ours" tried this formula?—Cressington.

[52189.]—**Transparent Varnishes for Glass.**—Are these procurable ready prepared—say red, blue, and yellow transparent varnishes, suitable to imitate stained glass? Perhaps some maker would kindly advertise. I feel sure there are many of "ours" in need of the above.—Cressington.

[52190.]—**Copper Reduction—Wet Process.**—Being an owner of a large deposit of copper pyrites, 2 to 4 per cent., and mixed with a large quantity of iron and magnetic pyrites, and other minerals, whereby, concentration mechanically is almost impossible, I have some thoughts of experimenting by the so-called wet process, viz.—Crushing, calcining with sodic chloride, and dissolving the salts of copper by water and acid, and from this solution precipitating the Cu by electricity. As I am not thoroughly posted up in the details of this process, and believing it will interest others as well as myself, I shall be glad if any reader will, through this medium, furnish me with details and sketch arrangement.—A Norwegian.

[52191.]—**Equal Increments of Temperature.**—Are there any tables in existence giving the expansion of liquids for equal increments of temperature, and do all liquids expand equally whatever be their gravity? Any reader of "ours" will greatly oblige by assisting me to where I can find information on this subject.—J. S. B.

[52192.]—**Musical Examinations.**—Will any of our musical correspondents acquaint me with the nature (conditions, subjects, &c.) of the examinations for the respective degrees of "A. C. O." and "F. C. O."?—and also, which of the two examinations is the more difficult to pass? A few hints as to course of instruction, would be esteemed.—Would-be F. C. O.

[52193.]—**Telescopic.**—In a recent abstract of the proceedings of the Liverpool Astronomical Society, I have read with interest some observations by Mr. Franks on the performance of telescopes, and there is a point on which I should like my darkness enlightened by your able correspondent. Amongst other things, Mr. Franks says that "many celestial objects,"—Mars, Jupiter, and Saturn, are instanced—"are best seen with certain amplification, independently of the aperture of the telescope"; and he mentions powers 200 — 400 as giving the best views, not only with 4in. apertures, but giants like Lassell's reflector, and the 26in. Washington refractor. Will Mr. Franks explain why this is so?—also the apparent contradiction between the above statement and what he says in a valuable letter in the "E. M." of Feb. 23, that for planetary work a small telescope is of no use, but "a large reflector with as high a power as the atmosphere will bear"? In the abstract of proceedings, I find the Rev. J. J. Muschamp Perry remarking that "with present telescopes at least, it was not profitable to employ a higher power than 750 on any of the planets." This subject seems to me full of interest. As one of the army of very small aperture observers, permit me to ask if single lens eyepieces are so much to be despised? I have a fair 2¼in. o.g., which, with a single lens (the eye lens of a badly defining Huyghenian) gives an excellent view of both Saturn and the Moon; power about 120. Will Mr. Franks kindly tell me if is possible to see the principal cloud belt on the ball of Saturn with such aperture and power? I certainly had the impression last evening.—Arthur Mee.

[52194.]—**Finding Gravity of Light Fluids.**—I am desirous of making a set of tables for finding the gravity of light fluids with the hydrometer, but do not know how to calculate the allowance for temperature, the temperature having to be reduced to 60° from whatever it may be at the time of testing. How is this done? Will any kind reader of "ours" inform me, that I may tabulate to every usual degree of atmospheric temperature?—J. S. B.

[52195.]—**Caoutchouc.**—Is flesh-coloured caoutchouc or indiarubber ever used by doctors to supply the place of any part of the human frame—the nasal organ for instance, if it has been removed or injured in a battle or by accident? Does any medical work treat of the subject, or instance any successful cases?—Enquirer.

[52196.]—**Becquerel's Oxygen Circuit.**—Can any of the readers of "ours" inform me how to make the above battery? What proportions of caustic potash and acid are used for this battery? What kind of acid is used? The cell I have is 6in. by 4in. inside measurement. Would a porous cell do as well as a glass tube closed with a piece of linen tied over it, to which is attached a piece of clay ¼in. thick?—R. Bell.

[52197.]—**Legal.**—Would a gentleman with legal knowledge kindly give some advice in the following case? We are the leaseholders of certain property bounded on three sides—north, east, and south—by land belonging to another, the fourth side being water. Access to our holding is had by a road starting from the extreme north-east angle of the other's land, and running obliquely across his land to our inclosure, the said road having been in existence for over 50 years certain. The owner of this surrounding land has now commenced, in spite of our protests, to do away with the present and old established road, and to make another running up at right angles, due east, through his land to a bye lane. This will cause us some inconvenience inasmuch as we shall have to traverse two sides of a right angle instead of cutting across its base; and secondly, our exit will be into a bye lane instead of the high road. It will, no doubt, be a great advantage to the other party, in squaring up his land for building, &c. Query. Can this party substitute a new road for the old one without our consent? If not, how should we proceed to stop him? And finally, supposing we allow it to be done, can our ground landlord in any way call us to book for it, or hold us responsible for any damage? It is a poor estate, or I should not bother you.—A Perplexed Trustee.

[52198.]—**Firing.**—Will "Engineer" or "Firer, Dewsbury," or other reader, give a hint or two as to the best mode of firing? There is great difference between the practice of firers at the present time: Some will consume from 20 to 40 tons more than others in 12 months time.—Country Lad.

[52199.]—**Ornamental Flowerpots.**—I shall be obliged if some reader would tell me the way to make and use plaster of Paris moulds for making the pots; whether the clay is pressed into the mould, or should it be oiled? or is oil injurious to the plaster? How thick need the plaster be?—M. W. S.

[52200.]—**Vacuum Gauges.**—Will any reader give particulars as to how the new vacuum gauges that are being put in the Midland Ry. guards' vans are fixed? Also what they indicate, as I see there are two pipes leading to them?—Historian.

[52201.]—**Discharging Water from Tanks.**—I have two iron cisterns holding about 400 gallons of water each. I require to get the water out of one into the other two or three times a day. Would any of your kind contributors advise as to best way to do it? I may say it is done by using injectors—but they make the water too hot.—J. Taylor.

[52202.]—**Deed of Gift.**—What is the form for making a deed of gift? Is it necessary to have a stamp? Are witnesses required? Will it answer the purpose of a will?—A. J.

[52203.]—**Legal.**—To Mr. Wetherfield or "Lex."—A. is a dealer in pianofortes and other musical instruments, and employs B. as a pianoforte tuner under the instructions of a written agreement to the effect that when B. ceases to be under the employ of A., he is not to trade for himself as a pianoforte tuner, &c., in any of the counties in which A. has branch businesses for six months or hereafter. What I want to know is (1) whether the term "hereafter" is legal, as the term "six months" is specified? (2) Can B. set up in business for himself as a tuner, &c., in any of the counties in which A. has branch businesses, if B. is employed by another firm for six months after he has left the employ of A.? (3) Can such a restriction be legal, beyond a certain period?—Perplexed.

[52204.]—**Long Pendulum Case Clock.**—The head of case of my new clock fits so closely that the sound cannot escape. The round dial is 13in. across, and some casing fits close up to it. What should be size of case so as to insure exit for sound to be heard over the house; or what is amiss? The clock stands on floor.—T.

[52205.]—**Lead and Antimony.**—I have had occasion to make a mixture of lead and antimony—four parts of the former to one of the latter—and have experienced considerable difficulty in keeping the metal in a workable state: it goes into a pasty mass quite unfit for pouring, caused by the antimony evaporating, I believe. Will some one kindly help me?—A. C.

[52206.]—**Lever Safety Valve.**—Will some correspondent kindly tell me if I am right in the following? I have a model lever safety-valve with an exhaust hole just ⅛in. diam. When the weight is at the end of the lever it registers on a correct spring balance just 1lb. To lift the lever up right over the centre of the steam outlet, I calculate it would require a steam pressure of 3lb. to lift the valve. Is my calculation right?—A. C.

[52207.]—**Lathe-making.**—Will some of your correspondents show me my error or convince me and others of the truth of our opinion in the following matter?—I was lately engaged in the Union SS. Co.'s factory in boring out a 12in. cylinder, horizontally, on the saddle of the lathe. I was obliged to raise the headstocks 4in. higher than ordinary. This I did by placing them on wood blocks. After placing the cylinder on its "feet" on the saddle, I brought it up to the back or running-head, and as it was lined off, I set this end from the centre of the lathe, bringing up the other head to the other end of the cylinder, ascertaining, of course, that the heads were fairly opposite each other, and in a line with the lathe-bed, or shears. Thus I set the cylinder fair with the lathe and the exact heights with the heads. I was to bore with a bar having a fixed head on it carrying cutters, the saddle carrying the cylinder along. Having the bar in, &c., I brought the boring head to each end of the cylinder, alternately, and corrected it to the lines on cylinder face, &c. The foreman coming up, applied the scribing block to each end of cylinder off the bed, and found it nearly 1-16in. higher in one end than the other. I protested that this did not signify, as the bar was not moving along the bed; but the job—at that part which was being cut—was always at the same part of the bed. He grew abusive. He had been a chief engineer. Told the superintendent I was confident, but not good at explanation. I was discharged. Was I right or they? Remember the heads were fair with the lathe-bed, and that when the cutter-head was brought—or rather when the cylinder was carried until each alternate end came to the cutters—it showed fair with the lines.—F. R. Clarke.

[52208.]—**Ink for Type Writer.**—I want good ink, preferably black, for use with a Hall type-writer. The violet ink is of a very objectionable colour. The blue, and so called black, will not give a press copy unless laid on so thick as to give blotted writing. I have used a rubber-stamp ink "U.S. patent A.A." blue, but it is not strong enough. Would the addition of aniline blue improve it? In what form can I obtain it? Can a good pen ink be boiled down without spoiling it? The ink I am using is very hygroscopic, which is a nuisance.—A. P. Trotter.

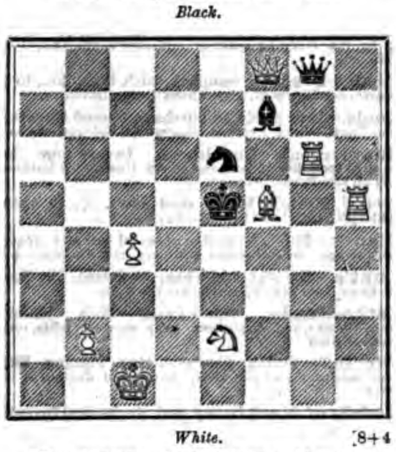
[52209.]—**Medical Coil.**—To "Sigma."—I have made a coil from the instructions on pp. 357-8 of your book, with the connections at 1 and 2, with the primary to be made at will. You say that when the connections are made, the induced currents are passed in only one direction; but I feel no difference when made or not made. I have tried some coils in which the current is felt in only one hand! I feel it in mine almost equally in both. Will you kindly say what is wrong? Might I also suggest that in the new edition an index of the tables would be a convenience?—R. P.

CHESS.

All Communications for this department must be addressed to J. Pierce, Bryn Rhedyn, Llandwrog, Carnarvon.

PROBLEM DCCCLX.—By J. B. Rowland ("The Wheel of Fortune") from *Land and Water*.

Black.



White. (8+4

White to play and sui-mate in eight moves.

Solution to 858.

White.	*Black.*
1. Kt to Q B 5	1. K-B 7 (*a*)
2. R-Kt 3	2. K-B 8 (best)
3. Kt-K 4	3. P mates or Kt discs. mate
	(a) 1. P (ch)
2. K-K sq	2. K-K 6 (best)
3. R takes B	3. Kt discs mate

The author terms the problem, whose solution is given above, "The Moth," and dedicates it to Mr. James Pierce.

The result of the Solution Tourney is as follows:—

First prize: Mr. C. Planck, full marks (190) "English Chess Problems."

Second Prize: Dicky Sam, 158, Pierce's "Chess Problems."

Third Prize: R. A. Bennett, 153, Miss Beechey's "Chess Blossoms."

The competitors next in order are:—

4. F. V. P.	134
5. Mortimer	108

Several other gentlemen started well in the race, among whom we may mention Messrs. A. E. Studd, Herbert Jacob, D. Mackay, and G. H. Mairwarning; but from various causes they found it impossible to go on with the competition.

We hope, now the stimulas of rivalry is over, that our solvers will still continue to send solutions, as the only real way to enjoy a good problem is to think out how it is done; and the harder the nut is to crack the more it is appreciated.

NOTICES TO CORRESPONDENTS.

Correct Solutions to 857 by D. Mackay and J. B., of Boxford; to 858 by J. Keeble (very good), and C. Planck (a charming problem).

Dicky Sam.—Please send name and address.

Problems and games received with thanks from G. J. Slater, J. A. Miles, D. Mackay, H. F. L. Meyer, J. Russell, and J. H. Blake.

B. B.—Your solution of 856 will not do, as Black escapes by 1. K-Q 4.

J. B., of Boxford.—Sui-mates, as you say, are not chess; but they open up some very pretty manœuvring, which is *sui generis* and well worthy of attention. The one given above is of this class: with regard to the number of variations in a problem, they tend to give it *volume*, and where they branch out naturally from the main idea, they enhance its value—otherwise, certainly not.

W. Andersson.—Your solution to 856 was quite correct; we thought receipt had been acknowledged.

W. Gurney.—In your solution to 857, you have not given Black his best play. There is no mate, for instance, if he play 1. Q-Q 3 (ch).

Every Workman connected with the Building Trades requiring a Situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make, and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty-four Words, and Sixpence for every Eight Words after

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 7, and unacknowledged elsewhere:—

Crossley Bros.—D. Bannatyne.—S. Lancaster.—G. T. Morecraft.—H. Stephens.—J. W. Caulfield.—F. A. Cobbold.—Miss Hamilton.—S. Copestake.—O. J. L.—J. P.—S. M. B. Gemmill.—W. Parker-Smith.—T. Gwyn Elger.—G. Fryer. — Assistant. — Geodesia.—Glatton. - Sitrander Sahib.—Perplexed Trustee.—Equation.—Wm. Binns.– A. D. L.—Preceptor.—T. Perkins, M.A. London.—G. C. R.

B. G. (Defy the firm. Commissioner Kerr only lately nonsuited a similar plaintiff. The touting system is a contemptible one, and in no case can you be made to pay, as you are a minor.)—Bull's Eye. (The labour and trouble are proportionately greater with the small lenses; besides, questions of cost must really be left to makers and their customers, as far as we are concerned.)—W. H. Gaze. (We regret we had not the space to spare for either letter. What were the queries? We remember nothing of them.) — Achromatic. (We cannot spare the space. Ask Mr. Holmes to send it privately, or buy the book.)—L. W. D. (We are afraid you can do nothing. If you could find out certainly that a balance remained after paying all the deceased's debts, you could recover; but you have left matters too long, and had better now consult a solicitor.)—A. A. (Desirable, but hardly imperatively necessary, and might be worked up later as you go on.)—Joulad and Others. (We have no further space for discussing New Zealand. Readers have heard both sides, and must draw their own conclusions.)—Turner. (We do not think there could be any difficulty, provided you are no nuisance to your neighbours. You must, of course, give notice to the surveyor of the local board or sanitary authority of your district.)—Tanner. (Commercial matters are beyond our scope.)—Wimbledon. (See indices of recent volumes. Better have medical advice before using the coil.)—Glatton. (Whichever you like. What do you suppose a chemist would say to such a question? Does he do what you say, and, if so, what does that prove?)—J. J. Gilbert. (We do not remember the article. Letter did not arrive in time for last week.)—Thomas Plunkett. (1. You will find answers in back numbers; but the question really turns on what is the resistance of the lamp? The battery must have sufficient potential to overcome that. 2. Crossley's microphone, illustrated on p. 544, Vol. XXIX., and Edison's loud-speaking receiver described on p. 25, same volume. Most of the useful instruments have been described in the last ten volumes.)—Inventor. (The rules can be obtained from the office. We forget the exact dimensions.)—C. T. Ball. (It means just what the dictionary gives; that is, as much as the solvent will dissolve.)—C. (We see nothing to reconcile; you forget the cave is to a certain extent open to the atmosphere just as a well, at the bottom of which, especially if dry, carbonic acid is sure to be found.)—W. J. Brighton. (Impossible to answer such a question without having the context—that is, the table.)—W. H. Goy. (If you, who saw it, cannot find an explanation, how can any one from your description? The simple answer would be threads; but you do not say whether performer's hands were always over the figure.)—E. W. Newton. (Bunsen's; what you want has not been invented yet, and is scarcely likely to be. Read up your back numbers.)—J. N., Dundee. (Why not write to the patentees? If that does not meet your views, you must wait until the specification is published. We shall, no doubt, publish all particulars as soon as available.)—W. J. C. (Have we not given sufficient? See p. 426, No. 929, and sundry replies and notes since.)—T. R. Allinson. (The address of the Anthropological Institute is 4, St. Martin's-place, W.C.)—J. McE. (If the information referred to is not sufficient, it will be found by searching the back volumes, or Capt. Galton's reports in the *Transactions* of the Institution of Civil Engineers.)—Winter Night. (How is it possible to answer such a question without knowing focal length of lenses? If they are worth anything at all they are probably too good for the suggested purpose. See pp. 267, 289, 336, Vol. XXXIII., and the indices.)—Loanhead. (For full directions how to make a phonograph, see p. 157, Vol. XXVII.)—A Sufferer. (Many remedies for neuralgia in back numbers. You might try that given on p. 435, No. 929.)—J. Johnson. (They are rolled out, and the colour imparted by tempering.)—Cupidus Audiendi Est. (You will find many recipes in back volumes. Perhaps some of those given on p. 510, last volume, would suit. See p. 404, Vol. XXXVI.)—Vulcanite. (He no doubt meant Vols. XXII. and XXIII. It commenced in No. 561, and was continued for many weeks.)—Edward Hart. (You have only to take or send it to him, and pay his fee.)—Artificial Eye. (Reduce to something near a polish on a grindstone, and finish with crocus on a bit of soft wood. Very fine emery would do.)—Dairyman. (You must be examined by a medical man. Any replies would be mere guesses, and no one with a sense of responsibility would reply without knowing what is the matter.)—X. (We do not know of such a book. The information would be found to a certain extent in various works on machines, and in the volumes of the technical journals. Search the indices for clutch and coupling.)—Dick Turpin. (Rather too late to describe a thing that everybody has seen or can see. Look in your back numbers. Briefly, it is a pear-shaped glass envelope inclosing a filament of carbon describing a circular loop at its upper part.)—J. M. (We can only refer you to the advertisements.)—G. (About one ounce to a cell about two-thirds full of water. Practically, put in as much as you like, and add water from time to time.)—W. F. (It should have been well worked at the time. If stiff now, rub over with soap, damp, and work it about well.)—Semper Fidelis. (See pp. 329, 338, 361, Vol. XXXV., and the indices. 2. See p. 506, last volume, and the indices. It much depends on the cause, which can be determined only by an expert on examination. Bathing the sores with permanganate of potash solution would aid.)—Hamish. (There is a description with illustrations in Vol. XXXIV., p. 571.)—Flying Machine. (We do not know that there are any recognised dimensions. Good sizes would be 14 to 18ft. in diameter; hole about a foot in diameter, and ropes from 10 to 20ft. 2. Fleeming Jenkin's in Longman's Series of Textbooks; and Dunkin's edition of Gardner's Handbook of Astronomy, Lockwood and Co.)—T. P. M. (Answered on p. 201, No. 893. They are carefully coated with size, and then with best paper or amber varnish.)—J. H. (You will find what you want illustrated on p. 310, No. 924.)—Stanfordham. (There are a number of recipes in back volumes; but much depends on the nature of the stains. 2. The expansion of steel by heat varies slightly with the physical condition; but for all practical purposes, you make take it as ·0012 between freezing and boiling of water. The coefficient is ·000012395 for each centigrade degree.)—Thor. (See p. 273, Vol. XXXII., and the indices since. We believe the identical case can be seen at Griffin's, Garrick-street, W.C.)—B. S. S. (See p. 528, No. 907. We cannot afford engravings of such matters. You should endeavour to see one, or procure an illustrated list from the makers. Fasten the netting in groove in wood, and make the best joints you can; dovetail would be best.)—W. F. H. (The Bunsen, if it can be placed outside; the bichromate if it must be kept indoors. Directions for making both forms have been given many times.)—Poser. (We do not know where working drawings can be obtained; but any mechanical draughtsman can make them from the illustrations we have frequently given. Try if you can find one to suit on p. 272, No. 870. If not, you may by searching the indices.)—Milo. (It is not an easy matter; but you will find methods in Vol. XXVI., pp. 44, 169.)—Zither. (See a reply on p. 460, No. 851.)—Rubber. (If it is vulcanised, you can do nothing with it but sell to the factory.)—A. J. Shaw. (Nos. 942, 944, 946, 948, 950, 952, 954, 956, 958, 960, 962, 964.)—Albert Dovaston. (If you had mentioned the signature you employed, you would have saved us some waste of time. Your question was answered on p. 162 to the initials L. S. See middle column of that page, fifteen lines from the bottom.)—Mechanic. (It is in No. 749, which can be had for 2½d. in halfpenny stamps.)—W. Walker. (The paragraph appeared on p. 36. We noticed the *Times'* report, not the "invention.")—A. B. C. (Try common paraffin oil and a clean bit of rag.)—Tweedledum. (Make your battery solution of 3oz. bichromate, 9oz. sulphuric acid to the pint of water. See p. 192, last volume. 2. Metal moulds are unusual; but where a deposit is not wanted, it is only necessary to cover with a good hard varnish.)—Country Photographer. (See a reply on p. 179. No. for Oct. 26.)—W. D. (You might succeed with gas and Fletcher's radial slit burners; but vertical boilers are always best for such dimensions. You will find many hints in back volumes.)—Aeronaut. (If you could dissolve it in that it might do, but you had better try bisulphide of carbon. Better use hydrochloric acid, as the resulting chloride of zinc would be useful; the cost will depend on the prices paid; but it will be much more than coal-gas. The other question is a mere sum.)—Dynamo. (See recent back numbers.)—Stella. (One illustrated on p. 112, which will give the principle.)—A. S. L. (We hope to give the first instalment next week. Do not colour future drawings; we can reproduce them better uncoloured.)

CHARGES FOR ADVERTISING.

	s.	d.
Twenty-four words	0	3
For every succeeding Eight words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling, the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O's.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

Holloway's Pills.—No amount of wealth, no means of pleasure, are of the slightest value without health. It is inconceivable how small a disturbance of the animal functions begets wretchedness, and how readily it may be rectified by a few doses of some purifying and regulating medicine, such as these world-renowned Pills, which are ever the sufferer's surest friend.

AND WORLD OF SCIENCE AND ART.

FRIDAY, NOVEMBER 16, 1883.

ARE CANNED FOODS DANGEROUS?

ALTHOUGH many millions of "tins" of meat, fruit, and fish are annually used as food in this country, it is only occasionally that we hear of any fatal result from the consumption of food which is, at any rate, cheap, and, so far as trustworthy evidence is available, certainly not unwholesome. A recent case which, according to the newspaper reports, ended in death—poisoned by "nitrate of tin"—recalls attention to a subject which is not without interest from several points of view. Except for the occasional reports of deaths in consequence of eating tinned foods, there seems no reason to suppose that the use of tinned vessels is in any way injurious, and we need scarcely mention that culinary utensils of both copper and iron are invariably coated with tin, and have been so for years without any one casting so much as a hint of suspicion upon them. So far as we know, tin is not used in medicine, except in the form of filings or powder, when, mixed with treacle, it is administered in the form of an electuary, to act as a vermifuge—tin being chosen presumably because it is inert in the human economy. It is attacked by most of the common acids under certain conditions; but diluted nitric acid produces the insoluble hydrated dioxide of the metal known as metastannic acid, with the evolution of nitrous fumes; and it is not easy to conceive how, in the ordinary methods of preparing canned articles, anything could get into the cans which would affect the coating of tin to such an extent as to produce a poisonous compound. The salts of tin, too, have mostly a powerfully astringent taste, which, if they were really formed in the cans, would be sufficient to condemn the use of tin plate as a preservative casing. It is obvious, however, that tin cans as usually made must have solder about them in some part or the other, and it is not impossible that the lead contained in the solder may, in some manner not understood, be acted upon so as to become a poisonous salt; and it is possible that in some factories a little of the chloride of zinc used as soldering fluid may be left; but even in that case the quantity must be very small. An examination of an empty can discloses the fact that the tin coating has been acted upon to some extent by the juices of the meat, fish, or fruit, aided probably by the heat employed in the preserving process; but the contents of so many cans have been usefully disposed of, that it is impossible to overlook the fact that if there were anything deleterious in the can itself, the number of cases of illness soon after partaking of its contents would be vastly larger than has been recorded. Assuming that mistakes have not been made, there are a sufficient number of cases of illness attributed to the consumption of canned food to call for an expert inquiry with the view of testing the truth of the charges brought against the "tins." The question is of importance to this country for another reason than mere considerations of the food supply. We are probably not overstepping the mark by estimating that of the tin cans which reach this country, about nine-tenths have been previously exported as tin plates, which are supposed to be (and we believe generally are) sheets of iron coated with tin that is practically pure. Of the bulk of the import into America, a large portion consists of what are known as terne-plates, used chiefly for roofing purposes, in which the coating consists of an alloy of lead and tin in the proportion of 2 or 3 of lead to 1 of tin. There can be no doubt that fruits packed in tins made of such plates, especially if a high temperature were used in the preserving process, would become contaminated with lead salts, and fish and meat would also be condemned as unwholesome; but although it has often been stated that some of the more "enterprising" packers, anxious to put their goods at a lower figure, have used terne-plates for their cans, we have not heard of any authenticated case in which such a can was found when sought for. Canned articles, especially fruits, such as peaches and tomatoes, are very largely consumed in the United States, and alarming statements have not unfrequently been made there as to the danger of using canned fruits as a regular article of diet. It is just possible that the primary cause of those statements may have been the use of terne-plates; but the makers of tinware are well aware of the difference in the appearance of the bright tin-plates and those coated with the alloy, and, so far as we know, no expert has yet succeeded in finding any large quantity of lead in even the commonest tinware, and no cans which were made of terne-plates. Most of the tinplate used in the United States is made in England, and is commonly known under the designation of bright plate and terne-plate, the difference being a matter of common knowledge. Analyses have been frequently made of these plates, with the invariable result of finding that the tin coating is practically as pure as the best English bar. In one instance a trace of lead was found in the tin removed from half a square foot of plate, which would leave the tin with the character of "commercially pure"; but although lead was detected in the commonest ware, not sufficient was found to establish the charge of intentional adulteration. One analyst reports that he has been assured on good authority that terne-plate is sometimes used to manufacture tinware, but he has failed to find an instance of its use in cans for preserving food. Altogether it may be assumed that there is not much risk of eating either flesh, fruit, or fish which has been rendered poisonous by any action on the tinplate in which it has been incased, and we are, therefore, reduced to an examination of the solder. The solder-joints in any tin can consist of the vertical seam joining the cylindrical part and those at the two ends. As goods of the kind are usually packed, it may be assumed that the contents of the cans are never in contact with both ends at the same time; and as the vertical seam is generally made by the folding plan, the solder being placed only on the outside, we have only the ring seam of solder at the foot and head of the can to consider. The solder used is probably in all cases made of lead 2, tin 1; and an examination will show that only a very small surface, compared to the contents of the tin, can possibly come into contact with the meat or fish, though of course where fruit is the article, the liquid will convey the poison (if any) to all parts. The acid juices of fruit will undoubtedly act on lead, and will probably dissolve that metal from the alloy; but, like other suggestions which have been made in connection with tinned goods, no proof has been offered that lead in an appreciable quantity has been found in the contents of the cans. The latter are generally soldered up in a machine by which the minimum quantity of solder is used; and, as a rule, a guard-plate is attached to the lid to catch any solder which may run through the hole where the final sealing is made. We can conceive it possible that infinitesimal quantities of lead frequently administered may be highly dangerous to life; but it is certain that they will produce unmistakable symptoms long before any fatal result can ensue. The cases of injury or death referred to above, are, however, comparatively sudden in their effects, if we are to believe the reports, and we are, therefore, compelled to assume that if they are due to the preserved provisions at all, the cause must be sought for in the provisions themselves, or in some unknown action which they may have on the tin coating of their envelopes. When we come to consider the extreme improbability of anything deleterious reaching the human stomach in that way, for it must be remembered that long before the "canned" trade attained its present dimensions, provisions were preserved in exactly the same manner and went the round of the globe without being injured, we can only conclude that the fatal cases which have been attributed to the consumption of "canned foods" were really due to causes which must have escaped the attention of experts. Those engaged in the importation of "canned" foods should, therefore, take note of the statements referred to, and should jointly make arrangements for an exhaustive series of experiments which would determine once for all whether anything deleterious to human life can be found in the cases of tinned provisions. It may be that some unknown injurious salt of tin is produced by prolonged packing—although well-known facts negative that idea; or it may be that the methods of preserving are defective, and not equal to those which were so successful a quarter of a century ago. It may be conceded that in the case of fruit, glass jars would be better than tin cans; but in the case of fish and meat there will be a difficulty in ascertaining whether the preservative process is complete if glass is used, and a much greater loss through breakage in transportation and subsequent handling. Altogether it may be said that the charges made against tinned foods are not merely not proven; but are, in reality, highly improbable.

PRACTICAL NOTES ON PLUMBING.—LXXXV.*

By P. J. DAVIES, H.M.A.S.P., &c.

(*Continued from page* 210.)

NOW that we have gone through the foregoing preparatory work, which has given my readers a general insight into the art of the trade, I will give, before proceeding to my roof work, a few tables and rules suitable for inside plumber's work.

The following rules and tables will at times be found useful to the working plumber; and in order to make them as simple as possible, I will begin by explaining the law of falling bodies, which, if understood, will enable the workman to calculate the flow of water through pipes by gravitation. I shall also give rules for ascertaining the amount of friction, or loss of head of water when running through long pipes and bends; the method of calculating the amount of water a pump will throw; power required to work it, and such like. But it should be distinctly understood that simplicity is the great thing aimed at; and therefore in some cases the plain figures will not answer for theoretical work, but in all cases it will answer every purpose for the practical plumber.

Gravitation;

Or the law of falling bodies which governs the flow of water when falling through pipes (also for suction pipes).—The plumber, in order that he may tell the quantity of water which will flow through a suction pipe, or from a cistern through a given sized pipe into a w.c., &c., in a given time, should make himself thoroughly acquainted with the following rules of gravitation or attraction, or law of falling bodies:—

A body falling from a height will, approximately speaking, fall 16ft. in the first second of time; but in reality it falls 16ft. 1in., which latter in practice is not taken into consideration. Say, 16ft. in the first second of time, it will, in the second second, fall three times this distance

---

* From the Building News. All rights reserved.

[illegible] second; [illegible] second, and so on: [illegible] every successive [illegible] of which will be [illegible]

Laws of Falling Bodies.

Time of falling in seconds.	Space fallen through.	Space fallen through in last second.	Velocity acquired at the end of the time per second.
1 second	16 feet	16 feet	32 feet
2 ..	64 ..	48 ..	64 ..
3 ..	144 ..	80 ..	96 ..
4 ..	256 ..	112 ..	128 ..
5 ..	400 ..	144 ..	160 ..
6 ..	576 ..	176 ..	192 ..
7 ..	784 ..	208 ..	224 ..
8 ..	1,024 ..	240 ..	256 ..
9 ..	1,296 ..	272 ..	288 ..
10 ..	1,600 ..	304 ..	320 ..

Explanation for working the above tables. For our purpose [illegible] Suppose we have a [illegible] of vertical piping [illegible] a bullet through the pipe and [illegible] its sides. What [illegible] at the end of the first second [illegible]

[illegible]

If required per minute, divide by 60, and if per second, divide the last quotient by 60 again. Thus, 23,040 gallons per hour is 384 gallons per minute, and 6·4 gallons per second.

I may here mention that an allowance of 10 per cent. is at times made for loss by friction; but this greatly depends upon the class of pipe, and, if required in minute detail, it may be calculated by the following rules:—

$$G = \left(\frac{(3d)^5 \times H}{L}\right)^{\frac{1}{2}}$$

$$H = \frac{G^2 \times L}{(3d)^5}$$

$$d = \left(\frac{G^2 \times L}{H}\right)^{\frac{1}{5}} \div 3$$

$$L = \frac{(3d)^5 \times H}{G^2}$$

In these rules d = diameter of pipe in inches.
L = length in yards,
H = head of water in feet.
G = gallons per minute.

Then, again, there is the loss of head by bends, junctions, or branches, &c., the latter especially, which causes great eddies, more especially when the junctions are made at right angles.

Capacity of Pipes, Pumps, &c.

Question.—What are the contents of a pipe of given bore and length, say, 2in. bore and 24ft. long?

Rule.—Square the diameter of the pipe in inches, and multiply by the yards in length, and divide the product by [illegible], which will give the contents in gallons.

Example.—2 × 2 = 4 × 8 yards (or the 24ft.) = 32 ÷ [illegible] = [illegible] gallons.

Having now seen the rules of gravitation and ascertained the quantity of water which will approximately flow by gravity through different sized pipes, I will give a rule for approximately ascertaining the quantity of water which pumps of different sizes will deliver per hour.

Pump Table (Computation of).

Question.—What amount of water in gallons will a pump whose barrel is, say, [illegible] in diameter, with a [illegible] stroke, worked [illegible] times per minute, give theoretically per hour?

Rule.—Square the diameter of the barrel in inches and multiply this by the length of the stroke in inches, and again multiply by the number of strokes per minute, and also multiply by 60, the minutes per hour; now divide the product by [illegible], and the quotient will be the gallons [illegible] per hour.

Example.—[illegible]

[illegible]

Pump Barrel Proportions.

[illegible]

Pump Power, or the Power Required to Work a Pump.

[illegible]

when going up a hill he cannot do the above amount of work by, say, ordinarily speaking, about ⅔ of the quantity; but as horses do not walk in a straight line when turning a pump, it may be asked when does the horse exert its strength to the best advantage when doing circular work. From experience the circle should not be less than 40ft. in diameter, and if the circle be reduced to half, namely 20ft., the horse's power will be reduced ⅔ of the above 33,000lb.

Question.—Raise 400 gallons per minute to a height of 28ft., what power will be required.

Rule.—Multiply the weight of water, which is 10lb. to the gallon, in lbs. delivered per minute by the height to which it is raised in feet, and divide the product by 33,000, and the quotient is the horse-power.

Example.—400 × 10 × 28 ÷ 33,000 = 3·39 h.p. (For pressure to the square inch on pump bucket and capacity of barrel see examples.) But although these figures are here as 3·39h.p., it would be impossible for three horses to do anything like this amount of work in pumping water, even though they may be working in a 40ft. circle, for the simple reason that in all pumps there is a certain amount of friction, and this friction in practice becomes a serious item. Generally speaking, you may take it for granted that it will amount to at least from 20 to 25 per cent.

Pump Labour.

The following table at sight gives the number of gallons which may be raised by a man, ass, or horse to the height of 1ft. in one minute of time with the ordinary pumps, according to certain durations of work in hours, from 4 to 10 hours a day, and which is the result of practical work. For increased heights divide the number of gallons by the additional height in feet.

Table (Registered).

No. of hours at work.	Horse.	Ass.	Man with winch.	Man with lever.
	No. of gals	No. of gals	No. of gals	No. of gals
From 1 to 4	1,653	473	[illegible]	[illegible]
.. .. 5	1,480	419	[illegible]	[illegible]
.. .. 6	1,330	374	[illegible]	[illegible]
.. .. 8	1,169	[illegible]	[illegible]	145
.. .. 10	1,042	[illegible]	[illegible]	130

For the necessary sized barrel see pump table (computation of).

Manual Power Pumps.

We have seen what one horse-power signifies, and know the necessary quantity of power required to work a pump of a given size, whose duty it is to lift water to a given height. The average strength of an ordinary labouring man is [illegible] writers say [illegible] the strength of a horse [illegible] high per minute. That is to say, [illegible] powerful men [illegible] the strength of a good horse, and [illegible] the horse [illegible] the best advantage, so should the man. The horse works best when pulling in a straight level line, and is equal to [illegible] men when [illegible] with the horizon.

A man exerts the greatest strength when pulling upwards from the height of his knees, is in [illegible] from the knees upwards [illegible] winch of an ordinary [illegible] pump, and he exerts the least power when [illegible]

[illegible] as shown in Fig. [illegible]

[illegible] I am speaking [illegible] done by horse [illegible] with ordinary every-day pumps, and for the man the work done will be greater if a proportionately balanced fly-wheel be used.

(To be continued.)

IMPROVEMENTS IN GALVANIC BATTERIES.

MANY inventors have recently turned their attention to the improvement of the galvanic battery, and we have from time to time given an account of their suggestions. Lately the public has been asked to believe in sundry rather wonderful improvements: but, until we get a battery the products of which will sell for almost as much as the original materials cost, there is small chance of the primary battery supplanting the dynamo machine. Mr. Slater, of Lancaster-road, Notting-hill, has recently obtained a patent the subject matter of which will be understood from the following:—The electrolyte or cathode of a galvanic battery or a battery for storing electrical energy is formed of quicklime (say one pound) slacked by pouring thereon a saturated solution of bichromate of potash.

To that is added, little by little, nitrous or nitric acid of about the ordinary commercial strength (say 6lb.), or instead, a saturated solution of nitrate of soda or of nitrate of potash in equivalent quantity, which quantity would be about three times greater in the latter instance than in the former one, covering the vessel containing the same until the fumes evolved have subsided. In another vessel is placed caustic soda or caustic potash (say 4lb.) and water (say four quarts), to which is added dry sawdust (say 2lb.), or other suitable form of cellulose, and left until it becomes a pulpy mass.

This pulp is then mixed with the lime, nitric or nitrous acid, and bichromate of potash, and when these have thoroughly mixed chloride of sodium (say 1lb.) is added, and after the mixture has been allowed to stand for a few hours it may be placed in the desired receptacle in contact with the elementary metal or other suitable substance constituting the one pole of the battery. This substance may be a strip or strips or other form of carbon or wrought iron or other suitable metal kept in position or supported by connecting strips or otherwise. This pole and electrolyte may be separated from the other pole of the battery by a porous diaphragm or other suitable means of separation.

Within the porous vessel, or otherwise, as the opposite pole or electrode of the battery, is placed a piece of zinc, or a suitable metal coated with zinc, and this electrode is excited by placing in the vessel a mixture of caustic soda or caustic potash, chloride of sodium, muriate of ammonia, and muriate of zinc in proportions sufficient to form a neutral or saturated solution, or in proportions such as will give a reguline deposit of zinc during electrolysis. Or the muriate of zinc may be obtained by means of a saturated solution of metallic zinc in muriatic acid, and then caustic soda or caustic potash is added until the zinc is precipitated as an alkaline oxide, and upon a further addition of caustic soda or caustic potash, in the proportion of, say, 1lb. of caustic soda or caustic potash to each gallon of such precipitate, a resulting mass will be produced somewhat like thick mud, which when cold will be ready for use and capable of giving the desired reguline deposit during electrolysis. In this latter case the employment of the chloride of sodium and muriate of ammonia may be dispensed with. The salts of ammonia and zinc may be prepared by mixing them in equal proportions and then evaporating the solution into a crystalline state, and the result may be used directly with the zinc in its deliquescent state.

In the preparation of galvanic batteries, when not for use in storing electrical energy, the introduction of muriate of ammonia can be dispensed with.

The following proportions of these substances answer well: 1lb. of caustic soda, about ¼lb. of chloride of sodium, three pints of water, and a quarter of a pint of a saturated solution of muriate of zinc. To these may be added, if found desirable, a small quantity of bitartrate of potash and oxide of zinc (say 1oz. of each in the proportions of substances already instanced). This mixture having been placed in the proper vessel, it may form the charge for the battery for use until the current is exhausted.

To recuperate the exhausted cell, pass in a current from a dynamo-electric machine, or other suitable source of electricity, until the energy of the battery is again restored, and the battery is again ready for use as may be required: the action of current being to precipitate the metal held suspended in the solution on to the plate or cylinder, or plates or cylinders, from which such metal has originally been removed by previous action.

Instead of employing sawdust in the second vessel, the patentee may use sugar, molasses, or starch, carbonised by mixing a saturated solution of sugar, molasses, or starch at a temperature of about 120° Fahrenheit with equal volume by measure of nitric or sulphuric acid, and whilst the mixture is hot add thereto for each pound by weight of sugar 2½lb. of bichromate of potash or bichromate of soda, 1½lb. of oxide of chromium, and 1½lb. of freshly slacked lime, and when the whole is cool it is ready for use.

Messrs. D. G. Fitzgerald, of Brixton, and T. J. Jones, of Princes-street, Hanover-square, have also obtained a patent for improvements in elements to be used for batteries, which is thus described:—In carrying out the invention the patentees construct a tank or tanks, preferably of wood rendered watertight by means of a suitable cement. Each tank consists of one or several cells or receptacles, the number of these cells arranged in series being greater or less, according to the electromotive force of the dynamo machine or other source of electricity used in the process. Each cell may be subdivided by means of a diaphragm (or two diaphragms with the electrolytic fluid between them) of porous earthenware, felt, or other porous material. Of the two compartments thus formed, one contains the positive electrode or electrodes and the other the negative electrode. Or one of the electrodes (anode or cathode), consisting of one plate or of several plates connected together, may be contained, together with the salt or oxide of lead to be converted, in one or several porous vessels, placed within the tank; and surrounded with the other material to be converted by the electrode of opposite sign, which is in contact with such other material. In this case the porous vessels constitute one of the compartments, and the surrounding space the other compartment. The anode compartment may contain plates of lead surrounded with red lead to be converted into peroxide of lead, and the cathode compartment may contain plates of lead or carbon in contact with an oxide or insoluble salt of lead (preferably in admixture with carbon fragments), to be reduced to metallic lead. It is advantageous, except when chromic acid is to be produced, to dispense with the diaphragms or porous vessels, and to construct the tanks or cells of dimensions suitable to allow of certain elements being suspended vertically within the tank or cell along its sides so as to hang at some distance from the bottom. Upon the bottom of the tank is placed the negative element, covered to any required depth with the oxide or insoluble salt to be reduced. In this case the tanks should be shallow—*i.e.*, less in height than in breadth. The bottom of the tank is preferably raised somewhat towards the centre.

Instead of producing in bulk both the peroxide of lead and the reduced metal (obtained respectively at the anode and cathode surfaces within the tanks), the peroxide of lead is obtained in the substance of numerous plates or separate anodes of suitable size, to be employed subsequently as the negative elements in primary batteries; whilst the reduced metal alone, or in admixture with carbon fragments, is obtained in bulk, *i.e.*, in considerable masses, which are subsequently subdivided into portions of suitable size for the corresponding positive elements of the primary batteries. These anodes may be used as the negative elements of a primary battery, not only in conjunction with a positive element of reduced lead, but also, if preferred, in conjunction with a positive element of zinc in lieu of the lead. The plates, constructed wholly or mainly of lead, to be employed as anodes within the tank or tanks, should be highly porous in structure, in order that a large proportion of the lead of which they are formed may be converted into peroxide.

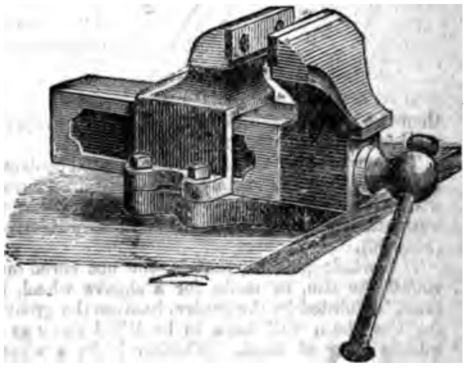
The tanks or receptacles may be connected together "in multiple arc," or "in series," according to the electromotive force of the dynamo machine, or other source of electricity employed to produce the reactions; each cell in series requiring an electromotive force of from three to four volts, although a higher electromotive force may be employed when rapidity of action rather than economy is required.

The electrolyte preferred is a dilute solution of sulphate of ammonia acidulated with sulphuric acid, in the proportion of one part of the concentrated acid to 12 or 15 parts of the half-saturated, quarter-saturated, or still more diluted solution of the salt. But in the treatment of sulphate of lead to obtain reduced lead therefrom at the cathode, the patentees sometimes employ a solution of acetate of ammonia, in which the lead salt is soluble. The cathode element, as in the case when porous vessels are used, should be lead or carbon in contact with an oxide or insoluble salt of lead, preferably in admixture with carbon fragments, such cathode, together with the material to be reduced, occupying, when a diaphragm is dispensed with, the bottom of the tank or receptacle. When a diaphragm is employed the cathode and material to be reduced occupies the whole of the negative compartment of the cell or tank.

Instead of obtaining the peroxide of lead as the material to be employed as a "depolariser" in the negative elements of primary voltaic batteries, the patentees obtain chromic acid by electrolysing the solution of a soluble chromate, such as the chromate or bichromate of potash with a platinum anode, and with a cathode of lead or carbon in contact with an insoluble salt, or an oxide of lead or tin. If such insoluble salt of lead be the sulphate, they find it advantageous to employ the sulphate of ammonia in solution with the chromate salt. The chromic acid and the reduced metal thus obtained may be used in the construction and working of primary voltaic batteries.

THE "HANDY" PARALLEL VICE.

THE annexed engraving represents the "Handy" parallel vice, a serviceable and cheap tool for both amateurs and mechanics. The body is painted and the jaws finished bright, the latter being of hardened cast steel, having faces of 2¾in. The vice will grip up to 3¼in., and its total weight is 9¼lb. Our attention has been drawn to it by Mr. A. S. Lunt, of 297, Hackney-road, E., who also sends us a useful catalogue of tools at low price.



PATTERN MAKING.—XVII.

Sheave Wheels.

A SHEAVE wheel is a wheel with a grooved or hollowed out rim for the reception of a chain or rope. We take the chain wheels first in order.

In a plain sheave the chain lies in its groove in the direction shown in Fig. 85. But a chain when in motion is always apt to twist, and when, as in hoisting machinery, a heavy load is directly dependent from it, a sudden return to its normal position will produce a jerk, and, as a consequence, a considerable extra strain will be put upon it at once. Hence it is customary where the wheel is immediately over the load dependent from the chain, and not merely acting as a carrier or support, to use, instead of a smooth sheave, one grooved out, so that the chain links may lie successively parallel with, and at right angles to its axis, Fig. 86. Further, in the differential pulley block, and in all cases where the wheel has to draw the chain along, the friction of the simple groove would not be sufficient to overcome the resistance of the load, and

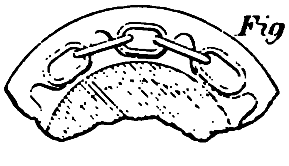

Fig. 87.

then the wheel is recessed at regular intervals to receive the alternating flat links (Fig. 87).

These wheels, if small, will have plated centres (Fig. 88); if moderately large, cast-iron arms [illegible] (Fig. 89); if very large, wrought-iron arms which will be usually strutted (Fig. [illegible]).

[illegible]

[illegible]

[illegible]

[illegible]

them. Similarly bosses and cross ribs (B B B B) will be fastened to these flat arm, having a slight amount of taper. Hollows may be put in or omitted at discretion.

Next take a large pulley with wrought-iron arms (Fig. 90). In some cases it will be advisable to use a complete pattern on account of the number of castings demanded. The ring could then be made in the usual way by building up in two halves and jointing (Fig. 90, side marked B). The bosses with their prints (C) on the inside of the ring will be jointed also. This would answer very well where the wheel is of stout proportions. But if it were light in section, such a pattern would not bear foundry usage very long, and an iron pattern would be advisable. But another method would be to build up a solid ring with a broad print (Fig. 90, side marked A), and to take out the groove with segmental cores—say ten or a dozen to the circle (Fig. 92, A). The advantage here would be that without making an iron pattern, we should have a rigid rim, not liable to become rammed out of truth—a matter of importance in a wheel of any kind. And further, although there is the additional expense involved in the making of the cores, we also save as a set off against this the trouble of the middle part box, since, instead of the joints top and bottom, we only want one joint at the top face of the print.

The core box will be made thus—Two sides will be prepared (Fig. 92, B B). Their outer edges (C C) will be worked to the same radius as the outer edge of the print (C). The inner edges—straight—will extend about a couple of inches below the line which represents the bottom of the wheel groove. In these sides, cut grooves (D D) ½in. deep, radial from the centre of the wheel, and at a distance apart, equal to the intended length of the segment of core; a 6th, 10th, or 12th of the circle, as the case may be. Into these grooves drop distance pieces of the width necessary to keep the sides at their proper distance apart—that is, equal to the thickness of the print. Then fit a couple of blocks (E E) between these sides and ends, parted longitudinally down the centre of the box. Work their edges F to the same radius as the rim of the wheel, then mark on their ends the rim section. Cut out the groove thus marked with templet very truly, so that when the cores are made and laid end to end, they shall correspond neatly, and not show a lapping joint in the casting. When worked, replace the pieces in position, and screw them, one to each side of the box. It only remains to put on the bosses for the arms, and to make the central boss with its prints precisely as in the case of a flywheel with wrought-iron arms.

Where the arms are strutted to give rigidity to the wheel, the bosses on the rim have to be bevelled alternately in opposite directions, and the prints on the central boss bevelled in like manner. These latter, too, in a strutted wheel should be *pocket* prints, and not round ones; for round prints would necessitate two joints in the body of the boss, coinciding with the centres of the prints, while with pocket prints the joint on the top face of the boss is alone required.

There is yet a common way of making a large sheave wheel without a pattern at all. A glance at the sketch (Fig. 93) will indicate the method to which I allude. The light portion is the wheel rim in section—the dotted parts indicate two cores, one outer (A), one inner (B), forming outside and inside of rim respectively. It is seen that these cores are jointed at B B. Of course the joint must be a curved one—both cores being worked to the same radius. The outer edges of the cores (C C) need not be curved at all, because they form no part of the wheel. Give sufficient sand there, say two or three inches in the narrowest part, and some lesser amount, say 1in. to 1¼in. at the sides.

To make these boxes, proceed thus—Frame sides and ends together for each respectively. Their ends must converge to the wheel centre, and must either cut through the centre of an arm boss or midway between two bosses. Thus, if the wheel have eight arms, there must be either eight or sixteen cores. Assuming there are eight cores, we have a half-boss at each end of the inside box. The boxes must be equal to each other in width, which will include width of rim and of two sand joints. Then blocks will be fitted between these boxes, as in the last example, those forming the wheel *groove* will be worked out by templet to the shape indicated in Fig. 94, The general principle of "telpherage" traffic is to send an almost continuous stream of small weights along a light, cheap line, instead of (as in railway traffic) sending a few large weights along a heavy and expensive line. This stream can be regulated by an automatic blocking system operated by means of two or more light telegraph wires run from post to post. The effect of this system is to check a following train if it approaches a preceding one too closely; maintenance is reduced to a minimum, whilst the automatic character of the whole system reduces the attendance necessary for the good working of the line to the engineroom, and the points of loading and unloading, as no driver or guard is required on the trains themselves.

To the uninstructed spectator the electric locomotive appeared to set itself in motion and drag its train along without any controlling power. It was in fact started from the engine-room or testing-room in the farmhouse. The locomotive consisted of a small electric motor about a foot long and six inches in diameter. This, on being brought into connection with the electric current, which was generated by a dynamo machine driven by a steam engine in a shed, revolved with great rapidity, and communicated its motion to a simple wheel, which in its turn caused two wheels, which gripped the wire rope, to revolve, and thus pulled along the train. The train itself consisted of cradles suspended on the wire rope, which was supported on rough posts, and each cradle would, perhaps, carry 100 or 200lb. weight. The wire rope on the posts serves both to carry the train and to conduct the electric power, which can be taken off at any point along the line and applied to other purposes than that of moving a train. This was illustrated by a small electric motor fixed to one of the posts at a distant point. This motor, having a current of electricity drawn from the overhead rope sent through it, easily worked a cake crusher, thus showing that it may some day be possible for the farmer to turn machines in the sheepfold and at other points of the farm, and even to plough his land, by power generated at the homestead and conveyed by a simple wire to any point where it may be wanted.

PAPER BOATS.

WE mentioned some little time ago that the Westinghouse Company had been making experiments with a launch made of paper, the object being to provide a light boat, bullet proof, and capable of carrying the new high-speed engines designed by Mr. G. Westinghouse. Some years ago Brown, the sculler, came over here with a wager-boat made of paper, and when Hanlan paid his first visit to the Tyne he also brought a paper "shell," and practised in it on the river, but neither Brown nor Hanlan thought enough of the devices to pit them against the usual cedar boats in a rowing match. The paper "shells" we need scarcely say are an American invention, the original patent being granted to Messrs. E. and G. A. Waters on June 30, 1868; but though they do not appear to have been a success, owing to the fact that the necessary strengthening timbers made them heavier than the modern racing boats, paper has been used with some satisfaction in the construction of skiffs and canoes. We glean much of the following information from the *Paper World*, of Holyoke, Mass. — A wooden model is prepared in exact form of the desired boat, on which the paper skin is moulded, sheet after sheet being superposed one upon another until the desired thickness is obtained, the boat which we saw in process of construction being composed of nine thicknesses of strong Manilla paper, making a thickness of about ⅛in. In preparing the paper the lines of the boat are carefully drawn out to its full size, and the paper which comes from the mill in rolls, similar to that which is made for printing on perfecting presses, is cut to the full size desired for covering the entire length and breadth of the boat, so as to leave no joint or seam, or perforation of any kind. For racing shells the best Manilla paper is used, but for gigs, dingeys, canoes, and skiffs, paper made from unbleached linen stock only is used. In manufacturing the racing shells, the first sheet is dampened, laid smoothly on the model, and securely fastened in place by tacking it to certain rough strips attached to its upper face. Other sheets are now superposed on this and on each other and suitably cemented together, the number depending upon the size of the boat and the stiffness required. If linen paper is used, but one sheet is employed, of such weight and dimensions that, when dry, it will give just the thickness of skin necessary. Should the surface of the model be broken in parts, as in the case of boats with square sterns, for instance, the paper is made to conform to these contours by suitable concave moulds, which also hold the paper in place until, by drying, it has taken and will retain the desired form. The model, with its enveloping coat of paper, is now removed to the drying room. As the paper skin dries all wrinkles disappear, and it gradually assumes the exact shape. Finally, when all moisture has been evaporated, it is taken from the mould, an exact *fac simile* of the model desired, exceedingly stiff, perfectly symmetrical, and seamless. When the skin is removed, the boat, as it then appears, is waterproofed, the frame and fittings completed, and the boat varnished. The advantages possessed by these boats over those constructed of wood are strength, stiffness, durability, and being without joint, lap, or seam, to admit of leaking by strain or shrinkage; they have no grain to crack or split, never shrink, and, paper being one of the best non-conductors, no ordinary degree of heat or cold affects them, thus rendering them admirably adapted for use in any and all climates.

The crowning glory of the paper boatbuilding business by Messrs. Waters and Sons, although an experiment, bids fair to be as successful as have been their efforts in the building of racing shells, canoes, and the like. This experiment is the construction of a steam launch or pleasure yacht, to be propelled by one of the celebrated Westinghouse steam engines, built at Pittsburg, Pa., where the boat is now lying for the purpose of receiving its engine and accompanying equipments. This is built of different material, and the method of construction is also different from that of the smaller boats. Unlike them the entire skin constituting the boat is formed the full size of the launch—it being twenty-five feet in length, necessitating the making of the skin in two halves, which are joined together on the keel. For this purpose two moulds, each representing one-half of the proposed paper launch, running length-wise, are built by logging up layers of clean pine. On building the two moulds for this launch, upwards of 3,000ft. of timber was used, in order to give great solidity to resist the tremendous pressure of the shrinkage of the paper. When these moulds are worked off to the exact lines required, the sharp edges are protected with ⅛in. boiler iron, which completes the moulds ready for the paper. This paper, which is made by Messrs. Crane Brothers, of Westfield, Mass., comes from the mill in one wet sheet of the required shape about ⅜in. in thickness afterwards drying to $\frac{3}{16}$in. The sheet is enough larger than the mould to admit of turning over the edges, where they are screwed and clamped to resist the process of drying. A flange is turned over the edge of the inner face, extending its whole length, by which flange, when the hull is completed, the two halves are bolted together. When this first layer of paper is dried to the required form, it is coated with asphalte, and another similar layer attached to the first, making the total thickness of the skins ⅜in. When these skins are taken from the moulds they are the perfectly-formed halves of the launch. These two halves are attached to the two halves of the keel, which is made of wood, and all firmly bolted together throughout the length of the keel, and the seam is subsequently made tight by the usual process of caulking. The tube for the shaft is cut through the wood only, and is cut in either half before putting together on the line necessary to connect with the engine. When these two halves of the hull are bolted together along the keel, the gunwales and deadwood are put in and attached to the keel, and the hull is complete. Ribs necessary to carry boiler, engine flooring, &c., are then put in, being suspended from the gunwales and resting on the keel, not, however, in contact with the paper. The finish consists in smoothing off the paper, which admits of a polish equal to the finest cabinet work, oiling and drying in hot kilns and painting in colours to suit the taste. Experiments have demonstrated that this paper, even with the paint entirely worn off from it, and if possible torn and gouged into, so that a mere layer of the thickness of a sheet remains, will still resist the action of the water.

The Westinghouse Engine Co. having made a special application of their engine for marine purposes, for which it seems peculiarly adapted, have built a number of boats this season which have proved to be very fast, and have also made a number of heavy engines for towing and pleasure steamers, and their success in this line has induced them to try the experiment of having paper boats constructed in which to introduce and use their steam engine, which, although of comparatively recent introduction to the mechanical world, has already won for itself an established place in the front rank of the many steam motors now in successful operation.

NEW METHOD OF INSULATING TELEGRAPH WIRES.*

HAVING had occasion for a year to apply, for the decoration of articles of jewellery, the procedures pointed out by Nobili and Becquerel for obtaining coloration by means of baths of alkaline plumbates and ferrates, I observed that the articles thus coloured became absolutely proof against all galvanic action: that is, their surfaces, when once coated with peroxide of lead or of iron, were insulated, and no longer conducted the electric current. A wire of copper, brass, or even iron, may thus be coated with an insulating layer like a stratum of resin or guttapercha. This principle, I believe, admits of easy utilisation in preparing wires and cables for use in telephony and telegraphy. The method of obtaining this insulating stratum is, from an industrial point of view, very practicable, and the cost trifling. The hardness of this coating, which resists all atmospheric action, is a guarantee of its durability. The insulation is absolute. The method of preparation is very simple. A bath of plumbate of potash is prepared by dissolving 10 parts of litharge in 1,000 parts of water, to which have been added 200 parts of caustic potash, and boiled for about half an hour. It is allowed to settle, decanted, and is then ready for use. The wire to be coated with peroxide of lead is attached to the positive pole and a small platinum anode to the negative. Finely-divided metallic lead is precipitated upon the negative pole, and the wire is coated with peroxide of lead, which passes successively through all the colours of the spectrum. The insulation is complete when it takes a brownish-black colour. The wire thus covered is perfectly insensible to electric action. Articles perfectly cleaned may be attached to it, and connected with the negative pole of a gilding, silvering, or nickeling bath without the current, however powerful, producing any action upon the objects to be coated. Such a wire, if placed in a circuit, and brought in contact with another wire in connection with a galvanometer, leaves the latter entirely unaffected.

LIVE DUST.

ONE of a series of "Lectures to the People," given under the auspices of the Yorkshire College, was delivered at the Philosophical Hall, Leeds, by Professor Miall, last Monday, the subject being "Live Dust." Professor Miall commenced by referring to the mode of collecting dust for examination, especially dust floating in the air. A glass slip smeared with glycerine had been extensively used for the purpose of collecting the dust; but this method was open to the objection that all germs were killed by the glycerine, and that the volume of air which had yielded the dust could not be measured. Water shaken up in a large flask of air had been used to separate the dust, but by this means a sufficient volume of air could not be examined without using a vessel of inconvenient size. Atmospheric moisture, condensed upon the surface of a vessel cooled by ice, had been collected and examined. The modern instrument for passing a measured current of air through a fine jet, and scrupulously collecting all the dust which it contains, was described in detail, and illustrated by means of lantern slides. Proceeding to point out the various kinds of dust found in the atmosphere, the lecturer spoke of volcanic dust, minute particles of magnetic iron (believed to be microscopic meteorites), the dead organic matter which forms a large proportion of common dust, and living organic dust. Of the last named the chief constituents are pollen, spores of moulds and mildews, and bacteria. The bacteria, he observed, were of special interest from their connection with putrefaction and with certain deadly diseases. It was shown long ago by Schwann that bacteria were indispensable to putrefaction, and that the most unstable organic fluid would not putrefy unless living bacteria obtained access to it. This demonstration ultimately led to Lister's antiseptic surgery. The life-history of some common bacteria was described, and an account given of the way in which a necessary connection between particular forms of bacteria and infectious fevers had been ascertained. The great number of bacteria everywhere present in the air made us feel that we were assailed by the germs of disease at every point. But two or three practical considerations might be shown to greatly diminish the risk. In the first place, the bacteria of disease formed only an insignificant proportion of the whole number of living germs present in the air; further, a great number of the bacteria of all kinds were dead, not more than one-twentieth being capable of germination in a suitable fluid; and lastly, the putrefactive and other less dangerous bacteria were very prone to get the upper hand of the more special and delicate organisms which constituted the germs of infectious disease. Practical remedies with regard to the dangerous forms of dust were explained, the principle of these being the use of antiseptic substances, the removal from the neighbourhood of large towns of dangerous trades such as created quantities of dust or involved putrefactive processes, the simplification of household furniture, and especially the doing away with any very elaborate woollen hangings in houses, the multiplication of grass spaces, improved cleanliness in streets, and complete detachment of the air of dwelling-houses from possible contamination with sewer gas. No public body and no individual who was careless about dust could possibly be careful about health; and he thought, [illegible]

---

*By M. C. Wiedemann in Comptes Rendus.

[illegible] notice of the work of the Selenographical Society has appeared in these columns, and that, like him, I regret the disappearance of selenographical matter from [illegible]. For this latter circumstance there may be two reasons, unnoticed by your able correspondent. In the first place, a large proportion of the matter was contributed by Mr. Birt. I am [illegible] that no contributions made in the "E. M." to this science, can be more valued by astronomers than the long series of papers and sketches which bore the signature of "C. Gaudibert", but these communications have become infrequent. A second reason may well be this—that much of what is now being published concerning selenography is so extremely technical as to be almost useless to those who are not furnished with a specialist's store of authorities. We cannot all be members of the Selenographical Society. We cannot all possess the works of Neison, Lohrmann, Beer and Madler, Schmidt; the "Selections," &c. In writing for specialists, selenographers cannot hope to be followed by those who are not specialists. But selenographical specialists are few in number. Again, there is a want of readily accessible direction as to what should be done. Valuable as they are, the "District Catalogues" in the *Astronomical Register*, are but unsatisfactory substitutes for "Telescopic Work for Moonlight Evenings," "Lunar Physics," and "Lunar Work." In thus neglecting to provide for the wants of observers less ambitious, or possessing smaller instruments, or commanding comparatively little time, selenographers are depriving themselves of much willing and valuable assistance. Concerning the specialisation of astronomical work, another remark may be made. In this most tantalising and tormenting climate it is [illegible] to limit ourselves to a single class of observation. For my own part, I know this, that I am compelled just to observe what I can see; there is very little use of my making up my mind to observe any given object on any given occasion. This circumstance is no doubt due in some measure to the locality of my point of observation in relation to the [illegible] part of this great manufacturing city. Mr. [illegible] recently remarked in "ours" upon the differences between different portions of the sky in the same evening. I can fully confirm what he said, and I always account for these differences on the assumption of drifting films of smoke. Anyone who does much in the way of estimating star magnitudes is bound, of course, to keep a look out for films and haze, wisps of smoke, or anything else which can tend to dim the light of the star under observation. So that, if I cannot observe one thing, I just observe another, and I think that [illegible]

[illegible]

found any fluctuation in the course of my own observations, I wrote to Mr. Proctor, who replied, "When I wrote that it had just been discovered that γ Cassiopeiæ is variable." Afterwards, I found γ Cassiopeiæ classed as a variable star, along with β Lyræ, in Roscoe's "Spectrum Analysis," edition 1869. My copy of "Spectroscope and its Work," is dated 1877. Neither Mr. Espin nor Mr. Franks can give me any information upon the subject; both these gentlemen knowing nothing of γ Cassiopeiæ as a variable star. I would much like information; perhaps Mr. Knott or Mr. Sadler can give it, or Mr. Baxendell. Mr. Proctor's word establishes that he had good grounds for his statement, but it is, nevertheless, singular that nothing can be found in the place where one naturally looks for information upon the variability of stars. Referring to the extract from Smyth's "Cycle," given by "F. R. A. S.," I must say that Sir John Herschel's words seem to me to have reference to the variability not of γ but of α Cassiopeiæ.

ϕ and χ Draconis.—I have reason to believe that one or other of these stars is variable, or (and more probably) that both are so. Last year they were practically equal, and about 3·9. This year they are separated by nearly one magnitude, χ being 3·7 and ϕ 4·4. On the 1st and 7th October χ was reckoned 3·6, on the 15th 3·7, and on the 21st again 3·6.

What a magnificent spectacle the sun has presented within the last week! On the 11th October I counted eleven great and complex groups, and there were, besides, several smaller single spots to be seen. We have had boisterous weather, and are now, in common with the rest of the country, having a heavy gale. I suppose the sunspot meteorologists would connect these facts; but I do not know what to think, having failed, in my reading of the newspapers, to find any accounts of that succession of desolating hurricanes with which, were the theories referred to absolutely and universally true, the world must have, considering the stupendous disturbances which during its course have taken place upon the sun, this year been visited. In saying this, I assume that effects are to be expected to be proportioned to causes. Perhaps Prof. Archibald or Mr. Westwood Oliver will give us some information upon the phenomena of *general* meteorological change within the past six or eight months. I ask in no carping or sarcastic mood, but in a spirit of impartial inquiry. I have no belief in the extremist doctrines held upon this matter, but am desirous of obtaining information which will throw light upon the more moderate ones. Did any consequences follow upon the tremendous and magnificent phenomena exhibited during June and September which were in any degree proportionate to their magnitude?

Saturn is a splendid object in the telescope at present. On the 23rd, about 14h., the air being pretty clear, and definition at intervals very good, I had a beautiful sight of it. Ball's division was visible, by snatches, all round; and the Crape-ring could be seen where it crossed the disc. The rings were a fine yellow. The equatorial zone of the planet was a pale whitish yellow. The principal belt was seen to have a very decided edge on the northern border, and to be of a pale cinnamon. To south of that was a paler zone; and to south of this, again, another dusky belt, its duskiest portion in the centre. I suspected that between this and the polar regions there was another whitish belt, and that it was ill-defined. This morning (26th October) about 2 a.m., conditions fairly good, I noticed that a portion of the chief belt seemed to be darker than the rest, and to have something of the appearance of a dusky spot. Observing Jupiter, between five and half-past five, I observed the brilliant equatorial spot. It was distinctly brighter than any other part of the disc; and roughly, though not quite, on the following side circular. It was preceded by a projection northward from the southern equatorial belt, which was distinctly the darkest marking visible. I used a 3¼in. achromatic (o.g. by Wray), power 145. Mars is in Præsepe—an exquisite sight.

I enclose two lunar sketches, pencil copies from views taken at the telescope. One is of the Mare Crisium, and was made upon the 18th; A is a small bright mountain which cast a short pointed shadow. It is, it appears, the centre from which one of the smaller ray systems which compose the ray system of Proclus issues. (Has anything been done recently with regard to the ray system of Proclus?) B points out two curious ridges. It will be observed that they do not run in a north and south direction, and are not parallel to the mountain border. They are distinct, but have the appearance of inclosing a space. C is the ridge east of Picard. D was a crater and very bright. E was a crater: it appeared, from the shadow which it cast upon the mountain ridge, to have a peak upon its south-western corner. The other is a sketch of Plato, and was taken about 17 hours on the 23rd. It is interesting, as showing the spots 1 and 17 as cones. Had the air been better, I have little doubt that I could have made out more detail upon the floor, for I seemed repeatedly to glimpse other markings. Considering what is said as to their delicacy, the cones were very easy—obvious, indeed, they were—with the 3¼in. The power used was 145. Is A a cleft or a valley? I suppose B is Schröter's χ.

S. Maitland Baird Gemmill.

Glasgow, Oct. 26.

P.S.—I observe in the reply on p. 225, that Ursæ Majoris has been printed for δ Ursæ Majoris.

JUPITER'S RED SPOT.

[22037.]—It may interest your readers to know that on Friday morning, Nov. 9th, at 4.30 a.m., I was tempted out by the sight of a clear sky to have a look at Jupiter, and found the great red spot about an hour past the central meridian; but I was surprised to see that its *form* and colour remain much as they were last April, when I took my last sketches of this object. The red spot is still partly imbedded in the southern equatoral belt, and the colour has certainly not faded since last April, being still of a light pink, and very discernible. My great aperture (18¼in.) will account for the ease with which I see this remarkable object, but it certainly would be visible in much smaller instruments. I mention this because, if I am not mistaken, it has been reported as being now quite invisible.

Jevon J. Muschamp Perry.

St. Paul's Vicarage, Alnwick.

JUPITER, MARS, SATURN.

[22038.]—Although for many days past here on the Dorset Hills, some 700ft. above the sea level, we have been more or less enveloped in mist and clouds, yet there have been a few hours of magnificent observing weather. On the morning of Oct. 26th, from 5 to 6 the mist lifted a little, and I had a splendid view of Jupiter and also (for the first time this season) of Mars. The snow at the North Pole was plainly visible, and also some dusky marking between it and the equator. Powers used—300, 500, and 600, on an 8½ Calver mirror. This planet will now evidently repay the trouble of observation after midnight.

On Oct. 28 the sky was for a while clear, and I saw the comet Pons; there seemed a bright nucleus with a diffused nebulosity round it; but Nov. 1, from 9.30 p.m. to 12 p.m. was the best night for definition we have had for some months. γ^2 Andromedæ was decidedly elongated with a power of 600, and Saturn, even with this high power, was sharp, clear, and steady. Cassini's division was a sharp, dark line, almost meeting above the planet's ball. The shading on the middle ring towards the crape ring was beautifully seen—the crape ring a lovely object. Encke's division, I am almost sure, I saw in the midst of the delicate shading of the outer ring; and the wavy edge of the upper side of the bright equatorial belt was well seen. The shadow of the planet on the ring seemed to terminate abruptly at Cassini's division. I tried several powers, and the beautiful definition (even with the highest) speaks volumes for the perfection of the mirror and the steadiness of the air. Clouds, however, unfortunately came up before Jupiter had risen above trees to the east of my observatory, and since then observation has been out of the question.

Shaftesbury, November 5.

DELTA CYGNI.

[22039.]—Mr. Holmes (p. 192, No. 971) asks whether "J. C. R." is sure he perfectly divided δ Cygni with 4½in. aperture. In reply, I beg to say that star was clearly divided with my 4½in. equatorial refractor on the 13th Oct. (moon 12·6 days old), by Mr. J. C. Ryan, myself, and a friend who is quite unaccustomed to astronomical observation. I have also perfectly divided it on a dark clear night, although I had understood that twilight or the moon was necessary to divorce it. The green companion was remarkable by its brilliancy and great contrast with the orange yellow primary.

Lake, Sandown, I. of W. **Wm. Binns.**

EQUATORIAL STANDS.

[22040.]—The suggestion of "Vigilans" is a good one. There are no doubt many mechanical amateurs who would be quite able to make a plain yet efficient equatorial stand if they had a plan to go by, and detailed instructions for carrying it out: I have, therefore, made drawings to a fairly large scale of two stands, adding also certain variations which may be adopted, if preferred.

The first illustration, Fig 1, is intended to show how the ordinary "pillar and claw" form may be altered into an equatorial, while Figs. 2 and 3 are modifications of it. Fig. 4 is a different stand in many respects, though the arrangement of the declination axis is intended to resemble that in Fig. 1. Commencing with Fig. 1, it is intended to utilise the pillar of the ordinary stand by making it rotate on a strong fixed axis (preferably of steel), which axis is secured into the upper surface of the foot marked *a*. This foot is a circular block of brass forming the base of the whole, and itself secured to

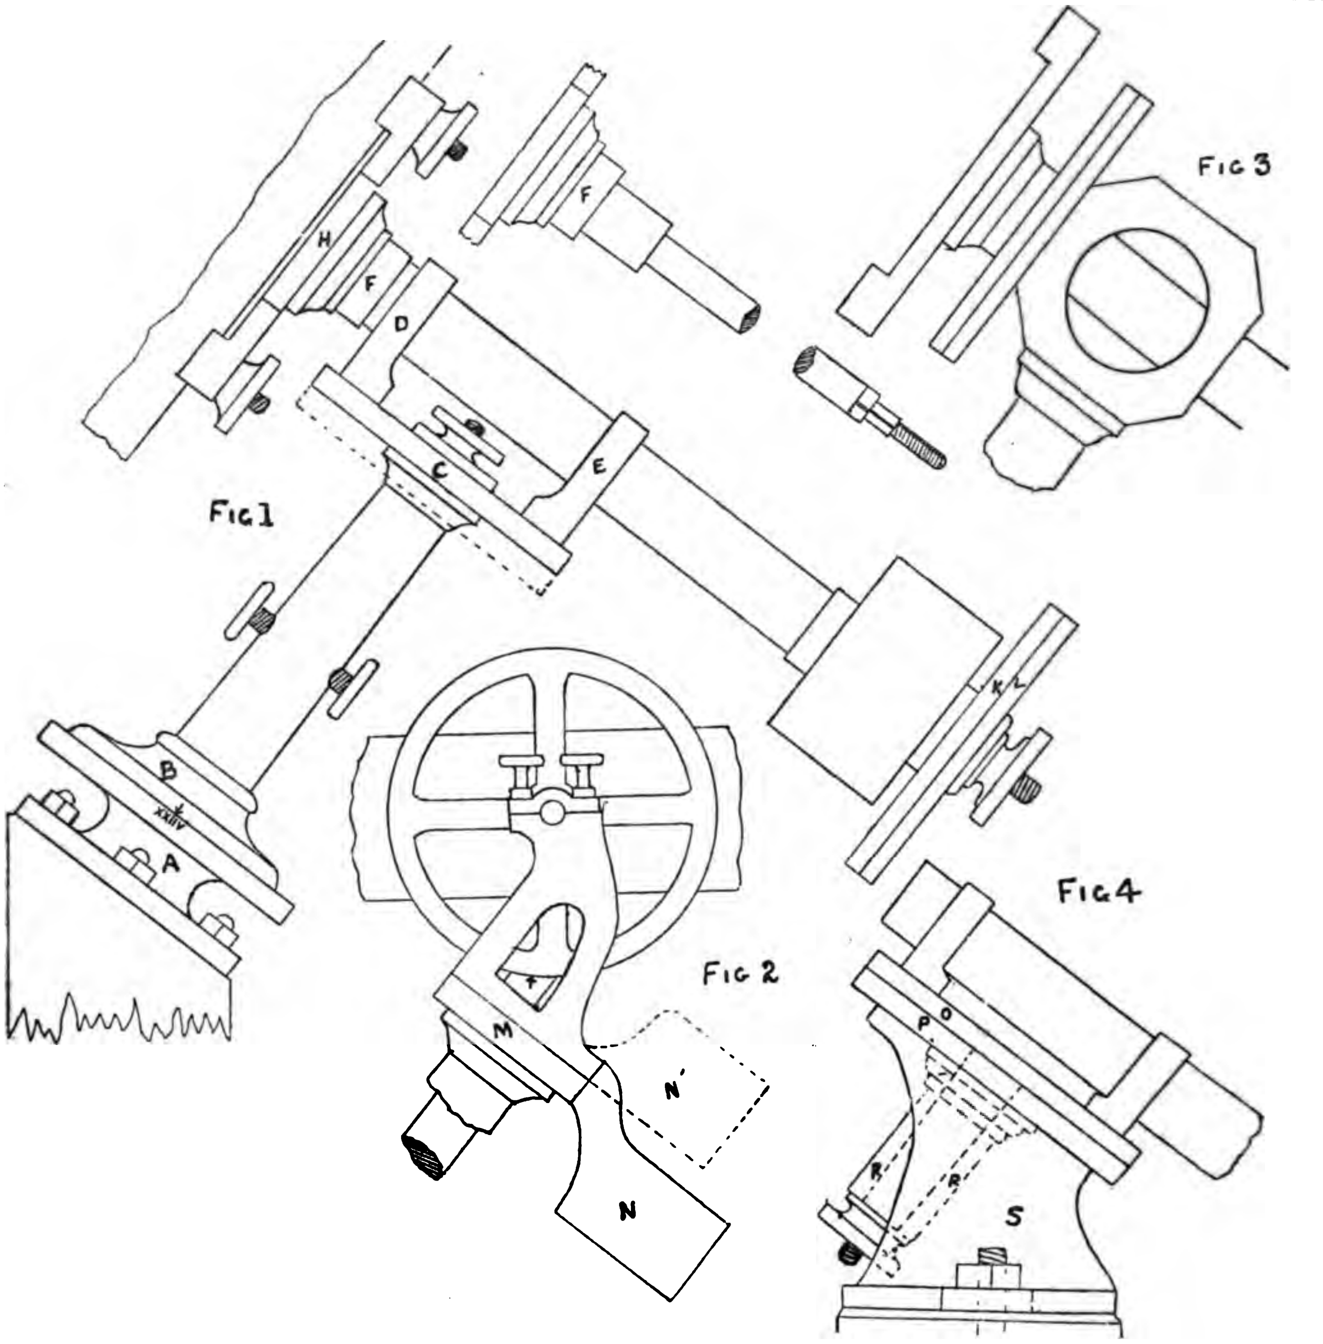

FIG 1

FIG 2

FIG 3

FIG 4

protractor, can be mounted on the *flat* of the disc instead of the strips round the edge; but it is less easy to manage. As regards the declination circle matters are less easily arranged, owing to the difference in value of a minute of arc, which, being the $\frac{1}{60}$th of a degree instead of $\frac{1}{4}$, is an extremely minute fraction of the circumference. For this reason it is usual to make the declination circle larger than the hour circle, the minutes being read off by a vernier, which is also used in better-class instruments for the accurate subdivision of the minutes of time. It is, of course, a question for the amateur to decide for himself *how* large his hour and declination circles shall be; but they should not be *less* than those shown in the drawings. I have before me a protractor divided to ½ degrees, but the marking is eye-straining to follow. The diameter is about 5¾in., so I consider 6in. or 6½in. the smallest that can readily be used without a vernier and magnifier.

Recurring to the hour circle, I may explain that it is not *necessary* to divide the circumference into degrees: it will suffice to divide it into the 24 hours *only*, if we have a corresponding arc divided into degrees, the length of such arc being equal to that between two hour divisions on the hour circle. This arc may be on the fixed or on the movable disc, according as the hour circle itself is movable or fixed. Suppose the degrees are marked 4, 8, 12, and so on up to 60: then when (say) the hour line X. is opposite the 0, or zero, degree, the reading is Xh. At the first degree the reading is Xh. 4m.; at the second degree Xh. 8m., and so on till the X. hour line coincides with the degree marked 60, when the XI. hour line will coincide with the 0, and read XIh. 0m. Thus, with 24 divisions of the hour circle, *and a short length (only $\frac{1}{24}$ of the circumference)* divided into degrees, we get as complete readings as if the whole circle were divided into degrees. I believe this to be novel (at least I have never seen it proposed before), and it will save amateurs trouble and expense. The same principle is applicable to the declination circle; but for this I think the complete division into degrees and the reading off of the minutes (or 10-minute intervals) by an ordinary vernier is best.

Let us, then, try and tackle this graduation business once for all. An amateur is not wont to be beaten if his heart is in his work, but this is certainly a tedious and difficult job. I have made divers trials with compasses and "stepping," also by repeated bisections; but even with delicate instruments and extreme care I have never succeeded in satisfying myself, and cannot recommend the method.

Another way is to purchase a cardboard protractor, cement it down on the plate to be divided, and then with a straight-edge and fine graver mark off the divisions. This is fairly accurate if care be taken to get the centres of the protractor and disc coincident, and to hold the graver always in the same position. A diamond may be used instead of the graver; but the lines come out very fine—more like scratches.

I have seen a disc in which the divisions were etched in by acid, the original dividing being cut through a thin film of etcher's wax. The result was bad in every way: ragged, coarse lines and irregular spacing. The best way I believe to be this: There is sold at the Ordnance Survey publishing office a very large circular protractor (I think about 15in. or 18in. diameter, but I have not used one for some years), engraved on very stout millboard (or rather cardboard). This is to be securely fastened to a flat board, and a circle marked on it concentric with the graduation, and of a *slightly* larger diameter than the disc to be divided. This circular centrepiece is then to be cut cleanly out with a proper cardboard cutter, fixed, if preferred, in a strip of wood pivoted on a stout pin.

The disc to be divided is then dropped into the central hole. If the disc is thicker than the protractor, the latter must be packed up on a ring of card or thin wood, or *vice versâ* if it is thinner, the essential condition being that the face of the protractor shall be flush with the surface of the disc. Two fine silk threads are next stretched across (forming two diameters at right angles to each other) from 90° to 270° and from 0° to 180° and the centre of the disc adjusted to their intersection. The disc is then secured in position by three slender wood screws—an operation requiring much care to avoid shifting the disc.

We may next strike with fine pointed compasses two or more parallel circles to determine the length of the hour and minute lines; also of twenty minutes or half-hour lines, if intended to be specially marked, which they should be.

We next require an accurate steel straight-edge of a length to reach entirely across the protractor. Against this is slid to and fro a little block of boxwood, or brass, carrying the point of a graver (like a miniature plane, in fact) to cut the division marks.

The graver point will evidently be removed a short distance from the edge of the straight-edge, and would, therefore, cut a line parallel to, instead of coincident with, this latter. It is, therefore, necessary to attach to the straight-edge, at the part where it lies over the graduations of the protractor, two narrow strips of boxwood or brass of the exact width that the *centre of the graver* is removed from the edge of the straight-edge.

It now only remains to place these strips to coincide successively with the divisions of the protractor, and then cut in the mark on the disc with the sliding graver point. If an inner and outer ring be marked to show where to move the graver *block* up to, in order to arrest the graver *point* at the proper places, the lines will be cut of even length, which makes the work look far better than if this is neglected.

This method is only applicable for dividing a flat surface; for an edge or rim divided circle I know no easier (or, for an amateur better) way than to divide by a scale and compasses a strip of brass, and either use that as the actual graduation, lapping it round and fixing it to the edge of the disc, or using it in a similar way to mark the edge of the disc itself. It is easiest to use a disc whose circumference is an exact number of inches, as in the case of the hour circle with the cardboard scale round its rim. Many circles are bevel-edged; but I know of no way of dividing these suitable for an amateur.

The next section will deal with slow-motion arrangements and clamps, and this will bring me to the end of the constructive details, and leave only the fixing to be dealt with. **A. S. L.**

TO MR. BRASHEAR AND "BOW."

[22041.]—Mr. Brashear has my best thanks for the information given on the heliostat mirrors. I always read his letters to the "E. M." with the greatest pleasure, and am glad to find that my *short* and very simple essays afford him some instruction and pleasure too. I wish I had time to be more extensive; I, however, do what I am able, and am well supported by my two fellow writers. Theoretically and practically, I am sure that Mr. Wassell and Mr. Bradbury are doing much towards the enlightenment of us all. Mr. Wassell's experiences and painstaking in watching for and reducing to figures every detail, cannot be too much valued. It is a work that no practical optician has time for who has hard business to push through, and yet it is needed to insure progress. Mr. Bradbury's essays are very complete compared with all I have seen; I am astonished at the perseverance and determination displayed by that gentleman, for I know something of the difficulties in the way of anyone employed in such a search as his has been.

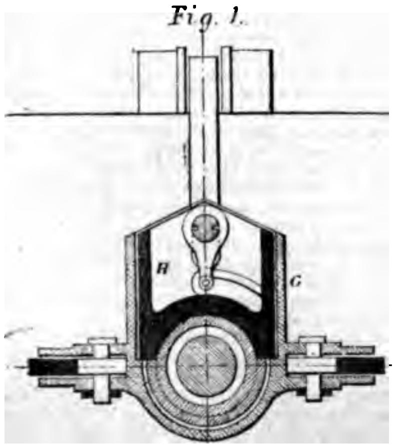
I hope "Bow" will not think me thin-skinned, or that my feelings were (h)arrowed (no pun). I hope we shall not come to that in the "E. M."

That which "Bow" states was certainly the case —viz., that there was not much trouble taken about the form of the curves so long as the complete o.g. was up to the mark. In looking back, say, 20 years, I can see how very much the old workers must have depended upon chance. Of course, it was never the practice to have a stock of *large* o.g. lenses. One pair was worked upon until a satisfactory result was obtained. I am prepared to say that all opticians use as a basis theoretical curves, *very much* modified by practical experience. As to practice and theory being jealous of each other, I really must differ with "Bow." I do not think there can exist a closer friendship. I did not intend unfairness to Newton; still, his experiments must have led him to theorise. I reverence the great name of Newton. **Prismatique.**

THE PARKER-SMITH BRAKE.

[22042.]—Several correspondents having lately expressed a desire that I should illustrate my Automatic Screw Brake in your valuable journal, I have now much pleasure in sending you some small drawings and a rough description.

Fig. 1.



SECTION THROUGH PART NUT

On one axle of each vehicle is mounted a screwed sleeve, formed in two halves, which are bolted together: this sleeve does not touch the axle, but rests on two bearings as shown, Fig. 1. A part-nut (H) is contained in a cast-iron box, G, and is raised and lowered so as to engage with, and be disengaged from, the screwed sleeve by means of a cam arm and spindle. A friction cone C D (Fig. 2), when forced together by a cast-iron ring of metal, A, on one side of which are inclined planes acting against inclined planes, joined on the side of frame, causes the screwed sleeve to revolve with the axle. The force with which the screwed sleeve revolves depends on the downward pressure applied to a lever projecting from the ring. The travel of the part-nut in either direction spreads abroad the arms I I, (Fig. 3), and pulls the brake blocks against the wheels.

Fig 2.

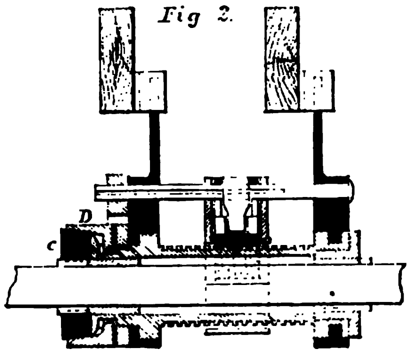


Fig. 3.

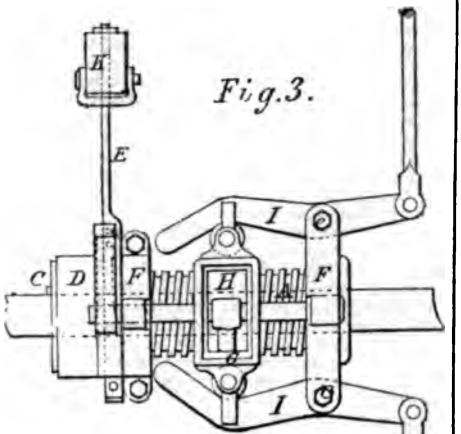

Fig. 4.

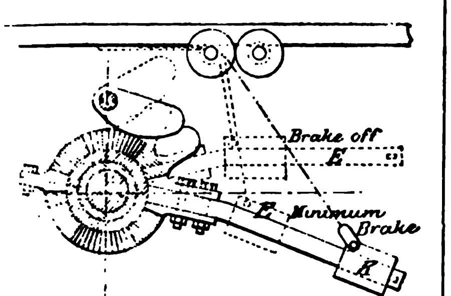

Fig. 5.

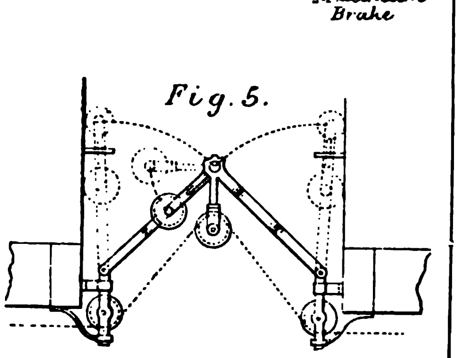

The action of the apparatus is as follows:— When the lever is held up to its higher position, the part-nut is clear of the screwed sleeve, and the friction cones are not in contact. When the lever E (Fig. 4) is permitted to descend to its lower position, the part-nut engages with the screwed sleeve. In this position if the weight K is permitted to slide down the lever, friction is produced in the cones, and the screwed sleeve revolves, causing the part-nut to travel either to the right or to the left, according to the direction the vehicle is travelling, thus making the side levers put on the brake as before described. As soon as the desired braking power is obtained, the weight is hauled up along the lever, thus removing the friction between the cones; the brake remains *on with the apparatus at rest*.

To take off the brake the lever is lifted to its higher position, which by means of the spindle and cam, lifts the part-nut clear off the thread, and it springs back to its central position on the screwed sleeve by the tension of the brake rods.

Fig. 5 shows the method used for connecting the brakes together, so as to use them as a continuous brake.

By this arrangement there is no movement in the continuous connections due to vibration in the length of train, height of carriages, &c., for it will be seen that the movement of the vehicle merely alters the angle formed by the three pulleys, and, like a pair of compasses, altering the angle does not alter the length. This has been the great difficulty with all continuous connections hitherto, and I may safely say that the arrangement I have designed effectually disposes of this difficulty.

It will be seen that this arrangement secures simultaneous action, and braking power throughout the train, for whatever length of chain is let out by the engine-driver, each weight along the train immediately descends the same distance, and produces equal effect on the apparatus it controls. The weights I am using are 10lb., and this is ample for a 12-ton vehicle at high speed, the power of the apparatus being so great.

I was led to design this brake after many years' experience on railways, and opportunities of witnessing the many defects of air and vacuum systems, and noticing that all fluid systems were supplemented by a mechanical screw brake, I came to the conclusion that if this mechanical screw brake, on which so much reliance is placed, and with which failure is unknown, could be made continuous, a powerful, reliable, and cheap brake would be at once obtained.

W. Parker-Smith.

MICROSCOPIC MOUNTING.—III.

Resinous and Air Mounting.

[22043.]—Here we have to describe (I.) the appliances, (II.) the materials, and (III.) the process of mounting.

I. *Appliances for all mounting.* These are:—

1. A *spirit lamp*, or a *Bunsen burner*. Ordinary lamps, candles, or gas unmixed with air give a smoky flame, which may spoil slides; the spirit lamp need not be a large one. For ordinary purposes the flame should be very low; it may be stoked up and down with a mounting needle.

2. Two or more *mounting needles*, which are stout needles broken short, and shafted into old wooden penholders, from which they project about 1in. or rather less. The hole may be made with the point of the needle, the broken end being afterwards firmly cemented into it, *e.g.*, with a glass cement, or with gold size. They are cleaned, as often as used, with pure water, or, if they have touched Canada balsam or other resinous substances, by putting them into the flame of the spirit lamp till it burns blue again.

3. *Glass tubing* of soft glass, and ¼ or ⅜in. external diameter (rather larger for dipping tubes). By putting a tube across the spirit-lamp flame, and drawing it out as it softens with the heat, dipping tubes, stirring rods, a rod for Canada balsam, and capillary tubes or tubes with fine rods or capillaries for endings, may easily be made. To close the end of a tube, and so make a rod, hold the end of the tube in the lamp, work it close with another, and heat well. To smooth a sharp end so that it will not cut the lips, hold in the lamp, and, if necessary, work with the end of another tube (or with a mounting needle to keep it open), cut into convenient lengths (say, 4in. for a Canada Balsam tube, or 8in. for a dipping tube), with a rat-tail file, or simply draw out in the lamp, and break.

4. *For Dissecting.*—One pair of *steel forceps*, 4in. long, with *rounded* points $\frac{1}{12}$in. broad or less, grooved internally so as to hold better, coming into contact with little pressure (2oz. or so). There should be no stud near the object end fitting into a hole; but the blades ought to be broad to prevent overlapping. One pair of small *elbow scissors*, with one of the points very fine. Two *holders*, like crochet-needle holders, for dissecting needles, which are stout short needles, ground so as to have three sides, the point being sharp, and the angles formed by the three sides capable of effecting a certain amount of cutting (glovers' needles). Small knives

may also be made of needles shafted into penholders, and then ground. Two or more knives, shaped like scalpels, with blades 1in. or so long. A similar knife, with a blade *very much curved [illegible]ward*, for cutting down on glass, or wood, or cork, to cut sections into shape, &c. For the dissection of larger objects there is nothing better than an ordinary medical student's dissecting case, with three scalpels, a pair of straight scissors, a larger pair of forceps than that described above, a blowtube, and a chain for holding objects, or, better, some dissecting pegs. A number of different kinds of fancy knives are sold; but the only other kind which will be really useful is a small knife with a blade whose edge is a straight line, so that an object does not slip away from the point when cut down upon. But none of these things should be got before they are really wanted; and the pair of forceps first described are alone necessary for mere [illegible].

5. A pair of [illegible] scales, with weights from a grain to four drachms, capable of weighing two grains with tolerable accuracy. Weigh a grain or two of paper, cut it into equal portions, and see how the scales turn with small fractions. Get the seller to explain the marks on the weights. Keep the whole dry; and remember that it is safest to weigh on paper.

6. A measuring-glass, measuring from half a fluid drachm to a fluid ounce—if larger, the half-drachm mark will probably be grossly inaccurate. Test it when buying, by [illegible] drops measured in a large measure; and notice where [illegible] drops come to in your larger measure.

7. The following — [illegible] A deal board to lay on the table for working on. A newspaper may be first spread out double as additional protection. The board I use is [illegible] by [illegible] it need not, of course, be exactly of that size. Some [illegible] or other boards, to raise the board in the dissection, so as to bring the object nearer the eye without stooping. [illegible] A [illegible] and [illegible] for filtering. The latter may be got from a chemist (Swedish paper), or made of white blotting paper. The paper should be loosely doubled (i.e., the finger-nail should not be used to make it double very sharply, as it may then run into holes) into a half-circle, and this again doubled across into a quarter circle. Two pockets will then be left, into one or other of which the liquid to be filtered should be poured. If the liquid is [illegible], pass clean water through the filter [illegible] which it is always to get rid of the [illegible] and [illegible]

[illegible] camel's hair pencils, which have been [illegible] to be put into a glass of water [illegible] slides and covering glass [illegible] watch-glasses [illegible] and [illegible] which are most useful [illegible] reagents employed in preparing them [illegible] and for crystallising [illegible] well in so thin a layer as can be put on a slide without running. [illegible], cut from any glass by a glazier, large enough to cover the lids of the pots when the lids are turned upside down. These may be used when, in [illegible] with gold, it is necessary to act on the object by light. A small object, moreover, may be put on a pot or lid, with only a drop or two of fluid. It might be difficult to find it again if a larger quantity were used. Circles are the best [illegible] will cut them, on being given a lid to measure by. Have the tumblers with wide tops, so that they can be inverted over a lid with a [illegible], to protect from the great enemy, dust. Additional protection will be given if a bit of velvet is glued to the rim of the tumbler [illegible]. It will be well for the tumblers and [illegible] to be of the same pattern as those used in the house. Cold fish [illegible], small, containing a pint and a half or so of water, are also useful for keeping small animals in, but the *shape* is not so convenient as that of a wide-rimmed, flat-bottomed tumbler. [illegible] bottles, especially wide-mouthed bottles, and [illegible] especially if stoppered, [illegible] small boxes, in which [illegible] may be kept, and preserve pots [illegible] of the form [illegible] cylindrical, the top [illegible] the underneath part, so as to facilitate [illegible] small objects [illegible] *test tubes*, which ought to contain nearly a fluid ounce [illegible], an ounce [illegible] measuring glass), and may be covered with paper to protect them from dust when holding anything. [illegible] to stand them in, and holders to hold them by when used for boiling. [illegible] be made after being seen. In [illegible] test tubes, move [illegible] of the spirit lamp, so [illegible] the heat on one part of the glass. The outside must be quite dry, and so must [illegible] tubes with the lamp [illegible] If the liquid boiled does not boil [illegible] clean and introduced will [illegible] be cleaned with a [illegible] with cotton linen or [illegible] sold. (*h*) [illegible] of different [illegible] and strengths, [illegible] *employed for pressing down the [illegible] glass on the slip. They are sold at 1s6d. [illegible] the same [illegible] tubes), or may [illegible] after having been seen. They are better* without cork, which is apt to become messy from Canada balsam, &c. (*i*) A *cupboard* or *closet*, in which these and other things may be kept, having a lock to prevent their being interfered with, and a close-fitting door to help in excluding dust. But the microscope ought not to be kept in the same cupboard, and must not be exposed to the vapour or action of chemicals.

II.—*M[illegible] for Resinous Mounting.*—For the actual mounting itself, gum dammar, Canada balsam, or chloroform and Canada balsam will be required. Procure about an ounce and a half of Canada balsam in a wide-mouthed corked bottle of such a size that the balsam fills two-thirds or three-quarters of it. Canada balsam is a semi-fluid gum resin, composed of a turpentinous essential oil, which gives to it its peculiar fragrant odour, and of, at least, two resins, one of which dissolves in alcohol, while both are soluble in chloroform, ether, turpentine, benzene, oil of cloves, and many other substances. Water renders it opaque, and the bottle which contains it, and everything which touches it, ought, therefore, to be quite free from moisture. It should be perfectly transparent and free from dust or specks, and great care must be taken to keep it so, the bottle being kept covered with paper. It gradually dries and hardens by evaporation of its turpentinous constituent or constituents, and the resinous matter contracts, but remains transparent when in thin layers, though it becomes brittle. It is by this evaporation taking place at the edge of a covering glass that the balsam beneath the cover of a mounted slide hardens and permanently fixes the cover and the object in their place; and from the same cause balsam kept in a bottle becomes gradually stiffer and thicker. When first bought, therefore, it may be almost limpid, and it is then unsuitable for mounting, as although the actual process of mounting is easier, the subsequent drying and hardening of the slide are very slow and tedious. Heat renders it more liquid for the moment; but increasing the evaporation renders it afterwards harder and more tenacious, so that to stiffen it it may be left, with the cork loosely covering the bottle-mouth, in a warm but not dusty place, the bottle being carefully covered with paper to exclude dust. The harder it is, moreover, the greater is the amount of heat required to make it sufficiently liquid for mounting, and the more difficult is it to exclude air-bubbles. Many delicate objects will not bear heat, but curl, contract, or blacken under its influence; and the combined advantages of dispensing with heat, or with more than very moderate heat, and of having a mount which will solidify more quickly, may be secured by adding chloroform to a portion of stiff old Canada balsam liquefied by heat, adding till the mixture is, when cold, as thin as fine oil. This may be labelled "Canada balsam and choloroform," and ought to be kept in a stoppered bottle to prevent the evaporation of the chloroform. Both the Canada balsam bottle and the chloroform bottle should be wide mouthed (say, 1¼in.), so as to admit of the introduction, without risk of messing the inside of the bottle-neck, of a small glass rod, by which a drop may be taken out and conveyed to the slip in mounting. If the neck, cork, or stopper are messed they will be likely to stick; they may be loosed by warmth, with the addition, if necessary, of a little turpentine round the edge, wiping the turpentine carefully off again before taking out the stopper or cork, so as to prevent it from entering the bottle. It is well, in order to prevent small particles of the cork from becoming detached and getting into the balsam, to cover its sides and under surface with linen glued to it, and afterwards saturated with turpentine. The bottle should be carried upright, so as to prevent the contents from messing the sides, neck, cork, or stopper. Gum dammar, or dammar resin, Kauri or cowdie gum, the produce of an Australian tree, is prepared for microscopic use by picking out the best pieces, dissolving in benzole to an oily or syrupy consistency, and straining. The solution is also sold. It may be thinned with benzole, dries very rapidly, and is said to be apt to crack. Other gum resins, such as balsam of copaiba (which dries very slowly), solution of copal, &c., may also be employed: but for resinous mountings I would recommend anyone to stick to stiff old Canada balsam, and Canada balsam and chloroform, and to try other media only where those fail. New media are continually coming into use, and as constantly go out of use again. They may appear to succeed in the hands of their introducers, perhaps because they take special pains with them; but till they have been employed for many years, it is impossible to say how they will behave in the long run. They may preserve an object beautifully for a year or so, and then, gradually changing, ruin it.

In mounting anything resinously, *i.e.*, in Canada balsam, &c., it is necessary previously to deprive it of the water which it contains. To effect this it is in some cases sufficient to let it become perfectly dry by exposing it to the air, either freely or with crystals, and other inorganic objects, or between two slips, as the epidermis of a plant. But most substances, if "dehydrated," or deprived of their water by simply drying them in air, are spoilt, so that it is necessary to dehydrate by immersing them in a fluid which will subtract their water, and at the same time support their delicate structure, and fill out their parts to their original dimensions. After they have been cut into sections, stained, or otherwise prepared, the more delicate of the objects which it is intended to mount resinously are consequently immersed in methylated spirit, which is used in this country instead of rectified spirit, because of the Excise regulations. It costs tenpence or a shilling a pint, is indispensable to the microscopist, may be kept in a corked bottle, ought not to be allowed to touch any varnished surface, such as a polished table, and should be as strong as it can be procured, and free from dust or sediment. It is well, by the way, to tell any chemist, in buying anything of him for microscopic purposes, of the special use to which it is to be put, since a little moisture or dust in the bottle or the measure would be of no importance in the ordinary way of business. If the spirit has to be filtered, the filter, should it have been previously washed with water, ought, of course, to be allowed to become quite dry before used for it. Methylated spirit is employed, not only for dehydrating, but also for cleaning slides, for the lamp, for hardening objects which when fresh are too soft to cut into sections, to preserve specimens or parts of animals afterwards to be used microscopically, and as an ingredient in many recipes where, because of its cheapness, it is employed instead of rectified spirit.

But methylated spirit contains a certain amount of water, so that some other substance has to be used as a bridge between it and the balsam. Of these, ether, commonly called sulphuric ether, has no advantages except for removing air. It is expensive, and vaporises with extreme rapidity, so that the object is apt to be left dry. However, it is indispensable in microscopy as a solvent for removing and thus detecting the existence of fats and oils, which it dissolves with great rapidity when they are fairly exposed to its action. It should be purchased in small quantities of an ounce or so at a time, and kept in a closely stoppered bottle covered with parchment paper or washleather. Chloroform is another indispensable substance, but too dear to be used for completing dehydration: it is employed for killing small animals, for preventing putrefaction, and for making the Canada balsam and chloroform solution spoken of above. It slowly decomposes when not under water, even in the dark; may be kept in a corked, but better in a stoppered bottle: and, like the other reagents spoken of in this paragraph, must be perfectly free from water. This may be known by the absence of water-globules and of dulness of the fluid. Benzole is more active than turpentine in cleaning Canada balsam away, and, as it evaporates more quickly, is preferable for varnishes; but it is very inflammable, has an abominable smell, and is more expensive than turpentine. It is variously called benzole, benzol, benzine, and benzene, and is C_6H_6, a hydride of phenyl, usually impure, though its impurity does not seem to be of any microscopic importance. Turpentine (by which I mean not what is called "fat oil of turpentine," but ordinary turpentine or spirit of turpentine) is useful both for cleaning and for passing objects into from spirit before they enter Canada balsam. Like the other substances, it clears them or renders them more transparent: but it is apt to make them contract or curl up, which oil of cloves is not so likely to do; and though the latter is more expensive, much less of it is required, and it acts more rapidly.

III. *The Process of Resinous Mounting.*—Having selected the objects for mounting, clean them, and clean a few covering glasses as directed for slides, but more delicately. Take a fold of the clean old silk handerchief between the finger and thumb, and dry the covering glasses by inserting them in the fold, and rubbing them, using the pulps of the fingers. Clean a few centred slips also, and cover all up till the moment of use, to protect from dust. Take a slip, and drop on the centre enough of the medium to surround and entirely to cover the lower side of the object. This may be done by a clean glass rod or tube drawn to a point: it may be kept closely wrapped in well-sized paper, and when in use should be protected from dust. The taking up and spreading of the medium on the slide may be facilitated by warmth from the spirit lamp: but of heat, no more should be applied than is necessary. The two things to avoid in this stage of the process are dirt and air-bubbles, both of which may be drawn away by a cold mounting needle: while air-bubbles may also be got rid of by almost touching them with a hot mounting needle, aided by warming the slip over the spirit lamp, which will cause them to come to the surface, to run together, and often to break. Next take the object which it is intended to mount, and place it on the centre, having cut it into shape and removed tags, if necessary, with the knife that cuts on glass. It ought to have on it no superfluous turpentine, benzole, or whatever may have been employed, as this protracts the hardening of the slide, tends to cause running in, and is apt to produce cracks as the slide ages. It may be lifted with a pair of forceps, a mounting needle, a camel's hair pencil (if small it is apt to be lost among the hairs), or the blade or flat end of a dissecting knife on and off which it may be floated. If delicate, take care that it does not project over the edge, as a section may thus be broken by its own weight. The stickiness of the balsam will retain it if it is made to touch by holding downward the side of the knife, &c., on which it is. Draw it on the blade with a camel's hair pencil; mount with the concave side upwards, if it has one, to avoid a bubble beneath: liquefy the balsam by heat, and work the object down with a mounting needle to the bottom of the drop, so that it rests on the slip. It will then be less likely to move with the covering glass, or, if it is foreseen that it will move, place it towards the side of the slip on which it is intended that the cover shall touch first. Examine it through the microscope with an inch or so objective, with the stage horizontally, lest it should run, and see if it is all right. Work out air bubbles, dirt, and threads, and then warm the slide for some time, so as to evaporate part of the essential oil in the balsam, thus making the object less likely to move with the cover. If much warmed, the object must be covered by the balsam, which may be effected by passing over it the glass mounting rod with the remnant of the drop of balsam attached to it; for if no balsam were on it, the turpentine, or other bridging fluid between the spirit and the balsam, would evaporate and leave it parched. Or, if there is any place which is free from dust, it may be allowed to remain there in the cold, when the balsam will consolidate more gradually.

Next, take a second drop of Canada balsam, dammar, or whatever else is being employed. This, by the way, is all that is required for crystals which will be already on the slide where they have been formed by evaporation. They ought, of course, to be in the centre of the slip, like other things, and it is preferable that they should not extend from edge to edge of the cover. Not only is it well to leave a clear space along which the balsam may adhere firmly to the glass, but damp may otherwise penetrate and spoil the crystallisation. But some crystals, and especially organic crystals, dissolve in resinous media, or at least, in the volatile substances which they contain, or which are used with them. With copper salts, for instance, this is evidenced not only by the crystals becoming worm-eaten, but by the whole slide turning blue. If this happens (1), use as little of the medium as possible, or (2) as little of its volatile part—*e.g.*, employ Canada balsam instead of Canada balsam and chloroform, and be careful about heat, as this favours solution; (3) previously saturate the medium, e.g., leave some Canada balsam in the bottom of a covered test tube, in contact with sulphate of copper, and let it dissolve as much as it can, with the aid of heat; or (4) use another medium. Pure cold-drawn castor oil, for instance, has been recommended, and, by Dr. Beale, his favourite liquid, glycerine; but he is speaking of crystals from animal sources. Another reason for not using too much heat with crystals is that they may lift from the slip, and so be spoilt; but the use of gum tends to prevent this. Canada balsam, moreover, and other highly refractive bodies, increase the transparency of objects mounted in them, and may thus finally render them almost invisible; so that from this cause they may *seem* to dissolve. Another way of mounting, then, is mounting in air, which needs no special description. All that is there needful is to use a cell, and to fix the covering glass with gold size in the way which will be directed for wet mounting.

Finally, having transferred the medium from the rod to the slip, allow it to spread till the object, e.g., the crystals, are entirely covered. This will be facilitated by heat, and by lifting the slip. If the medium is allowed to spread slowly, there will be less risk of air-bubbles. Then, taking a covering glass, warm it over the lamp, having made sure that there is no dust or thread on the side next the object: apply it as centrally and horizontally as possible, or let it touch first where the medium is highest, which should be at the centre. Carefully work it down with the mounting needles, touching it on the side toward which the object moves, so as to keep the latter in the centre. Work out air-bubbles if you can (they tend to *rise*), apply a spring clip, clear away gently superfluous medium with a knife, and put the mount away in a warm place. **F. G.**

"HOW TO MAKE A CHEAP LATHE."

[22044.]—It is a pity to spoil an otherwise satisfactory piece of work by a single weak point. To fit the bed on the top of the standards by a vertical screw is not to secure it efficiently; such screw will have no hold in the upright, which it enters in the direction of the fibres. Better far to cut the ends of the bed with short stump tenons, and mortise them to fit between the pair of standards, securing them with bed-screws and nuts. The holes for these screws should be large enough to allow a little play, and if the mortises are quite true at equal distances apart, the bed will stand truly parallel, and the bed-screws will brace the frame well together. No ordinary screw will hold if inserted into wood *with the grain*.

O. J. L.

FITTING CHUCKS TO HOLTZAPFFEL'S MANDREL NOSE, OF WHICH THE PITCH IS 9·43.

[22045.]—In 1881 Mr. Holtzapffel made me a pair of chasers, styled by him No. 3 screw tools. With them I have fitted several chucks, but to do so takes much time and labour, and I have been anxious to be able to make a set of taps by which castings might be fitted by simply boring them out to the proper size and tapping them with a wrench and three taps in succession. If I recollect aright, he told me that he chased the internal thread of chucks on a screw-cutting lathe with a leading screw of four threads to the inch, and finished them up with these chasers, using wheels 40 and 95, which will give a pitch of 9·45, leaving the chasers to alter them to 9·433. I have been thinking over the matter that you can cut them nearly exact on the screw-cutting lathe by getting a single extra wheel of 41 teeth.

Forty on mandrel drives 115 on stud, which causes 50 as a driving wheel to gear with 41 on the screw, thus $\frac{40 - 115}{50 - 41}$ 4 pitch of screw, proved thus—Drivers 40 × 50 = 2,000 ÷ 4 = 500; drivers 115 × 41 = 4,715 ÷ 500.

$$\begin{array}{l}500)4715(9{\cdot}43\\4500\\\hline 2150\\2000\\\hline 1500\\1500\end{array}$$

Most of the 5in. lathes have their wheels of 12 pitch, and Lloyd has not a 41 wheel in his list. If he had one no doubt he would sell plenty of them, as most people who had a lathe with a leading screw of 4 pitch would be pleased to be able to fit chucks to Holtzapffel's lathes if only for their friends.

There is a way of doing this by using 2 wheels 14 pitch by having one or two small wheels to use as idle wheels. If these numbers did not gear, it could be managed cheaply without having a special 41 wheel made: use, of 12 pitch, 40 to gear with 115, also of 12 pitch; let it carry as a driver a 50 of 14 pitch to drive 41 of same pitch on screw. If they do not gear exactly, they might be made to do so by one or two idle wheels.* Lloyd, of Birmingham, has wheels of 15 to 24 teeth at 4d. each, 50 at 8d., 41 at 7d.

If he only had his wheels of 14 pitch made in malleable cast iron, they might be used with 5in. lathes, and as he has every number from 15 to 101, except 68, 76, 78, 86, 88, 96, 98, and above that from 110 to 150, and a 180, the range of pitches at one's disposal would be vastly increased.

THE ELECTRIC ELEMENTS.

[22046.]—Mr. Sutcliffe (letter 22027) accuses me of "altogether ignoring the argument about zero." I must say I see very little argument in his remarks on this point in letter 21981.

Mr. Sutcliffe appears to conclude that if electricity be considered to consist of two distinct elements, we are unable to consider it as being a form of energy. I do not share this opinion. This simply means that I do not consider electricity to be the same form of energy as heat, light, &c., but that it belongs to a different category. Possibly this idea will be new to Mr. Sutcliffe. It is easy to say that the opposite states of positive and negative electricity simply correspond to the phenomena of heat and cold, but I think no one will really hold that there is anything in the phenomena of heat and cold at all comparable to those of the two opposite elements in the case of electricity. **Voltameter.**

[22047.]—It is strange that, in utter defiance of the opening words of the excellent Montaigne extract at the head of the Correspondence, letter 22027, p. 221, should have found its way into these pages. Does Mr. Sutcliffe really believe that the late Professor Maxwell, "a very giant of electricity," and one who enjoyed the reputation of being second to none in carefulness and accuracy, made a mistake for which any candidate in the advanced stage at South Kensington would stand a fair chance of getting plucked?

It would take up too much valuable space to point out all the errors amassed in the letter referred to, and it would be to the average reader quite unnecessary. We will observe a few.

Electricity measured as a physical quantity is, most certainly, *not* a form of energy, but only one of its factors. The energy of an electrified body is measured, not by the electrification, but by the product of the electricity and the potential, both being measured in the terms of a chosen unit. Sufficient electricity is evolved from a Daniell cell in a few minutes for all the effects of a violent thunderstorm; but the other factor of the energy, the potential, is insignificant, and hence the energy itself.

Again it may interest Mr. Sutcliffe to know that the fact that "*Maxwell failed to perceive*"—viz., that electric phenomena are due to a stress of the intervening dielectric, and not to a deposit of electricity upon the surface of the conductors, is a theory, which, if it does not owe its very existence to Maxwell himself, owes more to him than to any man else, and was his special study for the greater part of his life!

Again, in the case of electricity in motion, all the phenomena that show anything about the state of the dielectric, point to a rotary and not to a vibratory motion of the ether particles within it. As regards the theory of the voltaic cell, several physicists, whose names Mr. Sutcliffe will find in any biography of eminent men, have worked at it. Faraday spent some years at it, and, although his results are truly grand, and his works must for ever remain as a monument of thought and ingenuity, he made simply nothing out of those ultimate actions of atom on atom, of the mysterious connection that exists between electricity and matter. Helmholtz, Clausius, Kohlrausch, and others have experimented and theorised with like result. Finally, Mr. Sutcliffe has tried it and found "a perfect explanation." Will he not give us an article upon the subject? He may well rest assured that if he succeeds he will earn a name among the greatest scientific men of the day, to say nothing of gold medals from certain learned societies which may be turned to some sterling value.

Nabla.

DYNAMIC AND STATIC ELECTRICITY — ERRATUM — MESMERISM AND PHRENOLOGY.

[22048.]—I perceive that in my article, p. 208, I have stated the capacity of cable as 3·5 microfarads per mile; it should be 3·5 miles per microfarad. The calculations, however, agree with the correct figure.

In reference to the remarks of "F. R. A. S." (22012, p. 217), I doubt if the anatomists named have really *proved* anything about the local functions of the brain in mental actions: in fact, the subject seems beyond the reach of anatomical evidence. I have no great confidence in the details of phrenological doctrines: but the evidence of universal experience bears out the great leading divisions of mental, moral, and animal correspondence to the form of the head,—from the "forehead villanous low" of Shakespeare to the statues of the old Greek divinities, we find that the artistic observers of man have recognised these typical indications. But what I want to do at present is to indicate that the "doubt" "F. R. A. S." expresses is not well founded. The expression and acts of the subject when the mesmerist touches the organs, real or supposed, most probably have no relation at all to the organs themselves, but are the direct result of the will and expectation of the mesmerist. They simply bring us back to the point at which we started. **Sigma.**

OPTICAL MATTERS.

[22049.]—Our friend "Bow" (letter 21909) has hit the mark very correctly, and "O. V." has little more to say. "Dispersive power" is a term having really no definite meaning. If we make the sum of the radial reciprocals proportional to the differences of each selected pair of colour lines, which pair ought we to choose? Should it be C and G, or D and F; or might not some values between or near to these give a more satisfactory result? If this be so, and I am strongly inclined to think that it is, by what means can we ascertain what values to pitch upon? Or it may even be asked, can we hope to get a wholly satisfactory result in this way at all. Dr. Hastings says we cannot. Let us hear what he says:—"A reconsideration of the whole subject gave rise to quite a different method of determining the most appropriate value for the dispersive ratio. By it the question of limiting extent of chromatic aberration was not considered at all, but only a condition as to the amount of light-energy sent very near the geometrical focal image of a distant point. This theory (*American Journal of Science*, Vol. XI., April, 1878), after having been once formulated, was so satisfactory that there was no doubt as to its success even before testing it."

Now, what English or American friend will abstract and send to you, Mr. Editor, this important contribution to the literature of the object-glass?

I must thank "Bow" for his kind offer to copy out Airy's papers. I do not, however, need them for my own use; but if he thinks they contain anything interesting to the general optical reader of this journal, I trust he will make an abstract the most important parts, especially relating to [illegible], I send them to these columns.

As regards my essay, I find I shall have to spin it out much longer than I had intended; but I am anxious to collect together whatever seems interesting and useful, whether it be new or old. I fear there is not much chance of my articles ever appearing in book form: such a work could only have a very limited interest.

Orderic Vital.

AMATEUR WIND-INSTRUMENT MAKING.—II.

[illegible]—The measurements of a B flat mouthpiece are as follows:—See Figs. 1 and 2. A to B, [illegible]cent.; B to C, 4·1cent.; C to E, 3·4cent.; total, excluding A to B = 7·5; width of gullet at E [illegible]mill.; at C 8mill.; diameter of bore K 15mill. Mouthpieces vary a little, according to the views held by makers; but generally, the body from B to E is 7 cent. for a C clarionet, and 7·5cent. for a B flat clarionet. Some makers bore both clarionets the same size; this, of course, is also a matter of opinion. We now come to the most difficult part of the mouthpiece—viz., the lay—that is the part from D to E which gives the reed room to vibrate; it measures on a C clarionet about [illegible]mill., and on a B flat, 22mill. The bed G is made truly level to a surface plate, which is usually a piece of plate glass about 2cent. broad by [illegible]cent. long. We then form the part from D to E into a part of a circle, whose radius is about [illegible], the aperture being closed at D, and open about [illegible] mill. at E. This is effected by having slips of metal of known thickness to insert between the glass plate and the mouthpiece, cutting the latter carefully [illegible] amount of space is [illegible] that both sides of the wood are [illegible] and leaving the gauges [illegible] distance, so that they can [illegible] exact places. This [illegible] the usual rule- [illegible] employed among makers [illegible] keep a record of all the apertures [illegible] good ones, also an [illegible] mouthpiece bed, [illegible] measurements, the curve [illegible] It has not yet been [illegible] part of a circle, or [illegible] happens that a [illegible] considerably from any [illegible] a very care- [illegible] not give satisfac- [illegible] reed, [illegible] I now [illegible] measured by [illegible] the differ- [illegible] mouthpieces are [illegible]

[illegible]

without a squeak in a moderately quick passage. A set of measures or gauges for adjusting and altering mouthpieces are not easily obtained without expense and trouble, so I have carefully measured the thickness of paper used in printing the English Mechanic: it is four thousandths of an inch; thin foreign writing paper is two thousandths of an inch; and the plate in *Harper's Monthly* is seven thousands of an inch. Now, by using a number of these together, approximate sizes may be got if they are carefully cut and gently used. The inclination of the palate F, Fig. 1, has an influence on the pitch and freedom of the reed, especially in the higher notes of the instrument: a very concave palate making the high notes flatter and difficult to produce. The bore K should be the same size as the clarinet body: but sometimes it is desirable to have a mouthpiece that will flatten the instrument, and this is managed by having it narrower in the bore, and increasing the distance between B and C, the greatest amount practicable being about one-sixth of a tone lower than the tuned pitch. The breadth of reed for a B flat clarionet is 14·2mill. The C instrument has usually one a little narrower—say, 13·5mill. The body consists of a truly cylindrical straight tube, its office being to regulate the vibrations of the reed. By the opening of each hole in the side, a different length of tube is thus attached to the reed; consequently, more or less freedom is allowed to it: the column of air being longer or shorter, the rate of vibration is correspondingly less or more, and different notes are the result. A piece of cocus-wood is chosen and split up to 1⅜in. square by 17in. long for a C clarionet (the B flat requires about 19½in. long): this insures evenness of grain, which facilitates straight boring. The wood, after being rounded up in the lathe or dressed by a plane, is bored out thus. A Morse twist drill, of ⅜in. diameter and 5in. long, is fixed to the lathe mandrel by a socket; the wood being centred is screwed up against this drill by the back centre, and the boring proceeded with, the wood being gently turned the reverse way by hand, and the drill cleaned about every half-inch. When it has bored as far as it can go, it is then removed from socket and attached to a [illegible]in. round iron or steel shank, about 18in. long. The boring is then gone on with as before till it comes out through the end. Observe the following points, or an uneven hole, out of truth, is the result. Do not force the back centre up too tightly; clean the drill often; use a quick speed for lathe; and apply a little blacklead to the drill if it does not clear itself easily. The tube is then widened out by a scallop bit, well sharpened and adjusted with care to a little less than the size required, mounted on a long shank, same as above drill, and run in the lathe, the wood being held by both hands. As the bore is still a shade small, a sheet or two of very fine glasspaper, being heated gently to soften it, is rolled round a rod of metal, ⅜in. diameter and about 2ft. long, covering it about 8in., and brought up to the size of the bore, which it fits moderately tight; by pushing this slowly up and down a good surface is obtained, and the bore is equalised. When this rod becomes slack, unroll the sandpaper and insert a small slip of common paper, this will make it again fit the tube. The glasspaper is attached by resin to the metal rod, and wound tightly on. The bore now being up to size and parallel, a cork is fitted to each end, it is then filled with linseed oil, and both corks, which are extra long, forced in and kept under pressure by a joiner's cramp. It will be necessary to take out the corks and add a few drops of oil every day for a week or so, till the wood has taken up as much as it can. Sometimes it is best, however, to turn down the outside to its proper size before saturating with oil; and this is best done by fitting a plug of brass in one end for the back centre, the body being driven in the lathe by a turned-up pin of wood, projecting from the face-plate or chuck, accurately fitting the bore.

Vulcanite.

BICYCLE CONSTRUCTION.

[illegible]—I am much pleased to note that a correspondent has undertaken to instruct us on the art of bicycle construction, and I hope that [illegible] will come forward and do the same for the tricycle, which has now become such a popular favourite.

A Reader Since 1870.

CABINET-MAKING.—VI.

[illegible]—We will now set about making our [illegible], and we will start with our ends, the same as we did with the cabinet. Dress and square them up to 3ft. by 11in., running a ½in. check along the back inside edge to take the back; then serve the top and bottom the same, sizing them to 3ft. 3in. by [illegible]in. Dovetail them together the same as you did your drawer. Clean and sandpaper the insides, glue and drive together, and see that it is square. Prepare and nail in the back; make a moulding to go round the bottom, as shown in Fig. 1, letting it project ⅜in. over the ends and 1⅜in. over the front. Nail or screw it on to the bottom. Then we shall want a rack to support the shelves. To make this, cut a piece of pine 3ft. by 3in. by ⅝in., and make it like Fig. 2; then by cutting it into four you will have a piece to plant along each corner of your ends. They will then have the appearance of Fig. 3; and by making short pieces to fit between the racks you can have your shelves movable, so that you can shift them to the size of your books. You will want a cornice: you can make one to suit your own taste, or the same as Fig. 4, which is a section. To make it, you must cut two pieces 3ft. 4in. by 1½in. by ⅞in., and two more 11⅞in. by 1½in. by ⅞in., finished, dovetail them together, letting the ends into the front and the back into the ends. Glue and drive together, clean off front and ends, and cut a piece ⅞in. stuff 5ft. 6in. by 2in., round one edge, and then plant it along the bottom edge of the frame you have just finished, mitring it at the corners. Then cut a piece 6ft. 3in. by 4½in. by ⅞in. finished, make a mould of a piece of this wood the same as the moulded part of section, place it on the ends, and with your marking awl transfer the shape to the ends of the prepared piece. Run gauge marks along the face so as to keep the members straight, then with planes as near the shape as you have them run out the members to the shape and depth. To mitre the moulding you must make a box large enough to take the moulding when it is set on the angle of the bottom edge, then with a good tenon saw cut it, and if the box is well made you will have very little trouble in securing a close joint. Next cut notches along the back, as shown in section, and screw the front on, first fitting the two end pieces. Afterwards you can start with your doors. Proceed the same as with the cabinet, only the outside stiles should be about 1in. wider than the inside ones, mortice and tenon them together, then clean them off, fit them in their place, and they should just cover the front of the case at both sides and be about ⅛in. clear along the top and bottom: then dress ⅜in. of the edge of inside stile of right-hand door, cut a rod 2ft. 11in. by 1¼in. by ⅜in. finished size, run your gauge along the front edge set at ⅜, round it over down to the gauge marks; then check it the same as Fig. 5. Fix it on the edge of the right-hand door, and then hinge to the ends with 2½in. edge butts. Then make some beads to plant on the doors, the same as you made for the cabinet, and

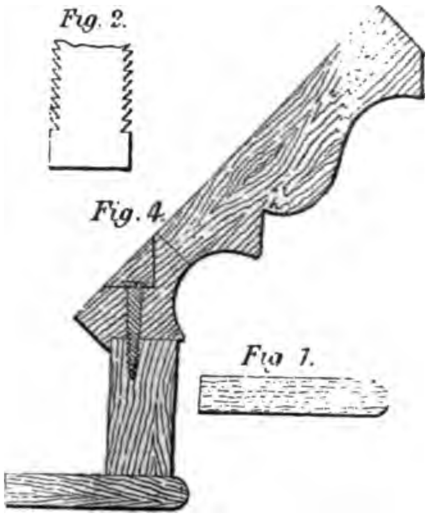

Fig. 2.
Fig. 4.
Fig. 1.

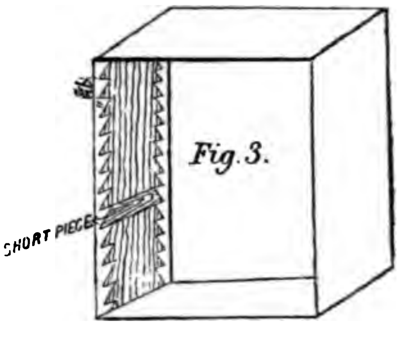

Fig. 3.

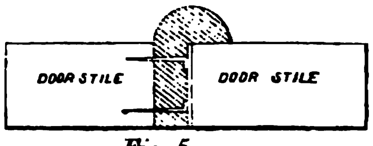

Fig. 5.

plant them in their place, allowing them to project about ¼in. to form a check to receive the glass.

You must now go over the whole job, and see that it is properly finished; then place the bookcase on the top of the cabinet, putting one 1¼in. screw in at each corner to keep it in its place. Fix the cornice in its place the same way, and the job is finished. J. P.

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51577.]—**Rushton's Self-Acting Fountain.**—I take the following description of the above fountain from "Amateur Work." The figure

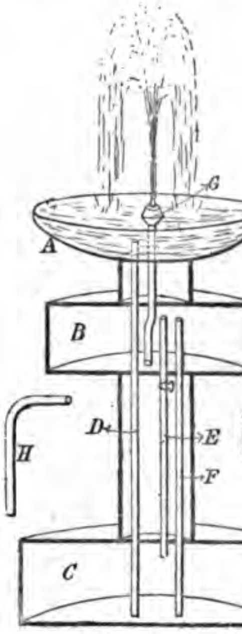

Fig. 1.

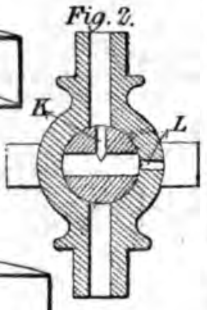
Fig. 2.



shows a basin A, and two cisterns B and C; to start, the fountain water is poured into basin and runs through pipe D filling cistern C, and leaving basin half full. The tap in pipe E is then turned, shutting off the only escape for the air, leaving only the way in through pipe D, and the way out through pipe F. Now take the small bent tube H placing one end in pipe D in basin, and blow for half a minute; this will drive the water out of cistern C, through pipe F, into cistern B. While the water is pouring into cistern B the air is escaping through pipe E by the tap, which acts as a vent as well as a shut-off from the cistern. Cistern C is now empty and cistern B full, and the fountain ready for playing off. Turn the tap, the water will then pass from the basin through pipe D into cistern C, drawing the air through E, and, pressing on the water in B, drives it through the jet G. When done playing, turn off the tap, place the bent tube on pipe D and blow as before; turn the tap and the fountain will recommence. This fountain is sold for 15s. 6d. It appears to me that the above description is incomplete; and that unless the cock is made with a small hole in its side as shown in Fig. 2, it would not act as stated.—Glatton.

[51619.]—**Specific Gravity.**—The constant 38·5 is found from actual experiment as follows:—Dissolve 1lb. of any simple substance in distilled water, and make the bulk up to 1 gallon by the further addition of water, then take the sp. gr.; the excess of gravity over water will be the constant required. If "J. R." is accustomed to laboratory work, he will get the same result by dissolving 10grm. of the substance in distilled water and making the bulk up to 100cc. by the further addition of water; the excess of gravity over water of the solution thus prepared, will give him the constants for the substance under examination.—N. C. R.

[51698.]—**Yeast.**—Mr. E. T. Scott, in his recipe, omits to say the quantity of water in which the ¼oz. of hops are to be boiled, but tells us that there is to be 1lb. of potatoes, rubbed fine (query, are they to be previously boiled?); we are to add ¼lb. of flour made into a paste with cold water and than usual (query, how warm?). I shall be glad if Mr. Scott will favour us with more definite instructions. It is with much surprise that I see hops so often mentioned in the manufacture of yeast. I cannot think they can have any effect, except to render it bitter, which is the very thing to be avoided. True they are used in the manufacture of beer—not, I imagine, to make it ferment, but to flavour it.—S. M. C.

[51865.]—**Scientific Library.**—Through pressure of work I have been unable to offer any remark on the above subject until now, but trust my experience may still prove of service. It was suggested by a correspondent that to purchase was a better plan than to subscribe to a library. Now, I think the following will perhaps cause a change of opinion. In the first place, it is taken for granted that every one wishes to see the latest edition of a work, and it is disappointing to find a new edition of a book appear when one happens to have bought a copy perhaps only a few months previously. In short, it does not seem to be generally known by "our" readers that this is a most excellent scientific library to which anyone may subscribe, the chief advantages of which are—1. All the works in the library are the latest editions. 2. The volumes can be retained by the subscribers any length of time, during the whole term of subscription if desired. 3. Books can be changed as one likes. 4. An unlimited supply of all the new and best standard works are added to the library as soon as published. 5. An extensive and classified catalogue is presented to subscribers. I need not add more, as the prospectus of the library will give any further information. I write in the interest of students and others, like myself, who have found my subscription to Lewis's Scientific Library, Gower-street, W.C., of immense value.—Preceptor.

[51880.]—**Pressure on Screw Propeller.**—I send a suggestion to find the pressure of a screw, on the basis that the pressure on an inclined plane will equal the amount intercepted at 90° at the same rate, but with a thrust of ·707, ·89, ·95, and ·97 of that of the screw for 45°, 22½°, 15°, and 11¼° respectively, and which will give a pressure of ·5, 1·6, 2·7, and 3·76 for each angle. Let the blades of screw in the case mentioned have a length of 4ft. and a turn of one in four at the rim: it will have an angle of 15° nearly at the centre of pressure. Then work per sq. ft. per sec. = (225 × 550) / 40 = 3093·75. Now to get the required pressure when moving, the screw would have to be turned ·414 faster. $\therefore 2{\cdot}7\ v\ (v^2 \times 62{\cdot}5) / (64 \times 1{\cdot}414) = 3093{\cdot}75$ $v = 11{\cdot}8$; and pressure per square inch = (3093·75) / (11·8 × 144) = 1·82lb.—J. Mead.

[51886.]—**Wimshurst Influence Machine.**—If the querist will but look through the last two volumes, he will find an answer to all his questions. On p. 426, Vol. XXXVI., there is an illustrated description. Twelve sectors will do, and they can be fastened to the glass with any of the usual cements, or with isinglass dissolved in acetic acid. The plates may be varnished with any hard varnish, such as shellac dissolved in methylated alcohol. The plates are fastened to the bosses with marine glue, or the common electrical cement. A metal spindle must be covered with ebonite, or some other good insulator. The other questions are fully answered in the article referred to, or in replies since.—Nemo.

[51890.]—**Tubular Pneumatic Action.**—This is simply the usual bellows connected to the windchest by pipes (gas tubing). Thus suppose it is wanted to add a rank of bourdons, they would be placed on a soundboard and be connected by tubes to the windchest instead of trackers to the keys. Wind being admitted by the pallet in windchest passes to the small bellows which opens the pallet of the bourdon. The latter is, of course, supplied with separate wind.—Organon.

[51893.]—**Simple Planing Machine.**—"Lumber" should look up his back volumes. He will find many illustrations of lathe-planers which he will be able to utilise.—Nun. Dor.

[51894.]—**Model Marine Compound Engine.**—The querist who asks whether it is possible for a compound engine to work without an intermediate receiver, the cranks being at right angles, should make a sketch with the positions of the pistons and valves accurately set off. That would open his eyes to see the difficulty of doing what he wants, especially in a model.—Nun. Dor.

[51914.]—**Feed-Pump.**—Make the feed-pump one-third the diameter of the cylinder, and its stroke one-half.—Nun. Dor.

[51917.]—**Battery for Bell.**—No doubt it is a manganese cell, and extremely doubtful whether "the cell is a zinc one," as you say.—Nun. Dor.

[51923.]—**Damp Cellar Vaults.**—I suppose it is possible to dig round outside and fill in with Portland cement concrete; or what is perhaps better, asphalte made of sand and boiled tar and pitch.—Junior.

a rule cheaper than they can be made; but "No. 23" can use logwood and sulphate of iron for black, and the aniline colours for red and green.—Manufacturer.

[51928.]—**Spectroscope.**—This querist should, I suppose, get Mr. Rand Capron's pamphlet (Browning), or read what has been said in recent volumes. See the index of Vol. XXXVI., and that of the last volume.—Nun. Dor.

[51931.]—**Lathe.**—This query has, I suppose, been answered by this time in the articles on "How To Make a Cheap Lathe": but if the querist has any peculiarities, surely he could ascertain the best height by marking it on the wall, standing as he would do in treading a lathe.—Essar.

[51944.]—**Coppered Wire.**—R. A. R. Bennett accuses "A Practical Chemist" and myself of being hard upon S. Austel; but, speaking for myself, I cannot see where the harshness comes in. My wish was to prevent any chance of the querist asking his chemist for copperas, and not to show up S. Austel in any way—although I do think that one should know the difference between sulphate of copper and copperas before sending a reply to such a query. Had the error been allowed to remain without correction, the querist might have ordered copperas, and, of course, would afterwards find that in place of a deposit of copper his iron wire would gradually disappear. With regard to the reply given by "Chemicus" on page 320 last volume, I may say that I never saw it—a fact which Mr. Bennett did not trouble himself about. The additional information given by B. is rather out. How would a pint of concentrated vitriol mixed with the same quantity of a solution of bluestone answer? Does B. think that the copper would continue to deposit itself after the wire has become coated with a film? If so, why use electricity in electro-metallurgy?—Ressorp, F.C.S.

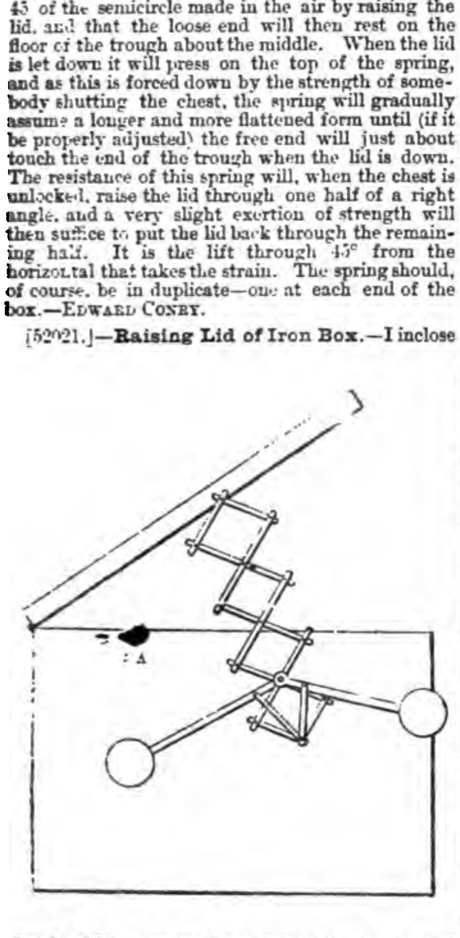
[51951.]—**Astronomical.**—By the inequality in the longitude of Mars produced by the Earth, amounting to 5 minutes in two centuries, is intended, if I am not mistaken, the motion of Mars's perihelion, produced by the action of the Earth, which thus affects the equation of the centre. A movement of 7″ per annum in 200 years will amount to 25 minutes, which, when Mars is in its perihelion or aphelion, will produce an effect of about 5 minutes in heliocentric longitude, with a plus or minus sign, as will be easily seen when we remember that the maximum equation of the centre of Mars is about 12°. Of course, the earth's perihelion is moved by Mars.—W. C. E.

[51961.]—**Cleaning O.G.'s**—I am with "Achromatic" obliged to "F.R.A.S." for the reply to query addressed to Mr. Lancaster and "Prismatique." It is best to clean as little as possible, yet damp should be removed, or the surfaces will stain in time. It is, I think, a good plan to put the telescope out with the cover on until all is at one temperature, or if it is used in an observatory, open the shutter some little time before uncovering the o.g.—this as a preventive. The spots are the result of damp which has evaporated and left residual pellicles behind it. As this is generally on the anterior surface, a little breathing on and careful wiping with a soft well-beaten washleather will remove them without taking the o.g. out of the cell. There is an increase of light produced by cementing o.g.'s; it is, however, necessary that the surfaces are perfectly in contact. This condition must be, or "Achromatic's" o.g. will not give good results cemented. I have used castor-oil and glycerine, the former with effect for some purposes; mixtures of oils have been used by an eminent optician for cementing large o.g.'s. I believe there is a tendency to slip down of the layer of oils—a sort of glacier is produced between the lenses, which makes the definition variable. Castor oil will, however, last a long time for a small o.g.; eventually it oozes out and makes a greasy mess of it.—Prismatique.

[51974.]—**Engine.**—To "Glatton."—I find that the diagram I spoke of, though all right in theory, does not give such accurate results as the ordinary elliptical diagram given by Rankine, without great nicety of drawing. I shall not, therefore, publish it unless asked to do so. As you do not give length of eccentric and connecting rods, I cannot give the *exact* point at which compression begins; but it is at about 1¼in. from end of stroke. Exhaust opens when piston has moved nearly 36in., and steam is cut off at 32in. If the Editor wishes it, I will describe the elliptical diagram, but, as it is so common, it seems scarcely worth the space. I do not know a simple rule. The plan of having both steam-ports open to exhaust at once is very bad.—Glatton.

[52020.]—**Raising Lid of Iron Box.**—The following arrangement answers very well, and is inside the box, instead of being attached outside and to the wall. Make inside each end of the chest a very strong steel spring of the best materials and of strength proportionate to weight of lid, the shape being that of a semicircle extended at one end something like the letter S laid flat, and with the top bend cut off. Screw one end firmly to the front of the chest, inside the trough, in such a manner that when the lid is up the spring will project to about 45 of the semicircle made in the air by raising the lid, and that the loose end will then rest on the floor of the trough about the middle. When the lid is let down it will press on the top of the spring, and as this is forced down by the strength of somebody shutting the chest, the spring will gradually assume a longer and more flattened form until (if it be properly adjusted) the free end will just about touch the end of the trough when the lid is down. The resistance of this spring will, when the chest is unlocked, raise the lid through one half of a right angle, and a very slight exertion of strength will then suffice to put the lid back through the remaining half. It is the lift through 45° from the horizontal that takes the strain. The spring should, of course, be in duplicate—one at each end of the box.—Edward Conry.

[52021.]—**Raising Lid of Iron Box.**—I inclose



sketch which may perhaps prove of use. It will serve to give an idea.—William E. Dawson.

[5203[illegible].]—**Caledonian Engines.**—Your correspondent, Mr. Spencer, asks about new C. R. engines. At the present time the first one is not yet out. There are 21 six-coupled goods engines building, 15 at Messrs. Neilson's and 6 in the Co.'s shops at St. Rollox. Neilson and Co. have also on hand an order for ten express engines, almost the same as N.B.R. "Waverley" class. The boilers in both goods and passenger are the same. The C.R. goods and passenger engines have a larger heating surface and slightly smaller firegrate. Besides these there have been rebuilt five of the 417—4[illegible] class, which have cylinders 18in. by 24in. and 6ft. 2in. coupled wheels. In a former volume I gave details of these engines. The rebuilt engines (Nos. 420, 427, 429, 432, and another) have boilers of the "Waverley" type, and cabs of G. & S.W.R. style, and working pressure 150lb. per square inch. The splashers, which were, for the most part, open, have been altered to solid ones. These engines were set to run the limited mail, and other express trains between Carlisle and the North and vice versâ. As I once pointed out in the "E. M.," the "Limited" is allowed 62 minutes to cover the 49¾ miles between Carlisle and Beattock Summit, and must run the first 40 miles in 44 minutes in order to leave time to ascend Beattock incline. Now this forty miles is anything but level:—First you have the Gretna bank about 15 miles (with a slight break) rising 1 in 200, and between Netherclench and Beattock (11 miles) there are 9 miles varying from 1 in 165, 200, 206, 300, &c., and lastly, of course, comes Beattock incline. There are no steep falling grades going North except about two miles 1 in 200, and about 30 chains of a decline leaving Carlisle, of 1 in 80 and 1 in 100. The rebuilds proved utterly inadequate to the task allotted them. They could not cover the first 40 miles in less than 55 minutes, and in some cases as much as half an hour was lost between Carlisle and Carstairs. The result is 420 and Co. have been relegated to work more suited to their powers. Now, it has lately been proved that the 76 to 87 class (eight-footers) can run this train, even with a stop at Beattock for *a pilot.* One of their number, about two months *ago, took 14 carriages from Carlisle to Beattock in 43 minutes (one minute less than the Mail is allowed). Most of the carriages* weighed about 14 *This was with the tourist* express. Now as I have, perhaps, made this letter too long already, I will conclude by saying that from these facts the engine of 1883 would seem hardly to have improved on that of nearly 24 years ago.—Carstairs, Glasgow.

[52043.]—**Induction Coil.**—To A. V. Nicholls.—Have made up coil according to your instructions, using, however, silk-covered wire for primary, but cannot get more than $\frac{1}{16}$in. spark. I should be obliged if you will tell me where I may be wrong. Would it be better wound in two sections? Also what would be the greatest battery power it would stand?—L. W. Willis.

[52062.]—**End Bearing for High-Speed Spindles.**—I am unacquainted with the principles of spindle machinery: but I should think that polishing hard rounded end of spindle dead true, and a fine polished flat agate or other hard stone for the bearing would do. It would reduce friction a great deal more than steel working on steel, especially if fit be not perfect—a watchmaker's experience leads me to suppose so. As an idea to keep oil from bearing, if a screw be chased about an inch or more on the bottom of spindle close down to rounded end, by the motion of spindle revolving forward the thread unscrews, so the oil which surrounds it will have a tendency to be forced down on the bearing.—H. W. Salter.

[52087.]—**Pressure on Crank-pin.**—From some cause or other, I see I have multiplied the quantities in this query crosswise; it ought to have been high-pressure 268·8 × 62lb. ÷ 2 = 8332·8lb.; low-pressure 490·875 × 18lb. = 8835·75lb., or total weight on crank-pin = 17168·55lb.—Engineer, Dewsbury.

[52103.]—**Engine.**—"Young Engineman" is right when he divides the whole length of the stroke by the distance traversed by piston at point of cut-off to obtain the number of expansions in one cylinder; but he will see by the following that this is not absolutely correct, when applied to the compound engine. For instance, let us take your engine, and suppose the high-pressure cylinder is 100 sq. in. area; and if the stroke of the pistons are equal, the area of low-pressure cylinder will be 400 sq. in.; and taking the stroke at 40in., the high-pressure piston will have traversed 20in. when the cut-off occurs; and here we have 100 × 20 = 2,000 cubic inches of steam, with an absolute pressure of 75lb. Here its volume is only *one*; but when it has passed into the low-pressure cylinder its volume will be eight times what it is now: for 400 × 40 = 1,600 cubic inches. I think this will suffice to show "Young Engineman" that he has obtained eight expansions, and not six, as he supposes. As such an interest is taken in compound engines, I will, with the Editor's permission, send a short article, showing the loss as compared with a single-cylinder engine with the same number of expansions. I see that, in answering this query, "Firer, Dewsbury," asks me how far the low-pressure piston will have traversed while the high-pressure piston remains stationary, to increase the volume twice? I will only say that the cubic capacities govern the volumes, from which he can calculate the distance at his own leisure. And I hope I shall not offend "Firer, Dewsbury," when I again say that his method of obtaining the number of expansions is not correct. For instance, suppose, from some cause or other (such as leakages), the back pressure was 9lb. (= 6lb. vacuum) instead of 2lb.; then the final effective pressure would be 9⅜ − 9 = ⅜lb.; then, by following out the method given by "Firer, Dewsbury," we shall have 56¼lb. ÷ ⅜lb. = 150 expansions, and yet the cut-off pressure, and all other particulars, except the resisting pressure, have remained the same.—Engineer, Dewsbury.

[52118.]—**Tarring Posts.**—The fence would last longer without the application of gas tar, if there were any sap in it, for if the tar were applied before the sap was dry the sap would gradually rot the wood away. If, on the contrary, the wood had been kept in a timber yard (or any other place where it might dry) for twelve months or so, the gas tar, under those conditions, would act as a preservative.—Rowen Valentine.

[52125.]—**Harmonium.**—If your instrument is an ordinary 2½ set harmonium, and contains one 16ft., one 8ft. and ½ set of 8ft., your soundboard will be divided into five registers, and for this you will require five apertures in valve board. The following dimensions for these will, I think, be suitable: Bourdon, 16ft. register, 6in. long by 2in. wide. Cor Anglais register, 5in. long by 1⅞in. wide. Flute register, 4 in. long by 1⅝in. wide. Clarionet register, 4½in. long by 1⅞in. wide. Celeste register, same as Flute.—G. Fryer.

[52127.]—**Platinum Crucibles.**—Metallic lead or salts of lead should not be melted in platinum crucibles, as it forms an alloy and destroys the crucible very quickly. Caustic potash or soda also injures it. Sulphur or sulphides also injure platinum.—William E. Dawson.

[52127.]—**Platinum Crucible.**—Compounds of the easily reduced and fusible metals, as tin, antimony, lead, bismuth, &c.; substances containing sulphur, as metallic sulphides; caustic alkalis, aqua regia, and many other substances are all more or less injurious to a platinum crucible.—W. Farquhar.

[52139.]—**Bearings.**—If "C." would apply some of Richards' plastic metal to his bearings, no doubt it would suit. The patentees are J. Richards and Co., Whitton-lane, Hill-top, West Bromwich, who supply full printed directions for using along with each ingot.—Whitewall.

[52143.]—**Chemical.**—In my reply which you printed last week, the third line from the bottom, which appears as "$\therefore x +$ [illegible] x [illegible] 32," should be "$\therefore x =$ [illegible] $x + 32$."—Spencer Collyns.

[52148.]—**Testing Lightning Conductors.**—The way to get over the difficulty is to make two temporary earths, which can be done by driving iron bars into the soil well moistened, and a few feet apart. Test the two first together, then test the lightning conductor earth against each of these separately. Tests should be taken with current reversed in all cases, to compensate for any polarisation effects due to difference in the several earths.—Sigma.

[52155.]—**Bicarbonate of Soda.**—Bicarbonate is manufactured by the action of carbonic acid on soda crystals, in iron chambers holding from a few tons up to 60. The CO_2 is obtained from chalk, or limestone, and hydrochloric acid, in covered tanks constructed of flags. The tank is partially filled with chalk, &c., and the acid run in by a pipe reaching nearly to the bottom, the gas escapes at the top. The chambers are best made of iron, as the heat is radiated away quickly; they are connected so that the gas enters the oldest chamber first, and leaves at the last-charged one. At the bottom of the chamber there are channels for running off the water set free during the reaction, and letting the gas in so that it passes through the whole of the crystals and leaves at the top. The inferior yellow crystals may be used, as the water set free carries off all impurities, consisting of sulphate and chloride, and colouring matter. The liquor runs off by a V-shaped pipe, preventing the escape of gas, and by the stoppage of the running it is known that the process is nearly finished; also tested by pushing a bar of iron into the chamber: when the bar meets with no lumps the process is finished. The bicarbonate has then to be dried, as it is very damp. This is done on shelves in rooms heated by hot air. The drying lasts about eight days. The dried bicarb. is ground in mills similar to corn mills, and sifted through a sieve with 20 holes to the linear inch. The mills must not get hot or CO_2 will escape, which will reduce the strength. It even loses strength by keeping for some time in the warehouse.—S. A. W.

[52160.]—**Battery.**—In reply to R. A. R. Bennett, p. 227, I have no idea how long any battery will last in action. It all depends on dimensions and work. I know no reason why a zinc and carbon battery should not keep in action for months, merely working a clock, if a sufficient supply of weak acid were available. A good Daniell of the Meidinger type, that is, supplied from a flask containing crystals of copper sulphate, on bird-fountain plan, will keep up such work for a couple of years. Mr. Bennett's plan is the worst he could use for his purpose. The salt should be at top, where it will dissolve and sink; when at the bottom of the cell it dissolves too slowly if a large current is wanted. It requires about five Walker cells to give the force of two Daniells, if in full work.—Sigma.

[52165.]—**Slide-Rule Formulæ.**—The formula given by "Glatton" may be put in this form—

s = speed of piston
d = diam. in inches
x = cub. ft. per minute

$$x = \frac{s \times d^2}{183}$$

or, 183 : s : : d^2 : x a proportion solved on the slide rule as given by "Glatton." It may also be solved with the inverted line I.

$$\begin{array}{llr} \text{A} & 183 & 29{\cdot}4 \\ \hline \text{I} & x = 11{\cdot}3 \text{ cub. ft.} = 70{\cdot}7 \text{ gallons.} & \\ & s = 130 & \\ \hline \text{D} & d = 4 & \end{array}$$

giving the result either in cubic feet or in gallons.—A. D. L.

[52165.]—**Slide-Rule Formulæ.**—As for calculations by slide rule, the figures and divisions on slides and fixed lines of instrument serve for mechanically obtaining, by additions and subtractions, what in the ordinary way of calculations require multiplications, divisions, squares, or square roots, &c.; so the formulæ for both systems are constructed from similar data and reasonings. Thus—To find the diameter of a pump for discharging a given number of cubic feet per minute, when the bucket lift is given in lineal feet, reckoning without loss, or deficiency in working. Here, 1st.—A cylinder 1in. diam., 1ft. deep, containing ·7854 × 12 = 9·424 cub. in., and a cub. ft. 1728cub. in.; then 1728 ÷ 9·4248 gives the contents of 183·346 cylinders 1in. diam. 1ft. deep = the content of 1 cub. ft.; or, 183·346 circular in. area = the area of 1 sq. ft. 2ndly. Cub. ft. discharge per minute ÷ lineal ft. bucket lift per minute, giving the content in cub. ft. of 1ft. length of pump; and 3rdly. Cub. ft. in 1ft. length of pump × 183·346 giving the area of pump in circular inches. Then, lastly: The square root of circular inches area = inches diam. of pump, 60. For simplicity, cancelling the decimals ·346 in 183·346, and using 183 for the constant or gauge point in finding the diam. of pump, to discharge, say, 285 cub. ft. per minute, reckoning the bucket lift 125 lineal ft. per minute, and no loss; from the preceding we obtain the arithmetical formula:

$$\sqrt{(285 \div 125) \times 183)} = 20{\cdot}42 \text{ diam. of pump}$$

60 Slide rule formula

Set 125 on slide $\frac{B}{C}$ opposite 285 on line A; and

Opp. 183 G.Pt. on do. $\frac{B}{C}$ is the circular inches area of pump on A = 417; and the inches diam. of pump nearly 20½ on square root line D—all at one setting; and supposing a Routledge or Soho class of slide-rule used, literally. The difference between the length representing 285 on line A and 125 on slide $\frac{B}{C}$, plus the length for constant, or G.Pt. 183 on $\frac{B}{C}$, giving the answer on D opposite the last sum in A.—BUTTERSHAW.

[52166.]—**Engine Power.**—The best thing that "C. C., Bradford," can do is to get some friend to indicate his engine; then he will get to know the power of his engine correctly. But we will suppose the engine to be a condensing one, with an initial gross pressure of 65lb. (of course that is allowing nothing for friction in steampipes, thoroughfares, clearance, &c.), and a back pressure of, say, 3lb. The theoretical h.p. will be 143·139 area of cylinder by 192ft. per minute by 52lb. average pressure (when cut off at half-stroke) ÷ 33,000 = 43·3h.p. When steam is cut off ⅜th of stroke, the h.p. will be 143·139 × 192 × 45·2 ÷ 33,000 = 37·6. When cut off at ⅝th of stroke, the h.p. will be 143·193 × 192 × 56·7 ÷ 33,000 = 47·2. When steam is cut off altogether I cannot see any power at all. Of course, if the engine be a non-condensing one, there will want 12lb. more deducting from the average pressure for the atmospheric resistance.—FIRER, Dewsbury.

[52166.]—**Engine Power.**—The following formula will solve such questions:—

$$\text{h.p} = \frac{A\,p\,n\,a \left\{ 1 + \log. \frac{l}{a} \right\}}{33000}$$

A = area of piston in square inches.
p = initial pressure of steam.
n = number of strokes per minute.
a = space described by the piston before the steam is cut off, in feet.
l = length of stroke, in feet.

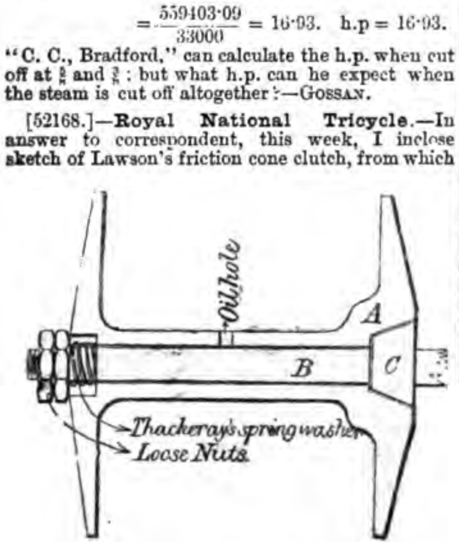
For the first case the h.p. will be—

$$\frac{141{\cdot}13 \times 50 \times 72 \times {\cdot}65 \left\{ 1 + \text{hyp. log. } \frac{1{\cdot}3}{{\cdot}65} \right\}}{33000}$$

$$= \frac{559403{\cdot}09}{33000} = 16{\cdot}93. \quad \text{h.p} = 16{\cdot}93.$$

"C. C., Bradford," can calculate the h.p. when cut off at ⅝ and ⅜; but what h.p. can he expect when the steam is cut off altogether?—GOSSAN.

[52168.]—**Royal National Tricycle.**—In answer to correspondent, this week, I inclose sketch of Lawson's friction cone clutch, from which he can see at a glance how it acts. Directly the steering handle is used to cause a divergence from the straight line, the tendency of the wheels to describe circles of different diameters causes the cone to be slackened in the hub of the loose wheel, and allows the shaft, with the cone which is fastened to it, to revolve in the hub. It is not really a double driver, except in a straight line, as during a turn to either side, one wheel, namely the one with the cone in it, runs loose. The whole affair is so very simple and so old-fashioned, that any lad can make it, and it cannot possibly get out of order, and needs no thought on the rider's part to look after it. I regret being such a poor hand at an explanation.—SECUNDUS HAUD ULLI.



A, section of loose hub; B, shaft of tricycle; C, cone fast on shaft.

[52167.]—**Good Time.**—Have a black board hung outside the time office, studded with nails, say three inches apart, equalling in number the maximum number of men employed. Get a corresponding number of brass or cardboard discs about 1½in. in diameter, and number them consecutively 1, 2, 3, &c. Have a box, like a child's money box enlarged, to receive the "checks." Each man, knowing his distinctive number, will take off his "check" and drop it into the box as he passes into the works. When all have gone in, the timekeeper empties the box, enters each man in his book, and hangs the "checks" up again in readiness for the next bell ringing. This is cheap and effective. —J. H.

[52171.]—**Legal.**—The Bank is entitled to stop the income tax. The daughter should pay her father the balance due to him, less the income tax on the balance, and pay her own share of the income tax herself.—J. R. PRIDHAM.

[52178.]—**Combustion without Flame.**—If you have a gas forge you can perform the same thing. Everybody who uses these finds out the same thing accidentally. I know we did in a shop I worked at nearly twenty years ago, and Mr. Fletcher is no exception.—JACOB MAGLOSKIE.

[52178.]—**Combustion without Flame.**—"Glatton" can easily repeat the experiment with a common sponge lamp. Take a piece of thin platinum wire about ·01 thick, coil it into a spiral a trifle smaller than the lamp tube. Light the lamp, and turn it down till only a small part of the white flame shows. Then hold the spiral in the flame a little above the wick, and when glowing blow out the lamp. The wire will continue to glow. A few trials will soon show the best size of flame and height the spiral is to be held. The result depends upon the power platinum has of condensing gases upon its surface, and bringing about their union—in this case, the spirit vapour and oxygen of the air; in Mr. Fletcher's experiment, gas and oxygen. The vapour of ether can also be made to unite with the oxygen, by pouring a few drops of ether into a tall ale glass, attaching the spiral to a card, making the spiral red hot, and then immersing in the glass. Some years ago, Prof. Dobereiner, of Jena, invented a lamp in which a stream of hydrogen was made to impinge upon a ball of spongy platinum. The union of gases was so rapid as to make the metal white hot and inflame the gas. It is said that gold and palladium possess a similar property. I have not tried these; but the first-named experiment has been a common one with me. I give it, as many may like to try the experiment where gas is not comeatable.—R. P.

[52178.]—**Combustion without Flame.**—The experiment referred to by your correspondent is one of many which collectively prove without question that flame is not only unnecessary for combustion, but its existence is a proof of sluggish combustion, low temperatures, and a low available fuel duty. It is possible to burn any fuel perfectly without flame with proper appliances. The experiment referred to was one devised to show clearly on a lecture table the possibility of burning a fuel extremely liable to make black smoke, without any flame or visible sign of combustion further than the intense heat, and also to show the difference in temperature produced by the same fuel with and without flame. The appliances necessary are a bundle of fire iron wire waste, say 3lb. to 6lb., a large blowpipe, and a good blower. Hold the blowpipe a few inches away from the ball of wire and direct the strongest possible flame which can be obtained with the blowpipe and blower on to the bundle of wire. When fully hot, pinch the gas supply pipe for an instant so as to extinguish the flame and let the unburnt mixture of air and gas be driven against the white hot wire. The heat suddenly rises, and in two or three seconds the wrought-iron wire fuses and runs into drops and, except this intense heat, not a trace of any signs of combustion can be seen. I have produced the same result with lumps of red-hot firebrick, both alone and mixed with coal slack. The latter appears to "evaporate," becoming converted directly into heat without the intervention of a trace of flame. This flameless combustion is utilised in my injector furnace, in the body of which no trace of flame can be seen when it is hot, and its practical application in many ways is possibly only a question of time. One application of it as an auxiliary to melting furnaces for coke, will be treated in a paper I have now in preparation for a lecture on the use of gas as a labour-saving agent in mechanical trades, a report of which no doubt will be published in the "E.M." before the end of the year.—THOS. FLETCHER, Warrington.

[52183.]—**Legal Settlement of Real Estate on Wife.**—If you settle the property on your wife and you were afterwards to get into debt, as you suggest, your creditors could not come on to her for satisfaction of their claim if you were free from debt at the time when you made the settlement. You say you were free from debt at the time, so I should advise you to do as you suggest—give it to trustees without power of sale, and they to pay her the rents, &c.—J. R. PRIDHAM.

[52188.]—**Lubricating Oil for Lathes.**—The neat's-foot oil, treated in the way mentioned by "Cressington," with a few bits of lime, and exposure to the light, will certainly be a very excellent lubricant; but anyone who wants a really good lubricant, should get hold of a good sample of neat's-foot oil, place it in a clear glass bottle, and shred into it a number of clean lead shavings. Then hang that in the sun for weeks, or until it is wanted. The lime acts more quickly in removing any free acid; but the action of the light, combined with that of the lead, produces the very best lubricating oil that can be obtained. Sperm may be served in the same way.—NUN. DOR.

[52189.]—**Transparent Varnishes for Glass.**—Add any desired pigment of the transparent class to the best white paper varnish, commonly called map varnish.—NUN. DOR.

[52190.]—**Copper Extraction by the Wet Process.**—If "A Norwegian" will refer to p. 362, No. 302, he will find a longish article on this subject. On p. 267, No. 298, he will also find an account of the process patented by Prof. T. Sterry Hunt and J. Douglas.—NUN. DOR.

[52191.]—**Equal Increments of Temperature.**—The expansion of liquids is very irregular, varying with the liquid and the temperature. A few liquids like mercury expand regularly within certain limits. The expansion does not depend on the specific gravity. You will find a good deal of information on this subject in Pictet's "Eléments de Physique."—PLUTO.

[52192.]—**Musical Examinations.**—This querist will get all the information he wants by writing to the hon. sec. of College of Organists, Great Russell-street, Bloomsbury, for prospectus, which gives a list of books recommended for study. —WM. A. TAYLOR, Dundalk.

[52193.]—**Telescopic.**—I think most of the statements made in my paper, read before the Liverpool Astronomical Society, are supported by the actual experience of observers. Possibly, though, a little further explanation may render my meaning clearer. With regard to magnifying power and aperture of telescope, I ventured to express some dissent from the usual ideas about 100 to the inch. It may do for moderate apertures, but breaks down utterly when applied to extreme cases, like many other empirical formulæ. Who would dream of using 100 diameters with 1in. o.g., perfect though it might be, on a double star? Theoretically it should be possible, but practically it would fail from want of light. Again, would the Washington 26in. o.g. bear a power of 2,600 diameters, or Mr. Common's 37in. speculum a power of 3,700 on stars? I believe not. The atmosphere is the great limit of magnification in telescopes. With regard to Jupiter, Saturn, and Mars, I found that powers of 200 to 250 suited the first-named best, with 4in. o.g., 5in. o.g., and 11¼in. speculum. But, of course, far more *detail* is seen in the larger than in the smaller instrument, with the same power. Saturn, with me, will bear a higher power than Jupiter—I have sometimes used 500 on it with good effect with the 11¼in. The sketches of Mars alluded to were those made by Mr. Green at Madeira; and the others with the 26in. Washington o.g.—both at the same opposition of 1877. Mr. Green's telescope was a 13in. reflector, and nearly the same powers were used on each instrument. The results may be seen on comparing together the plates on p. 13, Vol. XL. R.A.S. "Monthly Notices"; and p. 138, Vol. XLIV. R.A.S. "Memoirs." *Why* certain powers should be best suited to certain objects, is beyond my power to explain—I only know it *is* so. As to the apparent contradiction between the views expressed in the above paper, and those contained in the "E. M." of Feb. 23, 1883, I entirely fail to see it. When I spoke of "a large reflector with as high a power as the atmosphere would bear," I alluded to those usually found in the hands of amateurs, of from 8in. to 15in. or so of aperture—not imagining that I should be understood to mean reflectors of 3ft. or 4ft. diameter; nor did I intend to convey the idea of 100 to the inch, or anything of the kind. Powers of 200—400 diameters would be most useful. In reference to single lenses, I have had little experience; but a friend of mine tells me he tried experiments with both convex and concave single lenses, on a first quality 2½in. o.g., some 15 years ago, and, though they did give a very little more light, they were much inferior to a good Huyghenian eyepiece, on the whole. I daresay it might be possible to get a view of Saturn's belts with the aperture and power mentioned, as Grover has seen them with 2in., but it requires an exceptionally keen eye. I would strongly recommend my querist to get a good Huy-

[52225.]—**Raising Steam by Gas.**—At a meeting of persons interested in gasmaking the other day, it was stated that unpurified gas for heating purposes could be made at a profit at 1½d. per thousand feet; this result had been arrived at by a series of experiments. I should like the opinion of the readers of this journal as to whether it is practicable or not to use such gas in the furnace of an ordinary two-flued Lancashire boiler in place of solid coal? Of course, an intensely hot flame would have to be produced by mixing the gas with air—blowpipe manner. It seems to me if this could be put into practice, we need not have our long chimneys here blackening everything with their smoke—and without any increase of expenditure. There are readers of this paper quite competent to take this matter in hand, and I should be much obliged if they would give their ideas on the subject.—Kunst Macht Gunst.

[52226.]—**Equatorial Motion.**—I thank Mr. Vallance for his description of equatorial motion, letter 21933. I intend adapting it to a 10in. Calver altazimuth reflector; may I therefore ask for a little further information, viz.—Is it necessary for the tube to be "carried on a wheel," if so, how is it fixed? And I cannot clearly define the position and working of the meridian string.—Lox.

[52227.]—**Vacuum Brakes—L. & N.W.R.**—Would some of your numerous correspondents be good enough to tell me whether the vacuum brake that has been fitted to the coaches of the above line is automatic or not, as the moment the driver creates a vacuum it stops the train without him opening the valve on the engine? Also, whether there are gauges in the guards' vans? And is it the same that is used on the L. & S.W.R.?—H. W. Hudson.

[52228.]—**Electro-Magnets.**—I wish to make an electro-magnet with soft iron wire as the core. The wire I have is known as fine tying wire, and is covered with a coating of plumbago. I wish to know whether I had better put it into the fire and heat it so as to burn the plumbago off and soften it still more if possible; and also what shape I should bind it up. Will it be better to keep it in a round bundle in section or rectangular? Also are bobbins absolutely necessary? If I cover the limbs with brown paper paraffined or shellacked, and wind the covered wire on that, will not the arrangement answer as well as bobbins? I hope no one will waste space by telling me that soft bar iron is the proper thing to use. I do not want to know that, but the best way of making an electro-magnet, with wires for the core. I shall be obliged for information on the points indicated.—S. R.

[52229.]—**Induction Coil.**—Will Mr. Lancaster, or someone, kindly advise me? I have to light three gas-jets with an induction coil. I have run the leads in cleats, the wires being a full inch apart, and yet I get sparks as if they were in dead contact. The coil has a condenser. Has this anything to do with it?—Young Electrician.

[52230.]—**Legal.**—To Mr. Wetherfield.—I have for years had my life insured for £1,000, and have by this time paid up the amount in premiums. Can I by deed of gift, or otherwise, so make it over to my wife that at my death she may have it free from all legacy and probate duties?—An Anxious Husband.

[52231.]—**Self-Closing Door.**—Will anyone send description of contrivance for closing a door? No weights.—Chemicus.

[52232.]—**Brass Polish in Liquid.**—Can any reader give me the recipe for a good brass polish in liquid—one that will give a brilliant polish without injuring the metal?—F. W.

[52233.]—**Boiler Feed from Cistern.**—Will any brother subscriber kindly enlighten me as to the head of water necessary for the feed-pipe of a boiler for steam supply to a large cooking apparatus? Valve set at 5lb., and boiler fed by ordinary lever valve and float stove.—Putloo.

[52234.]—**Electrical Measurements.**—Will some of your many talented readers oblige by working out a scheme of electrical measurements as applied to a dynamo, so that I, and I suppose some others, can follow the working? I know the meaning of volts, ampères, ohms, coulombs, and so on, but think I should get a better grasp of them if I had but one practical instance of their application as a guide. I hope this is not too much to ask.—A Private in Electricity.

[52235.]—**Manganese Battery.**—None of the books available to me state the strength of the salammoniac solution for the manganese cell. Should it be saturated? Mr. Sprague's book says about 2oz. to the cell, but does not state the size of the cell.—Herne Hill.

[52236.]—**Combining Weights of Tartaric Acid and Bicarbonate of Soda.**—Will any reader explain the method of calculating the combining weights of bicarbonate of soda and tartaric acid?—Cabino.

[52237.]—**Jointing Material to withstand the Action of Soap Lees.**—We have a little trouble with some of the joints of our newly-laid suction and delivery pipes from a set of pumps used for pumping lees in a soapworks. The lees consist of dissolved caustic lime and caustic soda, and caustic potash, which causes some of the joints to leak? The pipes are screwed wrought iron, properly put together (as for steam), the threads were filled in before being put together with a mixture of red and white lead, and small quantity of hemp gasket laid in threads. I should be obliged to any correspondent who would kindly tell me of a better jointing material to withstand the action of lees in joints of screwed piping. For joints in flange pipe we use indiarubber, which answers perfectly. We also have some trouble with a few joints in the steam-pipes (chiefly at the backnuts) where the pipes unavoidably have to dip, and water accumulates at times when the pipes are not in use. We use lees in steam boiler to prevent incrustation. Would that have anything to do with leakage in steam pipes?—C. J. R.

[52238.]—**Induction Coil.**—To Mr. Lancaster.—Will this, or some other experienced gentleman, kindly tell me where I have gone wrong? Core of No. 20, 9in. by ¾in.; primary, 2 layers of No. 16 s.c.; ebonite tube secondary, 2½lb. of No. 36 s.c., wound barrel-shape in two sections, each layer insulated with hot paraffin and paraffined paper; condenser, 82 sheets of foil, effective area of each 6¼in. by 8¾in., and paraffined paper. Attachments: One standard of reel commutator to screw of break, the other to primary, and the springs to battery terminals, the other end of primary to the hammer; condenser, one part to each of the two parts of the break. Using five round Bunsen cells with 7in carbons, I get (without the condenser) a good ¼in. spark;—with it, none whatever. Are the connections right? Is the condenser too small or too large?—X. U. C. L.

[52239.]—**H.P. of Engine.**—Will any reader tell me the h.p. of my engine with the following dimensions? Length of stroke 4in., diam. 2in., piston making about 50 strokes per minute; pressure of steam 10lb. as indicated by boiler gauge. There is about 1 16 lead, and the port is ¼in.—A. G. B. W.

[52240.]—**Stone-Polishing.**—Would some reader kindly describe the bench and tools used in the shops—especially as regards the velocity and fixing of the saw?—Lapis.

[52241.]—**Defective Ejector.**—To S. Austel, "Glatton," and "Labor Omnia Vincit": Many thanks for your replies to my last query about defective ejector—having got it to work all right now by putting into it a new cone a little longer than the one it had when I took it in hand, lifting the water immediately steam is turned on, I would also ask you kindly to work out the following? What is the bursting pressure of a railway wheel press, diameter of which is 7in. Thickness of metal (cast iron) 2in. I saw one give way recently having the above-mentioned dimensions, with only a pressure on of three tons per square inch, and by Molesworth's formulæ it ought not to have burst at anything like three tons pressure. It was broken up to see if iron was defective, but was found to be made of very good iron. Now please explain, also, what is the pressure that engine wheels of 3ft. diameter are generally forced on axles by press, and where could I get a working drawing of one suitable for engine wheels from 2ft. to 3ft. diam.?—Hombre.

[52242.]—**Legal—Deferred Agreement for Lease.**—A. takes a farm for 12 months, with a stamped agreement for a seven years' lease at the end of the 12 months. B. refuses to grant the lease, as he says A. has not fulfilled the terms of the original agreement—nearly three years having elapsed since A.'s entry on the farm, can he now take proceedings to get a seven years' lease from B.?—Alton.

[52243.]—**Lifeboat.**—When will there be a lifeboat exhibition? Is there a lifeboat in use with wheels and axles for horse or horses to draw to the water's edge or along the beach or shore instead of the common process of mounting it on a "lorry," and dismounting it to launch it? If so, where can I see it?—Grace Darling.

[52244.]—**Analytical Theories.**—Of late years physical theories have been presented in very abstract mathematical formulæ in such works as Murphy's "Electricity," Fourier's "Theory of Heat," &c. I would wish to know whether the fundamental application of mathematics in such works proceeds on demonstrable principles like those in dynamics (which I doubt can be possible), or whether it depends on empirical results—results obtained by taking a formula at random and finding by experiment that it holds good in a certain number of cases, and hence concluding that it holds good in all cases.—Synthesis.

[52245.]—**Lever Watch.**—After cleaning the works of a lever watch I am unable to put the chain on fusee and barrel properly. Full instructions how to proceed will greatly oblige. I can get the chain on in such a manner that it will only wind up half the length of the chain. I tried a second time and got it on so that I could wind it fully on the fusee, but it stopped when half the length of the chain was wound on barrel from fusee.—G. Fryer.

[52246.]—**Payne's Battery.**—With regard to letter No. 22028, p. 221, I shall be much obliged to Mr. Payne if he will give a description of the battery he alludes to, also the number of cells required to work a two-candle power incandescent lamp? I presume the new cell requires about the same attention as one of the ordinary Leclanchés.—Thos. J. Inkster.

[52247.]—**Photographic.**—(1) Can someone describe the process by which microscopic photographs are made? I do not mean photographs of microscopic objects, but photographs that are themselves microscopic. I have not seen a description of this anywhere, and do not understand how a film is made of sufficient fineness to show such detail. The development, too, must present great difficulties. (2) What is the theory of the action of the alum bath?—Calculus.

[52248.]—**Trustee—Retirement under a Will.**—Testator died 12 years ago, leaving widow and one son, and all his real and personal property in trust, widow to have the interest therefrom until son attained 21 years, son then to have a portion of the interest paid to him quarterly, and the remainder to widow, and after her decease the whole of the property to be the son's absolutely. Now the widow and son still live, and son above 21, and the trust all square up to now, and I, as one of two trustees, desire to retire, and have notified widow to that effect, who, according to will, may appoint another; but she refuses to release me unless the other trustee retires, and he won't. I have always been the acting trustee, and have had enough of it. Now can I by law enforce the widow to release me, and how shall I proceed, and at whose cost will it be? The son is of drunken propensities, and I want to get clear of him and the trust.—Trustee.

[52249.]—**Chromograph.**—Will any correspondent who has actual experience state the mode in which the paper sheets sometimes used in lieu of the dish of jelly are prepared, giving the proportion of ingredients and mode of manufacture? Also the most approved mode of making the jelly? Also a practical recipe for preparing the multiplex aniline ink for the chromograph? Recipes for this have been given in back numbers, but I have not found them answer. I have tried in vain aniline crystal powder, 1oz. by weight with 7oz. by measure of water, and one of methylated spirit, but the recipes did not specify the exact nature of the aniline to be used, whether it was to be powder or fluid, nor whether it was to be weighed or measured. One recipe for "copying aniline ink" recommends the addition of 1½oz. of glycerine to the pint of ink; but this appears to be for common copying ink, yielding one copy only—not the multiplex ink to be used with the chromograph.—S. M. C.

[52250.]—**41 Arietis.**—As a quadruple star I find this in Proctor's smaller atlas, and in Letts's maps, but not in Webb's last ed. of "Cel. Obj." as such. Can any one direct me to it in this book, or give me magnitudes, angles, and distances?—J. C. L.

[52251.]—**The Sun and its Markings.**—A friend of mine has a telescope with very good o.g. 1¾in. diam. He persists in stating that he can see with it the "rice grains" appearance on the sun. Is this possible?—J. C. L.

[52252.]—**Bunsen Burner.**—(1) What is the proper shape and size for the orifice of a Bunsen burner? (2) Any advantage to have it of platinum? (3) Can reducing and oxidating flames be produced, as with a blowpipe, and how?—Thor.

[52253.]—**Spectroscope.**—Names of a few books on analysis by means of the spectroscope would be esteemed. Also replies to the following:—(1) Are the "rainband" spectroscopes suitable for analytical purposes? (2) If not, can the latter be obtained in the convenient size of the former—i.e., a small tube 3 to 4in. long? And (3) where are they to be had?—Thor.

[52254.]—**Lantern.**—In Pepper's "Cyclopædic Science Simplified" is illustrated a lantern for showing opaque objects—photographs, hand, face, &c., by reflection. As the description given is not quite sufficient for the making a lantern, would any kind reader oblige with the information? Can a surface as large as a man's face be illuminated by an ordinary-sized condenser? Size of screen about 10ft.—H. L.

[52255.]—**Parian Cement.**—I should be greatly obliged if some of your correspondents would inform me what is added to the sulphate of lime to form the above? I believe the patent has terminated some time since.—Finch.

[52256.]—**Brush Dynamo Machine.**—Will "Light" and "W. H. E." accept my thanks? I have acted on the advice of the first mentioned (Oct. 26th), and have connected A coils up in the way he explained, and find my machine will work, but not as well as I expected. In the first place, I connected a small Brush lamp up with the machine: this only gave poor results. This lamp will give a light of 30 c.p. on another machine made by Oppermann Bros., so the lamp is not at fault. I disconnected this and joined all coils up to brushes and started machine without any shunt, and found the energy so strong that 1 h.p. would barely turn "A" in this way, then connected a 15 c.p. incandescence lamp up as a shunt, and it gave full light. On adding another on same wires, the light fell to only 5 c.p. for the two. How can I alter this? The old two pieces on commutator I've replaced by straight ones, as well as new brushes made from No. 16 brass wire? The speed of my machine is from 1,400 to 1,500 revolutions per minute. If I join my wires up on the Gramme principle, shall I get any better results? Will "Light" or "W. H. E." kindly advise me on the above?—Williams.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 14, and unacknowledged elsewhere:—

NOTES BY MR. RUSSELL.

(a) In a recent number of the *British Chess Magazine*, Mr. W. T. Pierce recommended this move as superior to the usual continuation 8. Kt-Kt 5. In his able analysis, showing that this move results in a good game for White, there was one weak point—viz.: 8. $\frac{\text{P takes P}}{\text{B takes Kt}}$ 9. $\frac{\text{P takes Kt}}{\text{B takes B}}$ 10. $\frac{\text{Q takes B}}{\text{Q takes P}}$ 11. $\frac{\text{Kt-R 3}}{\text{Castles}}$, where Black has undoubtedly the better game. White's next move is a successful attempt to improve on this faulty variation.

(b) B-K 3, keeping White's Pawn isolated is perhaps better; but Black was afraid of the reply 11. Kt-K 4.

(c) Temporarily confining the White K B.

(d) A lost move, since White cannot capture the B P without subjecting himself to a powerful attack; a preferable continuation is 12. $\frac{\text{P-K B 4}}{\text{Castles}}$ 13. $\frac{\text{B-Q 3}}{\text{P-K B 4}}$ 14. $\frac{\text{Castles (K)}}{}$

(e) Injudicious, in view of the disposition of Pawns on his Queen's flank. Castling should be performed on K side as indicated in last note.

(f) A dangerous-looking move; but Black has no alternative, as otherwise White will play P-Kt 4 next move, followed by P-K R 4, and the phalanx of Pawns will bear down on K with deadly effect.

(g) A better line of play is 16. $\frac{\text{B-Q 3}}{\text{Q takes B}}$ 17. $\frac{\text{Q takes Q}}{\text{B takes Q}}$ 18. R takes B, followed by B-R 6 and Q R-Kt 3, and White has a good game.

HINTS ON CARPENTRY.—III.

CLOSE JOINTS.—Most, or rather all young hands experience the difficulty of making a close and accurate fit of the various parts of their handiwork. If it were easy to imitate skilled professionals in this respect, a tedious apprenticeship would not be required. But there is, in reality, no wrinkle—not even that suggested in a recent letter—that will prove satisfactory. The first requisite is an intensely sharp paring chisel, and a fine clean-cutting tenon saw; or, for very light work, the smallest mitring saw, which is generally made with a straight handle of boxwood, and not over 5in. or 6in. long. The teeth are fine, and barely set at all, and the cut made is almost as smooth as would be formed by a knife. These saws are just suited for picture-frames, and specially for Oxford frames. Another very handy saw is a fine fret saw set in a steel frame and called a piercing saw. I do not mean a fret-saw frame, which is much larger and heavier, but a small adjustable one such as are imported from Germany. They come into use for many small jobs, and are very inexpensive. Any fret-saw blades will fit them, and if they get broken they are easily replaced. Many will cut brass as well as wood, and answer capitally for nicking small screws. I have cut through a bit of mahogany an inch square and more without a break, and very quickly. The great difficulty is accurate sawing, and where it can be used there is no objection to "A.'s" plan of insuring a straight cut by making a groove with a knife; but there are many cases in which such a tool would be of little use—notably, in cutting dovetails, where the cuts do not go across the entire piece, but are disconnected.

I must, however demur to "A.'s" rounded tool edges. A hollow-ground tool is far easier to set on the hone, and is altogether superior to a convex-edged one. As to a guide to hold the tool during the grinding, no practical workmen use them; and it must be remembered that although the tool is to be held steadily at the given angle, it should be made to traverse from side to side across the stone, in order to prevent the latter from wearing hollow in the middle.

The lighter and smaller the job, the greater, as a rule, is the difficulty of accurately fitting the joints, because it is more difficult to square up the edges of a thin board than a thick one. You can apply a square to the latter and at once detect any roundness or convexity; but it is difficult to see it with a very thin bit of stuff. As a light job, a stamp box is a good one to work at. The olive-wood ones are beautifully neat, and the corners are jointed in a peculiar way, but a very strong one, allowing the outside angle to be neatly rounded. It is far superior in strength to a mitre joint. Looking down upon the edge of the open box, it will be seen to be like Fig. 6, A B; but the drawing is, of course, a much enlarged one. The ends are rebated like C, and the front and back grooved like D. In all boxes in which there is a deep cover similar to the box itself, it is as well to glue up the stuff wide enough for both box and cover, and then to mark it round with a gauge and saw it in two, thus separating the cover; the edges will need planing with a finely set and very sharp plane. There is more likelihood of making a good fit in this way than by making box and cover separately. There is still difficulty—and perhaps neat squaring of the edges is the worst of it; but careful paring with plane or chisel, supplemented, if needs must, by a file, will accomplish the task; and if sandpaper is used for a final touch, let it be wrapped round a flat chisel shank or bit of wood, so as to save the edges of the work from being rubbed off. They must be left as sharp and true as possible. Suppose it is required to make a box with similar joints, the first job is to clean up with utmost care, and with sharpest of planes, the bit of board of which it is to be made, and which may be ¼ stuff for a box not over 6in. long; and I may mention that as a rule it will be better to make the ends of an oblong box thicker than the sides, though this is not absolutely essential. In a very small box it is not necessary, and in a dovetailed one it cannot be done—i.e., if the joint is a *simple* dovetail, because it would appear as Fig. 7, A. But with such a joint as that last mentioned and illustrated there at B, or with a rebated dovetail, C, it can be managed satisfactorily. In the plain dovetail, A, of 45, a mitre block is used to shoot the edge; but the surface in small work may be also made true by a sharp chisel to gauge lines accurately scribed, as H of Fig. 8. The mitre shooting board is made like Fig. 8, A D; D is a piece of well-seasoned wood forming the bottom board; A a block with an accurately planed face at 45° to D, and firmly screwed to it; C is a stop block, B the board to be planed to a mitre at *e*. The plane is laid on its side on D. Attention must be called to *b c*, the small perpendicular face of the block A. This is necessary, because the plane iron does not quite reach the sides of the sole, and therefore would not cut the wood quite to the bottom of the face *e*, if the part *b c* were not so made as to lift the wood slightly off the base board D. The main difficulty here is, that the mitre has to be planed across the grain of the wood; and however well the plane is set, the edge of the wood next to the stop is sure to be torn slightly.

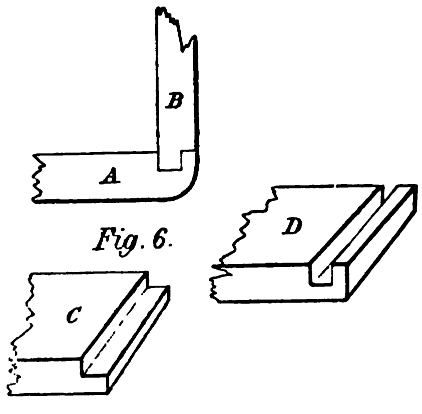

Fig. 6.

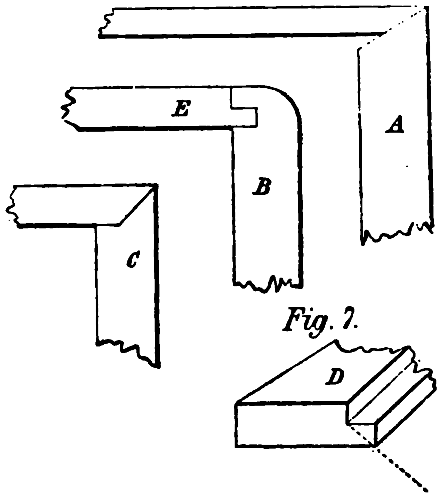

Fig. 7.

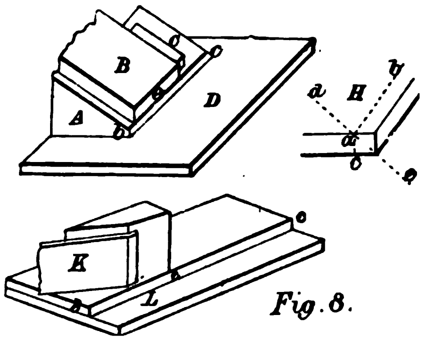

Fig. 8.

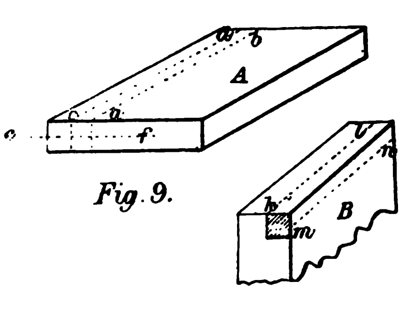

Fig. 9.

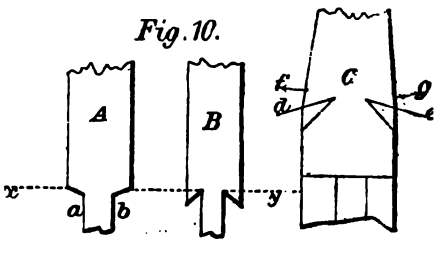

Fig. 10.

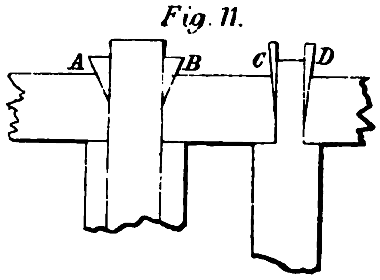

Fig. 11.

The remedy is to leave the wood wide enough to allow such torn part to be subsequently edged up true. But it is also possible to make the mitre board so that the plane will cut the way of the grain, as shown below; but in this case the width of the work is limited to that of the plane iron. This is shown at K L of the same figure, in which it is seen that the board to be planed stands on edge against its block. In this form, the face *b c* is formed by a separate board, screwed to the lower one. In both cases, this face serves not only to bring the entire surface to be planed into contact with the plane iron, but it also prevents the latter from damaging this face or that of the block, as the wood of the sole of the plane outside the corner of the iron rests against it. The wood to be cut is gently advanced after each shaving is taken. In H of this drawing I have shown how to gauge and saw, and finish with the paring chisel, any light piece of mitred work. The line *a b* is gauged at a distance from the edge of the board exactly equal to its thickness, and the piece is cut on the line *de*. This forms a perfectly accurate mitre, easy to make. To make such a joint as that shown at B of Fig. 7, set a marking gauge to the thickness

VOL. XXXVIII.—NO. 974.

meteorological conditions; but from a series of observations extending over three years, Miquel estimates the number of "germs" per cubic metre of air as 44 in winter (Dec.—Feb.), 76 in spring (March—May), 76 in summer (June—August), and 134 in autumn (Sept.—Nov.). Rain, he finds, cleanses the air; but humidity is an obstacle to the diffusion of bacteria, which is promoted by prolonged dry weather, with this result, however, that a very long continuance appears to rob the spores of their powers of reproduction in the liquids usually employed for their cultivation. The direction of the wind has some effect on the numbers of microbes found at Montsouris, N. and N.E. winds naturally increasing the numbers, as the observatory lies to the south of the city. As Paris is approached the number of germs increases enormously, until in the centre of the city the comparative figures are 462 as against 45 at the park of Montsouris, though it is noticeable that air taken at the height of the lantern on the Pantheon gives only 28. The same kind of increase is noted when dry dust such as falls on furniture is examined, for while one gramme yielded 750,000 at the observatory of Montsouris, a similar quantity in the outskirts of the city gave 1,300,000, and in the heart of Paris 2,100,000, the proportions of the different species varying at the same time. Thus in Paris more than two-thirds were micrococci, while at Montsouris more than two-thirds were bacilli. The vitality of the germs, gauged by their reproductive power, is greater in those found in deposited dust than in those which have been blown about by the wind; but although less numbers are found in the air of sewers, owing to the natural humidity of those places they are far more active, and consequently more noxious. Amongst the microbes found by Miquel in various specimens of air and dry dust obtained in different parts of Paris, it is curious to note that although the total number found in sewer air is less than in dwelling rooms, in the streets the percentage of bacteria is 26, as compared to a mean of 5 in nine other specimens, the air of the streets containing the largest percentage of micrococci, while that of the inhabited rooms contains about equal quantities of bacilli and micrococci. Not much is to be made out of that fact, though, for unless hard-and-fast lines are laid down, it is not always easy to separate bacteria or microbes into the groups above defined. In the park of Montsouris, 24,000 microbes were deposited on a square metre in 24 hours; but in the laboratory this number was multiplied by 100, which suggested to Dr. Miquel the advisability of ascertaining which was the most powerful antiseptic. He found that in peroxide of hydrogen, or oxygenated water, which, being obtained by the baryta process, was considered absolutely harmless. Five centigrammes of that, added to a litre of bouillon, stopped all fermentation promptly, as did 25 centigrammes of iodine, 60 of bromine, 320 of carbolic acid, 350 of permanganate of potash, 750 of boracic acid, and 1,000 of salicylate of soda. These quantities are rather too much to suggest that the last two substances might be used as preservatives for food, but if soup can be preserved by the addition of a little oxygenated water, a useful hint may be found in the discovery of the French *savant*.

The difficulties of making accurate estimates of the number of microbes in the air of different places are well known; but probably no better method of setting about the work could be devised than that adopted by Dr. Miquel. Strips of glass smeared with glycerine have been used by some experimenters; others have used the method of washing the air contained in a large bottle; but these, like the simple plan of exposing sterile putrescible fluids to the atmosphere, serve only to demonstrate the presence of germs, without conveying any adequate idea of their number. Dr. Miquel takes a piece of glass tube about 7in. or 8in. long, one end of which he seals hermetically, and closes the other with a plug of glass wool, which, like cotton wool, filters the air, it is believed, completely. In the centre of the length of this tube, however, he places another plug of the glass wool, and the whole being placed in a furnace, is subjected to a temperature of between 572° and 752° Fahr., sufficient, it is believed, to destroy every living germ. The tube is then placed horizontally some distance from the ground, and air forced into the tube through the middle plug, the hermetically closed end having been broken to make the connection. The air in passing through the plug of glass wool leaves the germs behind it, and the tube can then be resealed for examination at leisure. The middle plug, which contains the germs of the air it is desired to examine, is washed in sterilised water, and that is then put drop by drop into a number of flasks of sterilised nutritive fluid. If the liquids contained in these flasks (which should be protected from the external atmosphere) remain clear, it is tolerably certain that the air was free from germs; whereas if a number of them show signs of microscopic life, it is usual to allow one germ to each flask, and, the quantity of air being known, to estimate the number of microbes by a simple multiplication sum. Prof. Tyndall, it may be remembered, made a series of experiments on mountain air, and arrived at the conclusion that the atmosphere at high elevations is remarkably pure and free from germs, and the more recent experiments of Prof. Freudenreich support that view. The observations made by Prof. Giacosa, of Turin, on the Monte Murzo last year, however, would appear to indicate that bacteria are always present even in mountain air; but there is much reason to believe that in his case the test liquids were not properly sterilised, and showed signs of life simply because germs had obtained a lodgment in them before they were exposed. Be that as it may, the results of Prof. Freudenreich's observations on the air of the Swiss Alps confirm those already obtained by other experimenters, for as a general result specimens taken at heights of from 2,000 to 4,000 metres above sea level (say 6,600 to 13,000ft.) were found to be free from germs; at Lake Thun the proportion was found to be 0·85 per cubic metre, and at the town of Thun in free air 2·1, confined air 60. Prof. Freudenreich's samples were taken from the summit and the foot of the Eiger, on the top of the Schilthorn, and on the Strahlegg, all of which are more than 2,000 metres above the sea. Lake Thun is 560 metres, and the town 600 metres above sea level: hence it follows that the air over water is purer than that of towns at a higher elevation. Comparison experiments made at the observatory of Montsouris and in the Rue de Rivoli, Paris, give 760 and 5,500 microbes respectively to the cubic metre of air. A cubic metre is, however, a very small quantity of air, and it is obvious that before the question can be considered as definitely settled, a more extensive series of experiments, on a much larger scale, must be carried out. It is, however, already established beyond dispute that the air of towns and that which can be found in such apartments as the laboratory of the Montsouris observatory is, compared to that of even moderate elevations, heavily charged with microbes, the great majority of which are, happily for us, innocuous, and especially so when the wind can blow them about as it pleases. Hence, considering the number found in the dust of rooms, it is desirable to remove that without spreading it about, and also to provide for free ventilation.

PATTERN MAKING.—XVIII.

Sheave Wheels (*continued*).

A SHEAVE WHEEL recessed for alternate links of a chain can be made by pattern or core box. It requires almost as much care in pitching out as a spur wheel, because if there is a slight error in the pitch, that error increases with each successive link. Thus, when we commence to lay the chain in, suppose we find the recesses are $\frac{1}{16}$in. too far apart, the error will not remain at $\frac{1}{16}$in. all the way round the ring, but will be an $\frac{1}{8}$in. in the third recess, $\frac{3}{16}$in. in the fourth, $\frac{1}{4}$in. in the fifth, and so on, so that by the time we had got half-way round a large wheel no reasonable amount of clearance between the links and their recesses would prevent the chain from riding out of place. In pattern wheels we can always insure accuracy by roughing out the recesses to a slightly larger diameter than we deem necessary; and then, trying the chain in, gradually reduce the wheel until the chain fits neatly all round. But when a wheel is made with cores we have not this chance, and then we must take especial care in getting the exact pitch of the links first of all, and in transferring that pitch to the drawing from which the core box is to be made. Measure off the total length of a definite number of links, and divide that total length by the number of links measured; this average will be the pitch of the chain, which we forthwith transfer to our drawing-board. Working thus we shall not find our wheel at fault after it is cast. Some clearance is allowed sideways and endways for the links, say $\frac{1}{8}$in. all round, and the recesses are worked out of the solid with gouge and chisel, in pattern and core box alike.

In all other respects the directions we have given for the making of plain sheave wheels will apply to these as well.

A common rope wheel is similar to a plain sheave wheel, with the exception that its inner sides are inclined at a somewhat acute angle to bite the rope in the bottom of the groove. This object is sometimes also assisted by little semicircular bits, or nibs, pitched at regular intervals, and standing a little above the groove. Be the rope wheels large or small, the same methods of making the patterns will be adopted as in the previous examples.

But there is a modification of this form which is sometimes used, and which is somewhat puzzling at first sight—I mean the wave-wheel form. It is a rope wheel, in which the rim, instead of continuing in one circular plane, as in ordinary wheels, is bent or *waved* in serpentine fashion—the object being, of course, to increase the friction of the rope, and thus prevent it slipping.

This is a device which is seldom adopted in small wheels, and therefore it is so seldom necessary that a complete pattern should be made thus that we shall only consider it as applying to a wheel made entirely with cores. The remarks we previously made as to the method of procedure to be adopted in the preparation of the core-boxes will be applicable here until we arrive at the working out of the internal blocks. Then our difficulty will be to insure that the metal in the rim shall be of uniform thickness throughout. If we go working away at the curves at random, trusting only to the eye for accurate results, we shall probably find a variation of an eighth or a quarter-inch in the thicknesses of different portions of the castings.

So we work in the following way. Draw in elevation a segment of the wheel, equal in length to the intended cores, Fig. 96, A, B. Draw also lines on this view to the wheel centre, at the pitch distance of the wave—viz., at these points where it attains its greatest deviation from the plane of the wheel. Draw a portion of the rim with the width of the core box besides in plan, Fig. 97, and carry the lines representing the pitch across it. At these points draw sections of the rim in its extreme positions *relative to the sides of the boxes*, Fig. 98. Between these extreme deviations of the wave draw other lines at pleasure (not shown on engraving), projecting these to the plan and drawing corresponding sections, also in relation to the sides of the core boxes. Then making templets to the inside and the outside of the rim, all we have to do is to work narrow portions of the rim at the distances from the edge indicated in the sections, and to shape the intermediate portions with gouge and chisel as regularly as possible. If this is done care

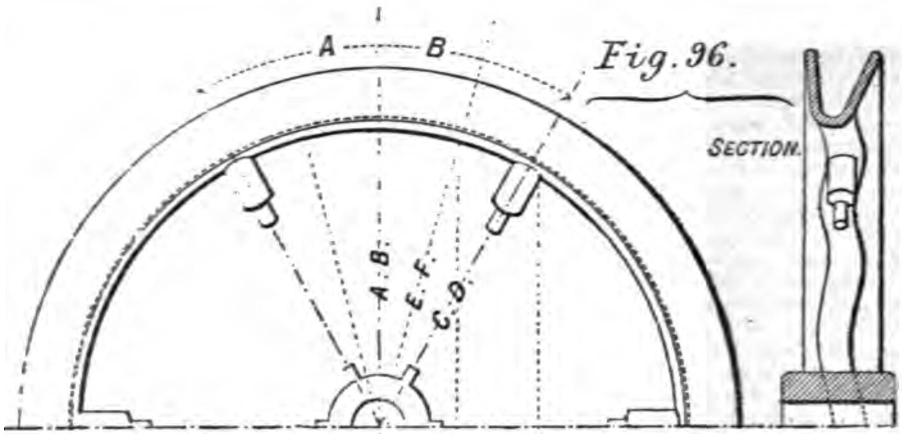

Fig. 96.

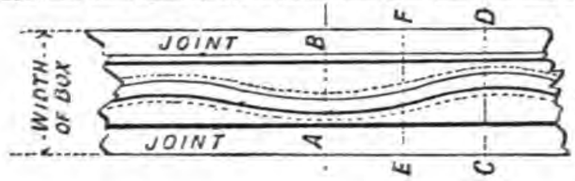

Fig. 97.

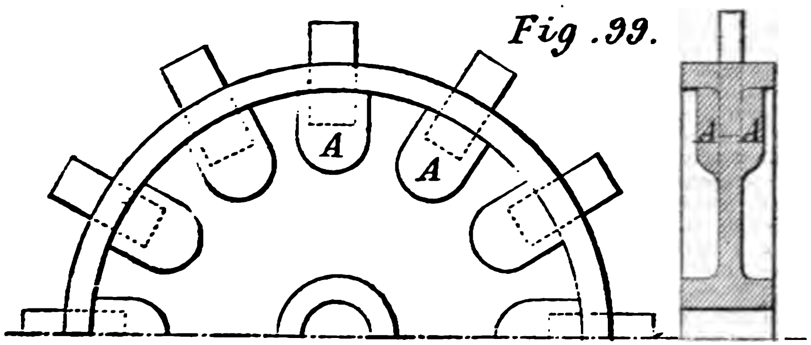

Fig. 99.

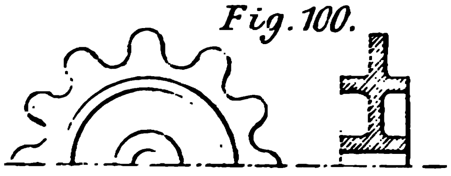

Fig. 100.

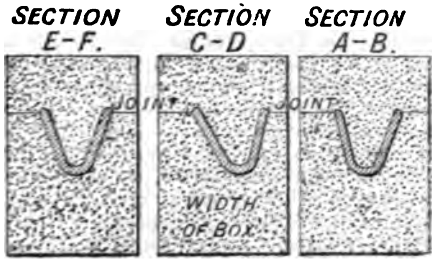

Fig. 98.

fully, there will be no appreciable difference in the thickness of the wheel rim when cast.

The last form of chain wheel we shall describe is that known as the *sprocket* wheel. It is a form which is in very general use for the transference of motive power by means of a "pitch chain," Fig. 99. Like the chain wheels, they require to be pitched out very carefully, else the pitch chain would ride on the projections, or "sprockets," instead of dropping over them.

These wheels are made in two forms, the first like the Fig. 99, where the sprockets are made of wrought iron and cast in the wheel body; the second like Fig. 100, in which the sprockets are a portion of the casting. In the former case they are dropped into prints, whose edges are their exact counterparts: in the latter the pattern and casting are precisely similar.

In these castings the links must fit the places prepared for their reception so nicely that it is sometimes necessary in a large wheel to throw away the first cast and make a slight alteration in the pattern, a variation in the anticipated amount of contraction being sufficient to cause an ⅛in. or ¼in. in the semicircumference. The wheel might be saved in such a case by filing a lot of clearance in the sprockets; but "fudged" work in not to be commended. The accuracy of a small casting can be depended on.

After what has been said about the building up of wheels, special remark is scarcely necessary in reference to these last named. Note, however, that a built-up plate made in two or three thicknesses or segments is better than a single *solid piece* of stuff, where the sprockets are cut *out, because stint (short) grain* and shrinkage are both avoided thereby. On this plate the two portions of the rim are built as usual.

The prints for wrought iron sprockets should be pocket prints, to be stopped over after the sprockets are placed in the mould.

Fig. 99, A A, are the boss thicknesses around the wrought iron sprockets.

THE DYNAMO: HOW MADE AND HOW USED.—VIII.*

By Selimo R. Bottone.

The Patterns.

§ 18. IN the dynamo we are about to construct, three separate pieces for patterns are absolutely necessary—viz., one for the armature, one for the legs of the field magnets, and one for the standard which supports the flywheel. There is no necessity for the amateur to put himself to the trouble of cutting out a pattern for the flywheel, since such wheels with handles already fixed can be had for two or three shillings. In constructing the wooden patterns, from which the iron castings are afterwards to be procured, the amateur should remember to choose dry, well seasoned wood, free from knots. Red pine, for such small work as is required, will be found as good as any. Any joints that are absolutely necessary (and joints should be avoided as much as possible) should be attached together with dowels and Prout's elastic glue. It must be borne in mind that the pattern-moulder places the patterns in *green* (moist) sand, and that this moisture causes ordinary glued joints to come undone or expand. Any roughnesses left on the pattern also swell up, catch the sand, and thus destroy the sharpness and beauty of the mould, and therefore of the resulting casting. It is therefore advisable, after having got the wooden pattern to the highest possible degree of smoothness and trueness by means of emery paper, &c., to give it a coating of melted paraffin wax, and polish the surfaces carefully with a roll of flannel. This renders the surfaces not only extremely smooth but impervious to moisture, so that the pattern does not warp or swell when placed in the sand. In order that the pattern should come clean out of the sand and not break away any portion of the mould, care must be taken that the edges be slightly rounded, so as to give what is technically called *clearance*. The possessor of a *lathe* can turn up many portions of the fittings with much greater accuracy and rapidity than one provided with only ordinary tools: but in the ensuing directions the amateur is supposed to possess tools of the simplest kind only.

§ 19. The pattern for the *armature* first demands our attention. When completed, it presents the appearance shown at Fig. 14, *a* being the elevation and *b* the section, on a scale of about half the real size, and consists of a wooden cylinder 1½in. in diameter by 3⅝in. in length, with a deep channel round the ends and sides. To construct this pattern, procure a piece of pine 8in. long by 1½in. wide and ¾ of an inch thick. Lay this on a table on its widest side, and draw a line along its whole length, that shall divide it into two halves of ⅜ of an inch each. Now, draw a line on each side of this central line, rather better than ⅛in. from it. Holding a metal rule against one of these side lines, with a sharp penknife, cut into the wood along the line to a depth of about ⅜ of an inch—rather less than more. Now, perform the same operation on the other side line to the same depth. With a sharp ½in. chisel, shave away the wood on the outside of the cut lines to the depth of ⅜in. on the outsides, but *rising up very slightly toward the centre*, as shown at Fig. 14 *c*. This precaution will ensure the pattern lifting out clear from the mould.

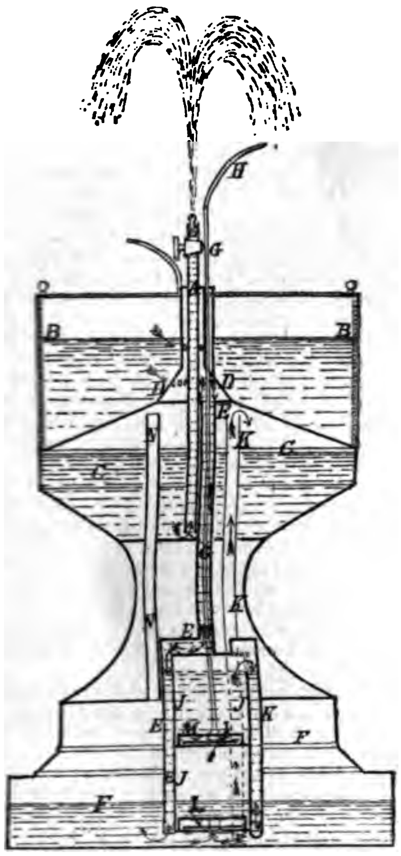
[illegible] the trough or basin [illegible] which the jet tube A [illegible] perforated to permit the [illegible] or basin B to pass into the [illegible] From the bottom of the trough [illegible] within the [illegible] D, a tube E [illegible] through the compression [illegible] and terminating near the [illegible] situated below the com- [illegible] tube serving, first, to [illegible] from the trough or basin B to [illegible] and, secondly, to allow of [illegible] pump rod G, the upper [illegible] a handle H outside [illegible] the pump works in [illegible] an opening in the [illegible] first downwards and [illegible] so as to form a U-shaped [illegible] then continued upwards, [illegible] of the compression [illegible] of the cylinder J is [illegible] a disc L, forming a [illegible] and a similar valve M is [illegible] so that as the piston I is [illegible] by its rod G, the water is [illegible] pump barrel or cylinder [illegible] valve L during the up- [illegible] downstroke passes the top [illegible] through its valve M, when the [illegible] through the U-shaped [illegible] compression chamber [illegible] connects the upper part of the [illegible] chamber C with the upper part of [illegible] chamber F, so as to allow air to pass [illegible]

[illegible] action of the pump raises the [illegible] chamber F to the compres- [illegible] compressing the air in [illegible] causing the water to be forced up [illegible] A and to issue in the form of a [illegible] spray, the duration of which will [illegible] the capacity of the compression [illegible] jet or spray continuing to play [illegible] chamber is entirely emptied. The compression of the air contained in the two chambers C and F is maintained by the water from the trough or basin B continually flowing down tube E and replacing the water issuing from the jet tube. The trough or basin B may be utilised as an aquarium, or it may be surrounded by a tray filled with earth so as to form a fernery. Instead of forming a trough or basin above the compression chamber, the water may be caused to descend directly to the lower chamber, and a small air pump or compressor be provided to compress the air in the compression chamber. Or instead of employing a pump to raise the water from the bottom chamber into the compression chamber, an air pump or compressor may be fitted to the former, so as to compress the air therein and force the water up a straight pipe or tube into the compression chamber, in which case the air tube between the two chambers would be fitted with a tap or cock, which would have to be closed during the forcing of the water up into the compression chamber, and which would be opened when all the water had been raised, when by two or three additional strokes of the air-pump or compressor the air would be compressed, and acting on the surface of the water force it up the jet-tube.



APPARATUS FOR ESTIMATING CARBON IN STEELS.*

A DESCRIPTION of the apparatus in use at the works of the Washburn and Moen Manufacturing Company, Philadelphia, will, I think, be of interest to those who desire an accurate method for the estimation of carbon in steels. The apparatus has been in use in the works for the past three months and has given entire satisfaction. The method of filtering carbon on to asbestos in a glass funnel, drying, transferring to a porcelain tube, and burning in a stream of oxygen gas, is accurate if all the carbon can be separated from the sides of the funnel, which in some cases is almost impossible. Again, the method of filtering on to asbestos in a platinum tube or boat-shaped apparatus, and putting all in a porcelain tube and burning as before, has also been used, and of course is less liable to error. My aim has been to do away entirely with the porcelain tube and combustion furnace, and to filter and burn in the same tube. The sketch shows the form of apparatus I have adopted, being made of platinum.

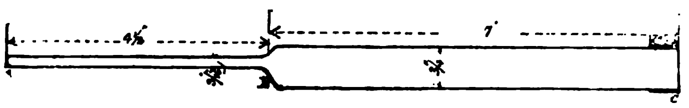
The following is the process I use: Dissolve from

---

* By Addison B. Clemence, Worcester, Mass., in Journal of the Franklin Institute.

3 to 5grm. steel borings in double chloride copper and ammonium, using 36grm. of the salt to 120cc. water for 3grm. of steel.

After the separated copper has completely dissolved, filter on to a plug of ignited asbestos placed at (*b*), and wash thoroughly with hot water. Any carbon that adheres to the sides of the tube may be swept down with moistened asbestos.



The tube is then placed in an air-bath and dried at a temperature of 150° to 175°C. for about one hour. A hard rubber cork, through which is a glass tube, is inserted at (*c*), the oxygen gas passing from (*c*) to (*a*). Around the tube at (*c*) is a single thickness of filter paper, about two inches wide, kept wet by a stream of water supplied from a reservoir on a shelf above.

Heat is applied at (*b*) for one-half hour, at the end of which time the potash bulb is ready for the balance. One Bunsen burner is sufficient for the combustion. The same precautions are taken to dry the gas before entering the platinum tube, as well as before entering the potash bulb, as in the case in the porcelain tube method. Six burners of a combustion furnace will consume 14ft. gas in one-half hour, while one Bunsen burner will consume 2ft. in the same time. The following table shows some results obtained by the "platinum tube" process:—A is a Swedish Bessemer, with ·10 per cent. of carbon; B an American Bessemer, with ·18 per cent.; and C an American Bessemer, with ·50 per cent., all obtained by the "porcelain tube" process.

	A.	B.	C.
1....	·09	·18	·49
2....	·10	·18	·51
3....	·10	·16	·49
4....	·10	·17	·44

Note.—If pure, closely-woven asbestos cloth can be obtained, I see no reason why with two potash bulbs twelve combustions may not be made in one day, for each filter with its contents may, when dried, be put in the platinum tube and burned.

MYSTERY-MONGERING.

"MESMERISM," says the *Saturday Review*, "has long been the stand-by of the contemporary mystery-monger. Now, more than ever, when science is lighting up the shadiest places and forcing recognition everywhere, must the true lovers of the occult defend their cherished idol, and descend into the arena of conflict with the sceptics seemingly equipped with weapons such as theirs, but ready also with plenty of verbal dust to confuse the vision of the judges. The modern mystic, indeed, of whatever colour he may be, must masquerade in scientific clothes, and not one of the departments of 'psychical' researches provides so rich a wardrobe as mesmerism or animal magnetism. 'Thought reading' may be annihilated almost without an effort, and 'Haunted Houses' may totter and fall at the first assault; but there is a solid foundation of fact deeply underlying the alien and flimsy superstructure of mesmerism, which, on the one hand, the scientific man of course admits and explains, and, on the other, the mystic faithfully preserves, cunningly professing the while that foundation and superstructure are the same in substance. The facts of hypnotism, or induced somnambulism, are well known to physiologists, being parallel, moreover, to those which occur in certain spontaneous conditions of nervous subjects, and the explanation implied in these terms is allowed by the most modern apologists of mesmerism to be largely true, and to cover with a little straining nearly all mesmeric phenomena. But there is a residuum of fact in mesmerism, say these last, that necessitates the hypothesis of a hitherto unknown manifestation of force. The difference between superstition and science on this matter may thus at first sight seem to be a small one, and more of degree than kind; but a little inspection will show that it is wide and important. Only force the mystic to define his terms and classify his phenomena—an operation he does not readily perform—and have a clear understanding with him where hypnotism ends as an explanatory agent, and the sphere of mesmerism begins, and exactly at that point of junction will rigid demonstration be found wanting, and the possibility, nay, the overwhelming probability, of imposture and collusion appear. But, to avoid this direct issue, it is a favourite device of the believers in mesmerism to falsely declare that the whole class of phenomena they adduce are stoutly denied and pronounced impossible by all scientific men.

The physiologist holds that some of the phenomena ranked under mesmerism are genuine and comparable to certain natural states, but that none exist to justify the supposition of any unknown force or effluence, most mesmeric manifestations of a certain sort being entirely due to individual or collusive fraud. For most of the facts alleged are of such a nature that it is infinitely more probable that all connected with them, both actors and reporters, are deliberate impostors, than that they should themselves be true. But the mystics refuse this logical standpoint, and argue, tacitly or openly, that the same amount and kind of evidence is valid both for the commonplace and for the unknown. It may be roughly said that the phenomena of so-called mesmerism which have long been familiar to all, and have from time to time excited the public mind, are mainly represented by actions formed by one person apparently under the influence of another, the subject being, for the most part, thrown into a more or less unconscious condition, and often alleged to be beyond the reach of any known means of communication by the senses. These phenomena, compounded of the true and the absolutely false, have been treated by different minds and methods. Science has sifted the alleged facts, and ascribed, with a large share of success, the established residuum to intelligible causes; while superstition has sought and specially cherished that element which apparently, on the supposition of its being genuine, could not be explained at all. In spite of the pseudo-scientific garb which mysticism has assumed in recent times, and of all protestation to the contrary, the love of the occult shines confessed in the credulous statements and writings of those who advocate the genuineness of the mesmeric phenomena which science rejects, showing itself, too, in their alliance with devotees of other, though similar, mysteries, in a captious impatience of the ordinary methods of investigation, and a constant seeking after new phenomena when some of the old have been completely explained or explained away. It is perhaps useless for these two classes of mind to seek for common ground; the ways of the scientific inquirer and the 'psychical' researcher can never meet; they cannot argue or experiment in common. The former, in his search for truth, is content to explain by simplification, and proceed from the unknown to the known, while the latter practically proclaims that nothing can be known at all. The scientific reasoner rests on the surest basis of the greatest probability; while to his opponent, with the quibble on his lips that probability is not certainty, the most rigid demonstration appears a trifle light as air, or even no probability at all."

PREVENTING INCRUSTATION IN BOILERS.

THE report of the engineer of the Manchester Steam Users' Association, presented at the recent meeting of the executive committee, after detailing the work done in the preceding four months, dealt at considerable length with the subject of the prevention of incrustation in steam boilers, a subject of great importance to boiler owners, and one which had for many years received attention from the Association. In 1858 the Association engaged Dr. R. Angus Smith to make an analysis of several of the waters used in the works around Manchester, and to prescribe remedies for their treatment, in order to guide the members on this subject. Subsequently several other analyses had been made of water containing carbonate of lime coupled with magnesia. Such waters were found to form a fine floury deposit, which led to the overheating of the furnace plates, even though covered with water at the time. In consequence of this many boiler makers had been unfairly blamed, and the straining of the furnaces attributed to bad workmanship, whereas it was due to the peculiar character of the feedwater. Cases of this sort had been met with in different parts of the country, in London, in Lancaster, in the neighbourhood of Widnes, and many other localities.

The number of anti-incrustation compositions was very numerous. Their component parts were veiled in mystery. Many of them proved positively injurious to the boilers on actual trial. Some lined the plates with a glutinous coating, which, while it had the desired effect of keeping off the scale, unfortunately at the same time kept off the water, in consequence of which the furnace crowns became overheated, strained, and bulged out of shape. The members therefore were warned not to adopt any of these compositions without the greatest caution. As the incrustation compositions were costly, blowing out was too often given up when they were used. The practice of neglecting blowing out was strongly objected to, and an explosion that occurred at Bury from that cause was referred to as an illustration.

The course recommended by the Association was to try in the first instance good soda ash. This was not to be introduced at the manhole or safety valve in large intermittent charges when the steam was down, but pumped in along with the feedwater at the rate of about 3lb. per day for a full-sized mill boiler so that the boiler might regularly be fed with weak soda water, while blowing out should by no means be neglected.

Boilers were not to be emptied violently by blowing the water out under steam pressure, as that would leave the surrounding brickwork hot, and bake the sediment on the plates; but the boilers were to be allowed to stand until cool, and then emptied gently by opening the blow-out tap and allowing the water to flow out of its own accord. To hasten the cooling the steam might be blown off at the safty valves, and then when the pressure was down, but not before, the manhole lid might be taken off and cold water poured in so as to mix with the hot, and thus lower the temperature of the mass gradually and generally, and not suddenly and locally.

Should, however, the soda not be found to succeed, and soda would not meet every case, it was recommended that an analysis of the water should be made by a practical chemist with a view to a suitable remedy being prescribed to meet the special requirements.

Soda ash was recommended in preference to soda crystals, because the crystals contained so large an amount of water, so that though the soda ash might cost a little more per pound in the first instance it was cheaper in the long run. It was stated, however, that as soda ash varied very much in quality it was important to see that it was good, as otherwise it might contain impurities which were injurious. In one case which had come under notice, the amount of carbonate contained was only 65 per cent., while in another it was as much as 98 per cent. Also in the first case the quantity of chloride and sulphate of sodium, which were impurities, was as high as 18 per cent., and in the second case as low as 0·5 per cent. Further, there was present in the first case as much as 16 per cent. of water, and only 0·3 per cent. in the second. Thus there was a marked difference between the two.

The report also spoke of the Porter-Clark process which had been adopted by some of the members. This process had the advantage of purifying the water before it was pumped into the boiler, whereas all boiler compositions treated the water after it was pumped in, so that while the Porter-Clark process threw down the impurities outside the boiler the compositions threw them down inside. The Porter-Clark process, however, at present was only adapted to deal with carbonates, whereas most of the waters the Association met with were impregnated with sulphates. It was hoped that the Porter-Clark process might be extended so as to render it applicable to waters impregnated with sulphate of lime as well as to those impregnated with carbonate of lime.

BLEACHING SPONGE.

THERE are several methods by which sponge may be bleached, but the following are the best:

1. First wash and squeeze out the sponges; then dip them into a 2 per cent. solution of permanganate of potassium. Here they become quite brown (from separated manganic oxide). After ten minutes they are taken out, washed in water, again well pressed, and then dipped into a 2 per cent. solution of oxalic acid—some prefer diluted sulphuric (1 : 20) or diluted hydrochloric acid (1 : 15)—in which they become perfectly white. Success mainly depends on the soaking in the permanganate solution. If they are macerated too short a time, they do not become thoroughly white; if too long, they are apt to become rotten.

2. Clean the sponges by immersing them in diluted hydrochloric acid; then soak them in a bleach, composed of hyposulphite of sodium one part, water twelve parts, and hydrochloric acid two parts. After some time remove and well wash. To the last wash-water a little glycerine is added in order to preserve the sponge soft. The liquid is best pressed out by passing the sponge through a clothes-wringer.

3. Toilet sponges which have been in use often become peculiarly slimy and almost useless, owing to some action of the soap. Mere washing in distilled water does not remove the dirt. The sponge should be pressed as much as possible, placed on a plate, and powdered chloride of calcium sprinkled over it and allowed to deliquesce upon the sponge. After about half an hour the sponge may be washed in water and dried, when it will become white.

All the above processes furnish satisfactory re-

The death is also announced of Dr. R. S. Hudson, the Secretary of the Miners' Association of Cornwall and Devon. He had been engaged for many years in introducing practical science to the miners by means of lectures and letters.

The Royal Dublin Society has appointed a committee to consider the best system of founding an Irish college of veterinary science, with power to confer degrees.

Continuing his series of lectures at the London

Institution, Mr. Skertchly, referring to the "fossil man," said that the evidence of man's antiquity on the globe was of a twofold nature, geological and archæological; the latter is found in the ground and polished celts which mark a distinct change from the age when flints were chipped; the former in the positions of the implement-bearing beds, some of which are below a very ancient glacial deposit. In the lecture on "Prehistoric Man," Mr. Skertchly illustrated practically the method of chipping flints, and gave a description of the flint mines of Brandon, and an account of the modern "flint knappers," who are supposed to be lineal descendants of the old workers amongst the Neolithic people. We reviewed Mr. Skertchly's work on this subject in Vol. XXIX. p. 482.

M. Dieulafait has recently presented to the Academy of Sciences a memoir on the extent and age of the Dioritic formations of Corsica, in which he shows that the Corsican diorites belong to three distinct systems: granites at San Lucia, di Tollana, and Ajaccio, the serpentine rocks of the Triassic, and Permian formations at Bastia and other places. With the last are associated exclusively the metalliferous sulphides which occur in the island.

There is a possibility that, before long, Switzerland will have a patent law, the result of the recent exhibition at Zurich having convinced the authorities that owners of new machines declined to exhibit on the ground that they had no protection from the enterprise of mere copyists.

The Gaulard and Gibbs system of electric lighting is now at work on the Metropolitan Railway at Notting Hill-gate, Edgware-road, and Aldgate. King's-cross and Gower-street will soon follow. The total length of the leads and return is 15 miles. The installation will be watched with some interest, for the current actually used to supply the lamps is produced by secondary generators. The primary circuit is said to be "metallically closed," and, consequently, carries an E. M. F. of 2,000 volts, without running any risk of accidentally injuring anyone.

Messrs. Shippey Brothers inform us that the carriage of the ex-Lord Mayor was illuminated by electricity whilst proceeding to and from the banquet at the Guildhall on the 9th. New universal glow lamps were used, the current being generated by Coad's patent primary battery in combination with the Woodward storage battery. As this is the "first time a carriage has been lighted by electricity in England," it is an item of news: but there is no difficulty in doing it, if owners of carriages like to pay the price.

The deepest well in the world is said to be Buchanan well, near Wheeling, West Virginia, which is 4,300ft. deep, and is still "going down." Oil has been struck, and it is intended to go 500ft. deeper; but, if necessary, the hole can be bored to a depth of 7,000ft.

It has at last been officially stated that applications for patents made before the 1st of January, 1884, will be subject to the old law as regards fees and procedure up to and including the filing of the final specification. The words, "or on applications then pending," in clause 3, section 45, of the new Act, should obviously not have been inserted, or the authorities are over-riding the law.

We are informed that Lieut.-Col. Ross has completed arrangements with Messrs. Crosby Lockwood and Co., 7, Stationers' Hall-court, London, for the publication, in book form, of the "Easy Lessons on Blowpipe Analysis," &c., which have recently appeared in the pages of the ENGLISH MECHANIC. The work, which has undergone considerable revision, will be issued at a moderate price, under the title of "The Blowpipe in Chemistry, Mineralogy, and Geology," and will include many additional tables and illustrations, and about forty analyses of minerals from the note-book of a student at Freiberg University, with a parallel analysis on Col. Ross's new system appended to each.

According to the report of the Science and Art Department, the sum of £45,376 (out of over £340,000 income from Parliament) was spent last year in payments to science teachers. The average payment for each class of at least twenty-eight lectures, lasting from September to May, being slightly more than nine pounds. Inspecting and examining the classes cost £22,235.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

⁂ *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

> "I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original."

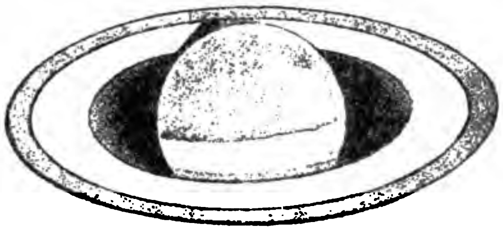
THE PLANET SATURN—A TOO AMPLE APOLOGY — CEMENTING OBJECT-GLASSES—HEIGHT OF THE MIDNIGHT SUN—THE TRANSIT INSTRUMENT AND ITS ADJUSTMENT—READING THE CIRCLES OF AN EQUATOREAL—THE LAST SUNSPOT MAXIMUM—SATURN'S SATELLITES AND DARK RING—THE TIME OF THE EARTH'S ROTATION; AND THE RECENT RESEARCHES OF MR. STONE — THE ANNUAL REPORT OF THE CHICAGO ASTRONOMICAL SOCIETY —POWERS FOR OBSERVING PLANETS — 41 ARIETIS — THE SOLAR RICE GRAINS—SPECTRUM ANALYSIS.

[22053.]—HERE is the sketch of Saturn which I made on the night of November 9th, in redemption of my promise to Mr. Franks, on p. 217.

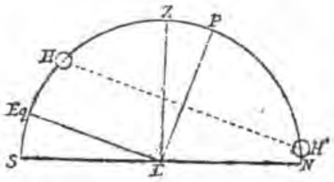


If the engraver will only reproduce accurately what I drew most carefully at the telescope, this will serve to illustrate the kind and amount of difference in the details exhibited by a 11¼in. reflector and a 4⅛in. achromatic when turned upon this planet. My own drawing—and I hope the engraving too—shows how I fail to see the inner edge of the crape ring C in the Ansæ as absolutely continuous with that portion of it which crosses the ball of Saturn. This is apparently from want of sufficient light. By the bye, the visibility and the colour of this inner ring varies very considerably. It was by no means conspicuous on Friday week, and was of a very dark grey colour. I have, however, often seen it of a bright slate colour, and also (if my memory serves me) brownish on occasion. Under the former condition it was, I had almost written, *glaringly* visible. Tethys, Dione, Rhea, and Titan were all visible when my sketch was made. I did not look for Iapetus.

Let me hasten to assure "Bow" (letter 22923, p. 221), that in no sense whatever could I possibly regard his note in letter 21996 as "a piece of impertinence." Referring to that excellent old lexicographer, Bailey, I find that his first definition of impertinent is "not to the purpose"; while the next dictionary I take down, that of Walker, defines impertinence as "That which is of no present weight, that which has no relation to the matter in hand." In what sense the supply of an omission which I made (writing as "Bow" but too truly says, *currente calamo*), can be held to come within either of these categories, I wholly fail to see. I am only too much obliged to him for pointing out that my answer failed in fulness.

In answer to the query contained in reply 51961 (p. 225), I have a strong impression, well or ill-founded, that Wray, the great optician, patented a process for the construction of object-glasses, in which castor-oil was employed as a medium between the crown and flint lenses. His object was, if I remember rightly, to destroy the secondary spectrum, so as to render the combination absolutely, and not merely approximately, achromatic.

"C. B. T." (query 52170, p. 227) may calculate the height of the midnight sun by simply subtracting the sun's North Polar distance from the latitude. A glance at the accompanying figure will explain how and why.



My querist, of course, knows that at any given part of the earth's surface the latitude = the elevation of the Pole above the horizon. Very well, then; in the diagram above, let E be the observer's eye: S E N, the horizon; Z, the zenith; P, the North Pole of the heavens; and P N its altitude, of course, in this case, 71° 10′ 20″, Eq., E will be the equator. Now, on June 21st, at midnight, the sun's declination Eq. H. is 23° 27′ 5″, and quite obviously his north polar distance P H is 66° 32′ 55″. If, then, finally from 71° 10′ 20″ we subtract 66° 32′ 55″, we get 4° 37′ 25″ (H¹N in our figure) as the altitude of the sun when due north, or at midnight. This is evidently his geometrical altitude. Refraction will increase this, and make his apparent altitude 4° 48′ 2″. On July 21st, at midnight, the declination of the sun is 20° 24′ 32″ north, and his north polar distance 69° 35′ 28″. Taking this latter latter quantity, as before, from the latitude 71° 10′ 20″, we get 1° 34′ 52″ as the geometrial altitude of the sun's centre at the North Cape on July 21st, 12h. 0m. 0s.; or, adding 20′ 38″ for refraction, 1° 55′ 30″ as his apparent altitude above the north point of the horizon there at midnight on that day.

I do not fancy that either Simms or Cook has wired the transit instrument spoken of by "Clock Star" (in query 52172, p. 227). The spider lines have probably been put in by some apprentice. As for taking his transits over the middle wire only, though, this depends upon whether such wire is accurately collimated, in other words, if it actually coincides with the optical axis of the telescope, and is really the *middle* wire. I presume that your correspondent knows how to collimate his instrument? If its collimation be accurate, I really think that for "Clock Star's" purpose transits over the centre wire only would be as accurate as he would be likely to get; as every observation would otherwise have to be reduced to the "mean wire," which differs materially from the middle one. In order to get his transit into the meridian, "Clock Star" had better carefully level its axis and then obtain his clock error by a star as near as may be to the zenith; such, for example as α Cassiopeiæ, α Persei, Capella, ι Ursæ Majoris, θ Ursæ Majoris, γ Ursæ Majoris, η Ursæ Majoris, β Draconis, γ Draconis, or α Cygni. His clock error thus determined, let him apply it to the tabular Right Ascension of Polaris, and threading the Pole star on the wire as it approaches the Meridian, keep it on such wire by the azimuth screw until the clock ticks the second which he has calculated it should show at the star's transit. His instrument will be very nearly indeed in the Meridian. High and low stars are better for determining azimuthal error with small transits such as his than circumpolars, but I am speaking of getting the transit as nearly as may be into the meridian, not of ascertaining the exact amount of its subsequent deviation from it.

In answer to the succeeding query (52173, p. 227), I have not seen Grubb's arrangement; but I have employed, in a friend's observatory, Cook's method of reading the circles of an equatoreal from the eye-end, which—as far as my limited experience enabled me to judge—was very pleasant, and free from objection.

I should prefer to wait for Wolf's results before attempting to answer query 52185 (p. 228), since they will be arrived at on purely scientific grounds, and without any *arrière pensée*, or attempt to "cook" them to fit in with any "cycle," real or imaginary. The maximum of sunspots must, I think, have occurred pretty late in 1882.

"Aziola" (query 52186, p. 228) should endeavour

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51[illegible].]—**Three-Cell Battery.**—Referring to "Electrician," I should be glad if he would be good enough to let me know the length of time it will continue to light a lamp before it runs down. What size cells, what size carbons, and zincs?—No Sig.

[51848.]—**Lost Watch Wheel.**—Having given some examples for calculating trains, and finding numbers for the teeth of a "lost wheel and pinion," in "E. M.," Oct. 19th and 26th, I hope the following will be useful by showing how the time of going can be calculated, and also the "up and down" motion. It will be seen in the above-quoted numbers, that all those relating to "lost watch wheel" were calculated from the centre wheel upward to the balance vibrations, and that only one rev. of centre wheel was taken into account, and consequently only one hour of time; but if a watch or any other timepiece is to go 30 hours, or more, then we start from the centre pinion downwards, which pinion may be any number we like (so long as not to make the teeth too fine or weak): usually the c.p. has from 10 to 14 leaves: let us use a 12. Now, to find numbers for great wheel, the centre pinion also turns to be cut on the fusee, or if a going barrel, then the number of teeth in the wheel and turns the barrel must make to go any number of hours we wish without rewinding, and the number of hours of going. Of these parts we must fix on three to find the fourth. Let c.p. = 12 leaves, fusee or barrel = 4 turns, to go 30 hours: find number of great or barrel wheel teeth. Rule 1: [illegible] number of hours by number of turns of fusee or barrel by the quo. [illegible] c.p. Example 1. 30hs. ÷ 4 turns = 7½ quo. [illegible] 12 c.p. = 90 wh.: now 90 wh. ÷ 12 c.p. = 7½hs., which being × 4 turns = 30hs., because the c.p. makes one exact rev. in an hour, the gt. wheel in 7½ hours, and 4 in 30 hours. To find number of turns of fusee or barrel. Given, number of gt. wheel, c.p., and hours of going. Rule 2. Divide great wheel by c.p., and hours of going the quo. = turns of fusee or barrel. Ex. 2. 90 wheel ÷ 12 c.p. = 7½, 30 ÷ 7½ = 4 turns. To find number of c.p. Given, great wheel, hours of going, and turns of fusee or barrel. Rule 3. Divide great wheel by number of hours of going, the quo. × by turns of fusee = number of c.p. [illegible] [illegible] great wheel. [illegible]

[illegible]

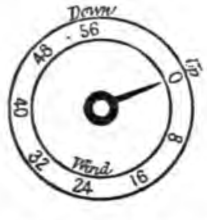
[illegible] number pinion in [illegible] considered two [illegible] 3, they [illegible] wheel 96, inter. pinion [illegible] if the pinions be two [illegible] = 32 [illegible] as at first; then [illegible] 4 = 12, [illegible] two pinions. To prove these numbers are right, multiply each pair of wheels together, and divide by the product of the pinions.

$$G\left\{\begin{array}{lllll}\text{1st Ex.,} & 90 \times 64 = 5760 \div 120 = 48 \\ \text{2nd ,,} & 135 \times 96 = 1296 \div 270 = 48 \\ \text{3rd ,,} & 108 \times 64 = 6912 \div 144 = 48\end{array}\right\} =$$

revs. of c.p. to once of fusee wheel, and, as the c.p is made to revolve once in an hour, the fusee wheel will revolve only once in two days, so that 18 turns of the fusee will employ 36 days, when all the chain will be unwound off the fusee on to the barrel. Rule 4. To find time of going, divide great wheel by c.p. the quotient, multiply by turns on fusee (or turns of barrel), equal time of going. Ex. 4. Given great wheel 90, c.p. 12, turns 4, then 90 ÷ 12 = 7½ × 4 = 30; if an inter. wheel and pinion be used (as in some 8 days or month), then, product of great and inter. wheels, divided by product of centre and inter. pinions, the quotient multiplied by turns of fusee or barrel, equal number of hours. Ex. 4*a*.—Given

$$\begin{array}{c}G \\ \text{Ex. 3}\end{array}\left\{\begin{array}{lr}\text{Great wheel} & 108 \\ \text{inter. ,,} & \times\ 64 \\ \text{centre pinion} & 12 \\ \text{inter. ,,} & \times\ 12\end{array}\right.\begin{array}{l}\}\ 6912 \\ \\ \}\ 144\end{array} = 48$$

× 18 turns = 864 hours = 36 days. The "up and down" motion is to show when the watch is wound up, how many hours it has gone since last winding, and when run down. The accompanying sketch of a 56 hour watch will make this clear. The circle



is divided into nine equal parts, seven being used, and every eighth hour marked from 0 to 56 (8 hours more than two days, as the watch is made to go that time, just as a one day is made to go 30 hours). Now an arc less than a circle can be used; in the above 280° are taken, and is similar to a two-day marine chronometer up and down circle. The wheel and pinion work consists usually of only one each, though sometimes two wheels and two pinions, in the former the pinion is fixed to the fusee pivot and gears into the hand wheel, so called because the up and down hand is fixed on the wheel's socket, which comes through the dial, and a little above it, so that as the fusee revolves, carrying the pinion, leads the wheel round, also the hand fixed on it, and when the watch is wound up the hand is again brought to O. A rule for calculating this motion is as follows: Given eight turns of fusee, nut pinion 10, arc of up and dn. circle = 280°, time of going 56 hours. To find No. of hand wheel, Ex. 5: multiply turns of fusee by No. of leaves in nut, thus 8 × 10 = 80, then, say, as 280° : 80 :: 360° : x = 102⁶⁄₇. Now we cannot have ⁶⁄₇ of a tooth, so we must proceed as follows:—Multiply whole number 102 by the denominator of the fraction. Add the numerator: thus 7 × 102 = 714 + 6 = 720; multiply the pinion 10 by the 7 = 70: much too high, so divide by 10. We get 72 and 7. Too low, but × 2 = 144 and 14. These numbers would do very well, the nut having a good body and the wheel being easily cut. Had we taken 300° of arc, a wheel 96 and a pinion of 10 would have done very well, as 10 × 8 = 80, then 300° : 80 :: 360 : 96, and dividing the arc into seven equal parts, marked as above, all would be right. Sometimes it is expedient to have two wheels and two pinions. First calculate as for one pair. Take the last numbers, multiply each by 10, we get—

$$\begin{array}{ccccccc} & & \multicolumn{2}{c}{\text{Wheel.}} & \multicolumn{2}{c}{\text{Pinion.}} & \\ 32 & \left\{\begin{array}{c}2\\4\\4\\30\end{array}\right. & \begin{array}{r}960\\480\\120\\30\end{array} & & \begin{array}{r}2\\2\\5\\5\end{array} & \begin{array}{r}100\\50\\25\\5\end{array} & \begin{array}{l}\}\ 10\\ \\ \}\ 10\\ \end{array}\end{array}$$

one nut fixed on fusee pivot and one on wheel 30, 32 carrying the hand. When it is necessary to plant the hand wheel at such a distance from the fusee that it cannot gear into the nut pinion fixed on the pivot, a wheel, or any number of wheels, may intervene (providing they have no pinions gearing); in such a case, the revs. of nut pinion fixed on the fusee pivot are to the hand wheel just the same as if they were geared into each other, the direction only being altered; that is, if one wheel intervene the hand wheel would revolve same way as the pinion; if two, then contrary, and so on *ad infinitum*. Before closing this subject, allow me to say that I have taken most of the foregoing from "Reid on Watch and Clockmaking," page 12, and following pages, but the method of finding "lost watch wheel and pinion" I think is due to—R. E. B.

[51879.]—**Locomotives (U.Q.)**—To "St. Aubins."—I have not my "Molesworth" at present by me, but can remember the pages to which you refer. The 9in. passenger is a Caledonian tank (single-wheel). The 10in. passenger was built for the Eastern Union Railway (four-coupled 5ft.) The 17 tank broad gauge was a 6ft. four-coupled tank G.W.R. The 18in. English goods engine was Sharp's Goods M.S.L.R. Those in the other list I do not at present remember.—Carstairs.

[51898.]—**N.B.R. Engines.**—"Glasgow" 474, and "Berwick" 475. Cylinders, 17in. by 24in.; leading and trailing wheels, 4ft. 6in.; driving wheels, 7ft.; rail to top of chimney, 13ft.—Carstairs.

[51912.]—**To Violinists who are Mathematicians.**—"Student," on page 179, states that he is informed that a person who has learnt music on the tonic-sol-fa system can tune a violin quicker than a person who has learnt on the ordinary method, and he asks whether any sol-fa-ist who is a mathematician can throw any light on the matter. As a sol-fa-ist, I must say that I think it is not so much a question of mathematics as of musical training. My experience is that the tonic-sol-fa method of teaching music endows its student with a delicate sense of interval, which I find from close observation is less acute in persons taught on the old system. The interval of a fifth is taken as from doh to soh (upwards) and the interval is the same between each adjoining string on the violin. I have had but little practice on the instrument, and am therefore anything but a good performer; but I experience no difficulty in tuning it perfectly true, and can instantly tell whether it is in tune by merely gently plucking each string in succession, and do not require to draw the bow over two strings at once in order to test the chord. It has often astonished me to hear persons who are fairly good performers on the instrument make such a bungle of tuning it. At a class to which I belong I have often heard some of them start playing when a trifle out of tune, evidently under the impression that all was right. I invariably find that where this defect exists the performers are old-notationists, and that it exists in its most exaggerated form amongst those who have learnt music on what is termed the fixed doh system.—M. W.

[51936.]—**Crystal v. Paraffin Oil.**—Doubtful if there is any method of distinguishing between what are practically identical; but for "paraffin" I suspect is to be read petroleum, or kerosene. Then the "crystal" oil is doubtless better refined, and shows least colour. For any useful method, however, of simply testing, it would be best to procure samples of the articles, and observe the differences of colour when placed in tall, narrow glass vessels. The clearest is the best—provided it is not benzoline; but you will use the flashing test for that.—Nun. Dor.

[51944.]—**Coppered Wire.**—I wish to inform "Ressorp" that the term "copperas" is applied to three metallic sulphates; that of copper is called blue, of iron green, and of zinc white copperas. A druggist, if a Londoner, would, on being asked for copperas, inquire which sort was wanted.—W. G.

[51944.]—**Coppered Wire.**—It appears that I have not worded my last remark on this subject in a sufficiently explicit manner. What I meant to say was, that if the copper sulphate solution is strongly acid, the copper will adhere more strongly to the wire than if it is only slightly so. I did not, of course, mean to say that querist was to use an unlimited supply of acid, and only very little copper sulphate.—R. A. R. Bennett.

[51944.]—**Coppered Wire.**—Iron or steel can be coppered by placing in a solution of tartrate of copper, which is made as follows:—In a solution of sulphate of copper pour a solution of caustic soda; the precipitate will be oxide of copper, which must be washed with cold water to free it from any acid; then dissolve in a solution of tartaric acid. Place the articles to be coppered on a piece of zinc, and immerse them in the solution.—Les Dents.

[51944.]—**Coppered Wire.**—This is a nice little bit of logomachy about "copperas," isn't it? I suppose I may express the opinion that, although copperas is the name of crude sulphate of iron (though why it should be, goodness only knows), I suspect if you go into an oilshop or drysalter's and ask for it, as often as not they will ask which you mean. At least as far back as I can remember there were blue, green, and white "copperas," a word that is sometimes supplanted by vitriol; and there was also calcined copperas, being the calcined green vitriol which was used as an astringent and as driers. Iron pyrites is also sometimes called copperas. It would be really interesting to learn how a salt of iron came to be called copper-as.—Nun. Dor.

[51950.]—**Loss of Smell.**—How can any one even suggest anything without knowing *why* our unfortunate friend has lost his sense of smell? Has he consulted a medical man?—Nun. Dor.

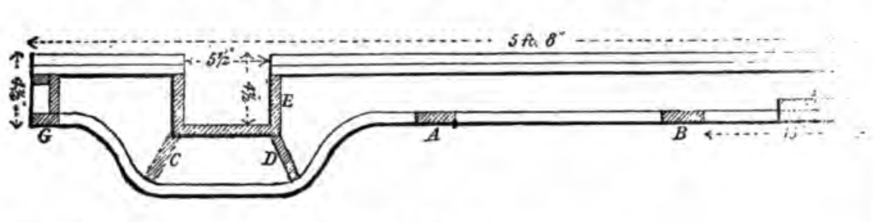
[51967.]—**Seasoning Boxwood.**—Box is not liable to heart-shake, but does split spirally, which cannot be prevented. Better stack it in the usual way, under cover.—Nun. Dor.

[51990.]—**Carriage Lift.**—Cannot "Tynedale" rig up an inclined plane, and lower the carriages down that? Or can he not make a lift, to be raised by a differential pulley? I suppose a crane is out of the question; but there is not sufficient detail in the query to enable one to say which arrangement would be best.—NUN. DOR.

[52033.]—**Caledonian Engines.**—Since writing my last, three of the goods engines by Neilson have been turned out—viz., Nos. 294 to 296 (the class will be 294 to 308), and one from St. Rollox, No. 349. They are painted like the passenger engines —i.e., blue and frames morone, lined with black, and picked out with white. The rebuilds are doing rather better now.—CARSTAIRS.

[52043.]—**Induction Coil.**—To L. WILLIS.—Probably the insulation is not as perfect as it might be. After you have wound on the two layers of primary, insulate it from secondary with paraffin paper, and bake with paraffin wax; then after each layer of secondary a piece of the paper, and so on, till all secondary is wound; the wire should be wound as smoothly as possible. The amount of battery power the coil will stand depends on insulation. I use Bunsen's battery, with 7in. carbon. —ALEX. V. NICHOLLS.

[52074.]—**Lathe.**—I give the longitudinal sketch of bed asked for by J. H. The shaded parts are the webs. I made a mistake on p. 183, in that the shaded part occurs again 4ft. from the mandrel end; on referring to my drawings I see it does not. A and B and G are 2in. × ¾in. thick, C and D are ⅝in. thick, E ¾in. thick, F is 2in. × 11in., and is for fixing an additional piece of bed. I wish to know if these sizes are sufficient. I have adopted this form in preference to the ordinary double flat bed, as I find this has more disadvantages than advantages; for the headstocks soon work loose in a gritty atmosphere.—SHAKESPEAR, Dresden.



[52083.]—**Punching Machine.**—I have to thank "Loanhead" and S. Nichollis for their answers. I have gone a little more fully into the question, and I find the punch 2in., but the hole in the "bolster" 2¼in. Now, for the quality of steel which was punched, 34 tons per square inch is allowed, and the thickness of the plate $2\frac{1}{16}$in. What is the pressure required in tons, and how do you arrive at it?—CRADO.

[52103.]—**Engine.**—I hope "Engineer, Dewsbury," will send his promised letter on compound engines, showing the "loss," as compared with a single-cylinder engine having the same number of expansions. That will indeed be carrying the war into the enemy's country; and I hope "Engineer" will take care to "keep his communications open," or he may lose himself. I know that a good single-cylinder engine can be made to give an economy very nearly approaching that of the compound; but never yet heard of one that really beat a good compound.—ESSAR.

[52125.]—**Harmonium.**—Might I ask Mr. Fryer what size holes he makes at the top of the windtrunks to supply the reservoir of the harmonium whose valve-board has holes of the dimensions given on p. 248? Will he also say how he fits the escapements for his valves?—FLIEGEN.

[52165.]—**Slide-Rule Formulæ.**—Corrections: —"60." before "For simplicity," eighth line from top, and "60" before "Slide-rule formulæ," 15th ditto, should be "or."—BUTTERSHAW.

[52165.]—**Slide-Rule Formulæ.**—The question to be solved is this: Given the rate in feet per minute of the piston of a direct-acting pump, and the number of cubic feet of water that it is required to deliver—to find diameter of the pump in inches. "Glatton" requires to know how the number 183 is obtained in connection with above question when worked on the common single slide-rule. The number 183 is called the "gauge point"—that is to say, it is a number obtained to facilitate the working of all such questions on the slide-rule. To obtain it we must go direct to the bottom of the subject.

Let x = dia. of pump in feet. (For the other dimensions are in feet.)
c = c feet of water delivered per minute.
b = the rate per minute in feet that the piston travels.

The quantity of water delivered per minute is evidently equal to the number of feet that the piston travels per minute multiplied by the area of the pump. The area of the pump is equal to $x^2 \cdot 7854$. Hence,

$$c = bx^2 \cdot 7854.$$

$$\therefore \quad \frac{c}{b \cdot 7854} = x^2 \text{ (in feet).}$$

As there are 12in. in a foot, and 144 is the square of 12, it follows that

$$\frac{c}{b} \times \frac{144}{\cdot 7854} = x^2 \text{ (in inches.)}$$

That is—

$$\frac{c}{b}\ 183 \text{ nearly} = x^2,$$

which is reduced to the form required for slide-rule calculation thus—

$$\frac{183}{b} = \frac{x^2}{c}.$$

Therefore, if b, the rate per minute, be placed under 183 (which number, it will be perceived, is quite independent of all the other members of the equation, hence it is applicable to all similar questions). Then, over c the cubic feet of water delivered per minute will be found the square of x, the diameter sought. But as the slide-rule is so constructed that the line D is the square root of the numbers in line A, we read the square root at once under c without reference to the line A. Example:

Let c = 30 c. feet per minute.
b = 120 lin. feet per minute.

Thus, by slide-rule—

A	183	
B	120	
C		30
D		6·75

Hence 6¾in. is the required diameter. It has been said that 183 is the "gauge point" for the present question. It is this gauge point that has been the chief cause of the slide-rule not getting into more general use, for such a multitude of questions require a previous calculation to ascertain the correct gauge point before the question can be solved on the single slide-rule. If "Glatton" looks into all published works upon the slide-rule, either Bailey, Ingram, Hoare, or the more recent one, Dixon, he will find them overladen with gauge points, so that the calculator must either recollect them, or have the book to refer to, before he can work out the question by slide-rule practice. In fact he must study slide-rule arithmetic to know what rules and gauge points are to be used. Sheppard's double slide-rule for cubing quantities, made for and sold by Stanley, Great Turnstile, Holborn, does away with the host of "gauge points," except in the most abstruse cases, which seldom occur. The operator has only to know what he requires, when he can in simple cases obtain the result in the same form as on paper—length, breadth, thickness, contents. As this question involves two operations, we must prepare the rule by turning the upper slide so as to bring the line of square roots under the line of lengths; then referring to the question as previously stated $\frac{30 \times 144}{120} = x$ (in inches in the area of the pipe), that $\frac{30}{120} = \frac{x}{144}$. Then by the lower slide place 30 over 120, then over 144 36. Thus 36in. is the area of the pump. The diameter of a circle equals the square root of the area divided by the square root of ·7854, that is—

$$\sqrt{\frac{36}{\cdot 7854}} = 6 \cdot 76.$$

Now place the line of square roots exactly under the upper line of lengths. Then place 1 on the lower slide over ·7854 in the lowest line, then over 36 on the lowest line is 45·57. As this is the square of the diameter in inches, its root found on the upper slide is 6·75, thus solving the question without the use of any gauge point—that is, by common arithmetic instead of by slide-rule arithmetic.—F. A. SHEPPARD.

[52166.]—**Engine Power.**—When the steam arrives at the cylinder, its pressure is about 40lb. per sq. in., about 10lb. having been lost through condensation, &c. Then when cut off at ⅔, horse-power = 24·6, when cut off at ½, horse-power = 28·2, and when cut off at ⅜, horse-power = 30·5. Try cutting off altogether: you will find you will economise coal wonderfully.—SABATA.

[52166.]—**Engine Power.**—Multiply area of piston (143·139in.) by average force of steam in pounds and by velocity of piston in feet per minute; divide this product by 33,000; $\frac{7}{10}$ths of this quotient equals the effective horse-power. If steam be shut off at any portion of the stroke, divide length of stroke by length of space into which the dense steam is admitted, and find the hyperbolic logarithm of quotient, to which add 1; the sum is ratio of gain.—C. T.

[52166.]—**Engine Power.**—I do not wonder at the remarks of "Firer" and "Gossan" about the steam being cut off altogether. What I had meant was, What power would it have when *not* cut off at all? Which, if I understand "Gossan" aright, is what is meant in his answer, to be the power of the engine when so working. "Firer" suggests that I should get some friend to indicate it for me. Could "Firer" or "Gossan" tell me how to go about to get it ready for an indicator, and what it would cost? The engine is a vertical high-pressure one, cylinder at the bottom.—C. C.

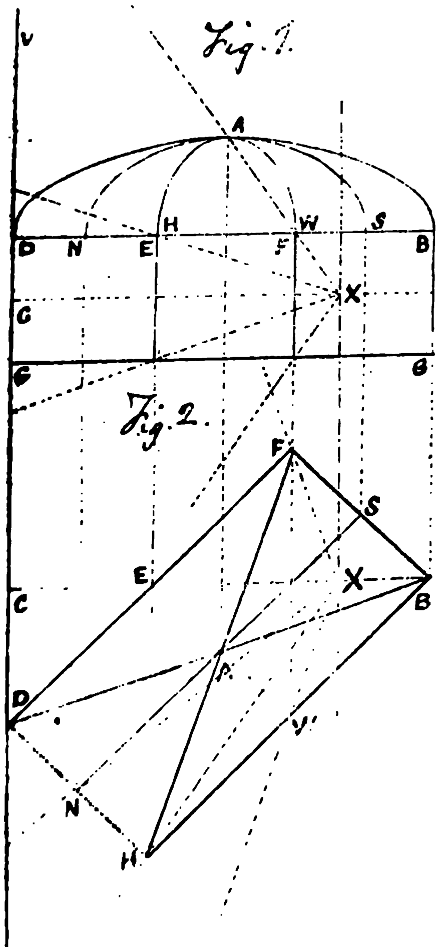
[52167.]—**Good Time.**—Will find a simple and efficient plan for taking and recording time in "ours," page 244, Vol. XXX. Should he desire any further information, I shall be happy to give it if he will advertise his address.—J. J.

[52168.]—**Royal National Tricycle.**—I regret to see an error in my reply to this inquiry. On the sketch it should be "lock" nuts, not "loose" nuts. Any practical hand will discover the error, though not all amateurs. The correction is due in fairness to the makers.—SECUNDUS HAUD ULLI.

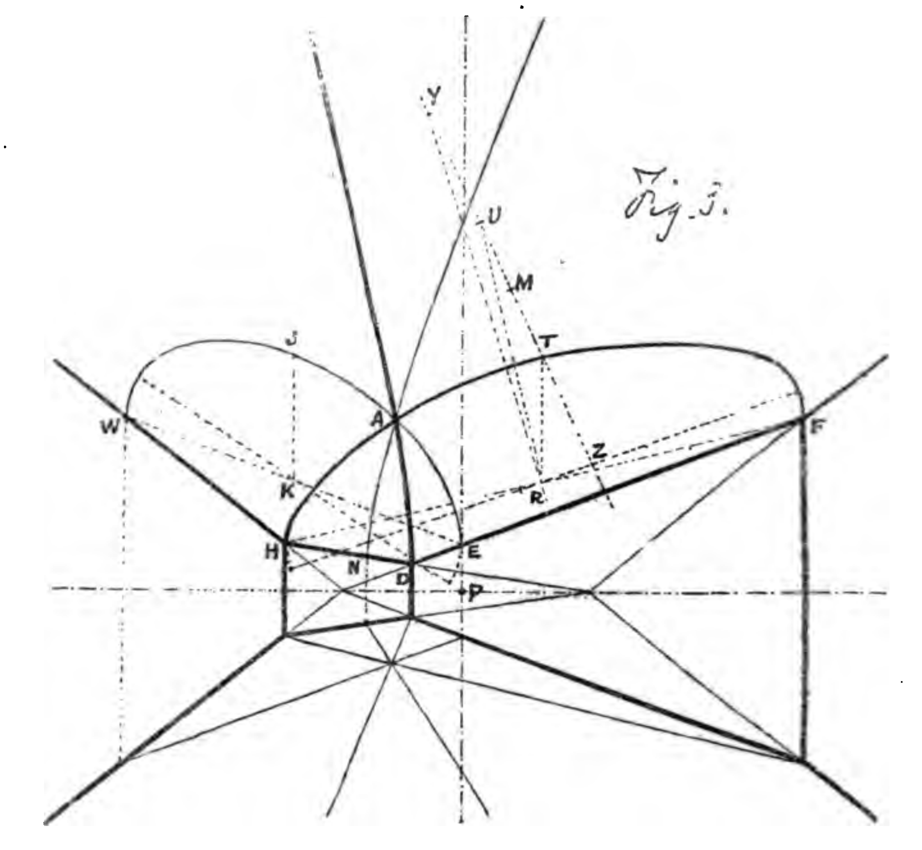
[52169.]—**Atomic Weights.**—There is an uncertainty as to the weights at present attached to some of the uncommon elements. Uranium is now generally given as 120, but cerium is given as 92 and 141·3 by the best authorities. "Experimenter" will find it necessary to bear this difference in mind until the question is definitely settled.—LABOR.

[52174.]—**Slide-Valve.**—"One who is Perplexed" is evidently not a practical engineer, and from the wording of this query I conclude that in the first instance the valve was not properly set, and in the second, that the valve face and the valve is not true, and as a consequence the steam blows right through; it makes little difference when he admits the steam to the valve chest, as the pressure of steam will keep the valve up to the face. "Perplexed" has not given the width of the ports and how much the valve overlaps them, so it is rather difficult to give him the cause of his difficulty without further particulars. I have had nearly 20 years' experience in the engineering, with stationary and marine engines, but more particularly the marine, both in the merchant service and the Government, and will give "Perplexed" a few little hints which perhaps may be of service not only to him but to other readers of the ENGLISH MECHANIC. The slide-valve (as I believe Mr. Burgh justly observes) is to the steam-engine just as the heart is to the human body. I never gave that attention to the slide-valve until I was engaged in a large engineering works in the North of England, in the experimental department. My duty was to test oils, gas burners, the action of oils on indiarubber valves, and a hundred and one different subjects which would come under the notice of the management of a large works employing over 3,000 hands. During the time I was in their service I constructed a skeleton model, and that is just what "Perplexed" should do: he will then see the action of the valve. This model to which I refer was made in order to demonstrate the action of certain improvements contemplated in the link motion, and I can say that I learnt more from this experiment than I had before from either reading books on the subject or from drawings. It is a subject, the slide-valve, that to go fully into would occupy many pages of our valuable journal; but with your kind permission I will give you a sketch how to construct a skeleton model, as I am sure it will interest many, and show many curious features which would perhaps pass unnoticed to those only partly acquainted with the action of the slide-valve. Now, to the practical, I always like to see the slide-valve overrun the valve face; for when it is not so, the valve wears itself down just where it is in motion, and the end of the stroke forms a nasty ridge, that when you adjust your valve the valve must leak. Speaking of leaking valves, it was formerly the practice of engineers to file and scrape up the valves and faces. In the States (U.S.A.) that practice is nearly abolished, as it has been found in practice to be a waste of time. It stands with reason, if it is properly looked to, that such is the case. Now if a valve was a piece of iron, and was one equal thickness, then under all moderate changes of temperature it would maintain its form; but it is not so, as it has been proved in practice that a valve scraped to a perfectly true surface at a temperature, say, of 60deg., was perfectly tight under hydraulic pressure at that temperature, yet leaked under 60lb. steam. How is this? Well, simply because the valve is of unequal thickness in different parts, and this unequal thickness causes unequal expansion, that although tight at, say, [illegible]deg., its shape is so altered that it leaks at [illegible]deg. I have seen many valves taken out after trial trips that had never been touched either by the file or scraped, but had just been put in as they had left the planing machine, and after a few hours' run brought themselves up to a fine face, especially the high-pressure one; in the low-pressure one the case is different, as the pressure is not so great, and, of course, the temperature is not so high, consequently the alteration of the form of the valve is not so great by the unequal expansion. If "Perplexed" gives further particulars, I shall be happy to assist him, either through the medium of our valuable paper or personally, if he will advertise his address.—INGENIERO.

[52175.]—**Perspective of an Interior.**—As "Murano's" case is interesting, and as it is impossible to answer the query without diagrams of a somewhat complex nature, I trust the Editor will consider it worth while to engrave them. My methods can be demonstrated to be mathematically accurate. "Murano" does not give all the requisite conditions of the problem, but I have arbitrarily fixed upon such as were wanting. I have arranged matters so as to have the point of sight P (Fig. 3) in the picture in a middle vertical line, where it ought always to be. I derive the perspective from orthographic projections in a manner which is applicable to every possible case. Fig. 1 is the elevation, and Fig. 2 the plan, the latter being first drawn, and the former made to agree or square with it. The parallelogram, D F B H, is the plan of the hall, B being the S W corner, at which "Murano" says the spectator is to stand. As, however, he is to be 5ft. from the S. and W. walls, I have put him at X, of course within the hall. I assume a vertical plane, C B, to pass through the angle B, and through the viewing station X, and I assume the plane of the picture to be vertical, and at right angles to C B. The distance of the plane of the picture from the station X does not matter—the greater the distance the greater the scale of the perspective drawing, that is all—I have, therefore, for convenience, assumed the vertical line, V L, to represent the plane of the picture in Figs. 1 and 2.



In Fig. 2 the lines D B and F H represent the diagonal lines of the ceiling, and I have added lines, N S and E W, representing middle longitudinal and transverse sections of the ceiling for further illustration. In Fig. 1, G G is the ground line, G X is the height of the viewing station X, and D B the top of the walls, whilst A is the apex or top of the ceiling at the middle. The semi-ellipse, D A B, in Fig. 1, corresponds to the line D B in Fig. 2, and the semi-ellipse, E A W, corresponds to both E W and H F in Fig. 2, whilst N A S corresponds to N S. From X, in each of the Figs. 1 2, draw lines through every necessary point of the elevation and plan, so as to cut the picture line V L. These lines, only a few of which are shown, and in a dotted form, mark on the line, V L, distances from the centres C C, to be used for obtaining the perspective picture Fig. 3, the distances got by means of Fig. 1 being vertical distances (or ordinates), and those of Fig. 2 being horizontal distances. I must here remark that the distances actually used for Fig. 3 are considerably reduced in scale from those on the line V L, Figs. 1 2, in order to get Fig. 3 of a convenient size. In Fig. 3, horizontal and vertical lines are drawn through the point of sight P, and the distances obtained from Figs. 1, 2 are set off from that point. Then the perspective points are obtained as intersections of vertical and horizontal lines drawn respectively through the points set off on the horizontal and vertical lines through P. There is, of course, no difficulty about the straight lines; but the curved lines of the roof require special treatment. Now, any line which is a circle or ellipse in the object, and entirely in front of, and not touching, the station plane—that is, a plane parallel to the picture plane and passing through the station X—will be represented in the perspective by a circle or ellipse. The line E W in Fig. 2 represents a semi-circle, which is represented by a semi-ellipse in Fig. 3 and the line F H in Fig. 2 represents a semi-ellipse, which is represented by a semi-ellipse in Fig. 3, these both being in front of the station plane; but the lines D B and N S in Fig. 2 represent semi-ellipses, which cut the station plane, and which have to be represented in Fig. 3 by portions of hyperbolas. The perspective of a circle or ellipse touching the station plane would be a parabola. It is usual to obtain the perspectives of circles and other curves by finding points and drawing curves through by the eye; but in the present case it happens that the axes of the perspective ellipses can be very easily found, and that the curves can be drawn with much more accuracy than by means of points. Thus, if we take the ellipse H A F, the vertical lines at H and F are tangents to it, and are represented by parallel lines in the perspective. Then from the properties of ellipses, if the diameter H F is bisected in R, and a line R T be drawn parallel to the tangents at H and F—that is, vertically—R T will be a conjugate semi-diameter. By working back from Fig. 3 to Figs. 1 and 2, it is easy to find the perspective length R T, and then the major and minor axes of the ellipse can be found in the following manner: Draw R U equal and at right angles to R F: draw a line through U T, and bisect U T in M: and set off from M distances M Y, M Z, equal to M R: then the axes will pass through Y and Z respectively, whilst the minor semi-axis will be equal to Y U, and the major semi-axis will be equal to U Z, with which data the ellipse can easily be drawn. The line E W in Fig. 2 represents a semi-circle, and its perspective is the ellipse E J W in Fig. 3. The hyperbolas N A, &c., and D A, &c., are most conveniently obtained by means of points, as, although not difficult to find their axes, asymptotes, &c., it would be laborious and tedious to do so. In Fig. 3 I have shown much more than, with "Murano's" conditions, an artist would show in a picture; but I have done so to indicate the character of the lines the more clearly. The true point from which to view Fig. 3 is only seven-tenths of an inch in front of the point P; so that if the picture were drawn to a scale twenty times as large, the proper viewing point would even then be only 14in. off, and the portion included in a circle round P of about 30in. diameter would be as much as would be comfortably seen. The lines shown on the floor in Fig. 3 are perspectives of the lines D B, E W, F H, and S N, in Fig. 2, as projected down upon the floor, and are put in as likely to afford assistance to the artist in filling in details. As to the patterns spoken of by "Murano," even if it were more precisely described, the drawing of its perspective could scarcely be given, except upon a scale far too large for the pages of the "E. M."—E. H.



[52178.]—**Invisible Combustion.**—The experiment first described by "R. P." to illustrate invisible combustion is one of the many discoveries due to England's greatest chemist, Sir H. Davy, and was the result of an experiment with his safety-lamp in order to ascertain the limits of the combustibility of gaseous mixtures of coal-gas and air; indeed, invisible combustion is the explanation of the most remarkable features of the Davy safety-lamp. If the ordinary miner's Davy is supplied with a coil of platinum, fixed, and of the size as described by "R. P.", the platinum coil will remain incandescent after the light of the wick is extinguished as long as there is any hydrocarbon left in the lamp. This phenomenon is of intense importance to the miner, who, when in the dark and, by reason of firedamp, dangerous recesses of a coal mine, finds his lamp extinguished, but leaving the platinum coil incandescent, and giving light sufficient to permit his escape. If, instead of the wick and spirit of the lamp, a cylinder of camphor is substituted, the result will be the same, with the addition of the exhalation of highly odoriferous vapour. If oil of turpentine is used, invisible combustion ensues, unaccompanied with the incandescence of the platinum coil, but producing dense columns of vapour. By adding various fragrant aromas to the oil, sweet-scented odoriferous vapours will be obtained. The instances of invisible combustion, as described by "R. D.," and those given above, are far more remarkable than that described by Mr. Fletcher, and known to Mr. Magloskie and others for years. I should be pleased to know from Mr. Fletcher if he has any analyses of the products of invisible gaseous combustion, as carried out by him, as these would show the economical advantages (if any) possessed by this method of combustion. In ordinary visible combustion the zone of hydro-oxidation is colourless; it is only the carbon atoms set free and incandescent which give the light until it is oxidised. In the action of invisible gaseous combustion, I believe the carbon is set free as carbon monoxide, and this has a reducing or deoxidising action on the incandescent coil of wire.—B. H. T., F.C.S.

[52184.]—**Altitudes.**—I have calculated these by a table of Sir George Shuckburgh, given in Drew's "Meteorology," where—

h and h' = barometer reading at upper and lower station,
t and t' = temperature of the air ditto,
T = tabular quantity opposite the mean of $t + t'$.
Formula—

$$\frac{30\,(h - h')\,\mathrm{T}}{\frac{h + h'}{2}} = x$$

$$(1) \qquad \frac{30 \times \cdot 536 \times 936 \cdot 0}{29 \cdot 874} = 503 \cdot 8 \text{ feet.}$$

$$(2) \qquad \frac{30 \times \cdot 531 \times 932 \cdot 0}{29 \cdot 844} = 497 \cdot 5 \text{ feet.}$$

I fancy the above is correct as well as simple.—LYMINGTON.

[52186.]—**Saturn.**—The brightest sat. is always Titan. The others are difficult to identify because of their changes of brilliancy, but are not of much consequence. Iapetus is sometimes bright at W. elongation. I have seen the crape ring crossing the planet with 2in., and in the Ansæ with 4½. Why not reduce objective until crape ring disappears? You would then know smallest aperture at which it is visible. Clockwork helps detection of details by keeping star in the field.—C. J. RYAN, Ventnor.

[52186.]—**Saturn.**—With regard to "Aziola's" question *re* the crape ring, back numbers may be consulted with profit. The Rev. T. W. Webb, in his delightful "Celestial Objects," remarks: "It has been well seen with a $3\frac{3}{8}$in. achromatic by Ross; I saw faint traces of it with my $3\frac{7}{10}$in.; anything larger, if good, is sure to bring it out." Proctor says somewhere, a 4in. aperture is necessary. Barnard (ENGLISH MECHANIC, Jan. 7, 1881), finds one crape ring "seen distinctly in moonlight" in the clear American skies. Yet another correspondent, armed with a 6in. Calver, complains (March 30, 1883), that he can never see the crape ring distinctly, though Encke's division is within his grasp. Surely in these and other cases eyesight and experience as well as aperture must be taken into account. I well remember, through the kindness of an accomplished contributor to these columns, gazing at Saturn through his noble 12in. Calver. His practised eye could detect crape ring, Encke's division, and all, whilst to my inexperienced eyesight not even Cassini's division was revealed.—ARTHUR MEE.

[52193.]—**Telescopic.**—I am greatly obliged to Mr. Franks for his kind and lucid reply to my query. Will wait, however, until I get a larger aperture before obtaining compound eyepieces.—ARTHUR MEE.

[52195.]—**Caoutchouc.**—Doctors can, and occasionally do, restore noses from flesh taken from the forehead or other part of the patient. These are very different from the indiarubber noses recommended by "Os."—W. G.

[52198.]—**Firing.**—If you wish to gain information about firing stationary engines I would recommend you to read "Stationary Engine Driving," by Michael Reynolds, published by Crosby Lockwood and Co., London, where you will find the subject fully treated of, and in a most practical manner. "Locomotive Engine Driving," by the same author, contains equally clear directions for firing locomotives in the best and most economical manner.—MACHINA.

[52199.]—**Ornamental Flower Pots.**—In my query on page 228, the word "dry" was omitted after "mould" in the fourth line, which is, I think, the reason I have not received any information.—M. W. S.

[52200.] — **Vacuum Gauges — Continuous Brakes.**—When the automatic vacuum brake was introduced upon the Midland Railway by Mr. Sanders, vacuum gauges were placed in the guards' vans; but these were afterwards removed by the railway company with a view to obtain fewer parts and greater simplicity, the result being that efficiency has been sacrificed. Major Marindin, when reporting upon the collision between a passenger train and the buffer-stops at Northampton, April 3rd, 1883, stated that it furnished "a strong argument for the necessity of placing gauges in the guards' vans, so that they may see at all times what is the condition of this continuous brake, which is particularly liable to become useless when running, in the event of a driver disregarding the rules." The directors, in accordance with this report, and also in consequence of several other cases, have ordered that vacuum gauges shall be placed in the vans without delay. These gauges are duplex, the left-hand side shows the vacuum maintained in the brake pipe, and the right-hand side indicates the vacuum in the reservoir and above the one piston placed under the van itself. Any person riding in a van cannot fail to remember the words of Colonel Rich, that the efficiency of this class of brake is materially interfered with by the leakage hole in the piston head, for the new gauges show, what I have so often pointed out, that the moment the brake is applied the power begins to leak away, and that it is all gone in less than two minutes.—CLEMENT E. STRETTON.

[52204.]—**Long Pendulum Clock-Case.**—If clock-case stands out from the wall, and on the floor, it would be difficult to say why it does not give out the sound of the bell if it is struck. Are you sure it is? The head of case ought to draw off; usually a button inside case, just under six o'clock, fastens it on, and is got at by opening the front door and passing the hand up inside. Get the head off, turn minute hand round to about one minute past the hour, or twelve; listen if clock strikes, if it does, then set minute hand about one minute before the hour (and have the clock going), put head on again, listen if you can hear it strike (by putting your ear close to the case, which you will, if you can hear the clock tick); should you hear the striking but faintly, I would advise you to have the sides of clock-case head cut out, and fitted with silk and fretwork; the sound will then come out, I venture to say. If you cannot hear any striking when the head is on, but can when off, look to the hammer; it may catch some part of inside of head, or the bell may touch it.—X.

[52207.]—**Boring Cylinder.**—If your cylinder was $\frac{1}{16}$th higher from the bed at one end than at the other, then it would be impossible for the lines to show true with the bar when the cylinder was carried from end to end, as that part which is being cut is, as you say, always at the same place on the bed: therefore, when the high end comes to the cutters they will take out $\frac{1}{16}$th too much at the bottom, and leave the same amount too much at the top. When doing a job of this kind it is absolutely necessary that the job shall be parallel every way with the bed. It does not matter much about the bar. If it was 1in. higher one end than the other, it would still bore true with the bed. It is different when the job is fixed, and the boring head slides on the bar; then it does not matter how the job, or the bar, stands with the bed so long as the job is true to the bar. How did you try the lines to see that they were fair with the bar? Calliper from the bar, while standing, with a pair of "jennys," or try it with a V scribing block? Both of these ways being practically alike and bad; as if the bar is bent, it throws the job just that much out. The only right way is a tool, taking the place of a cutter, drawn to a point and bent to suit, so that you can turn the bar round, and thus check it as if it was actually cutting. Now, if you used a tool like this, and it showed all right at each end, your job would have been all right, whatever the scribing block showed. If the job was all right, the only way I can see to account for the scribing block showing wrong is that the bed is not flat across. It would be all right at the back poppet end; but close up to the headstock you will find old lathes worn all shapes, some rounding, some hollow. Now, if the foreman set the block at the unworn part of the bed, and then tried it at the worn part, and if that part was hollow, the point of the scriber would of course hang down, and show as if the job was high that end; and the further the scriber was out to reach the centre the worse it would be. You should have run the job along, so as to let him try from the same place in the bed, each end of the job. I have been for months on this class of work, and never used or heard of using a scribing block as a check, as it would only be a check vertically, even on an unworn bed; the work may be out any amount sideways, and it would not show it. You should have got them to let you run a cut through, and see if it showed parallel with the lines.—WESTON.

[52212.]—**Engineering School.**—There is a good school for training engineers held at the Crystal Palace, where a young man would get a good practical insight into all the branches of the profession; it is called The Crystal Palace Company's School of Practical Engineering; Principal, J. W. Wilson, M.I.C.E.—T. R. SAXTON.

[52211.]—**Electric Formula.**—The determination of the attraction between two coils is not such a simple thing as Mr. J. Crocker seems to imagine, nor is it capable of being expressed in an algebraical formula in the general case. If the coils are upon the same axis and parallel, and not very near each other—say, not less than five or six times their radius—the attraction is given approximately by the formula—

$$4\,\pi^2\,\mathrm{C}_1\,\mathrm{C}_2\,\frac{a_1^{\,2}\,a_2}{r^3}$$

Where C_1 C_2 are the currents in the coils (supposed simple), a_1 the radius of the larger, a_2 that of the smaller coil, and r the distance between their centres. If the coils are on square frames of side a, and situated in parallel planes with distance h between, the attraction is—

$$8\left(\frac{a^2}{h\sqrt{a^2 + h^2}} - \frac{a^2 h}{(a^2 + h^2)\sqrt{2a^2 + h^2}} + \frac{2h}{\sqrt{a^2 + h^2}} - \frac{h}{\sqrt{2a^2 + h}} - 1\right)$$

If Mr. Crocker is pretty well up in mathematics, I should recommend him to read "Electricity and Magnetism," by Mascart and Jubert, of which there is now an English translation. If he is not strong in mathematics, I should advise him to devote some time to them before doing practical electrical work.—NABLA.

[52217.]—**Bassoon.**—Some notes do not admit of a shake, others present difficulties, and the rest shake naturally and easily—all which information can best be gained by purchasing some instruction book. Jancourt's "Méthode pour le Basson" is a good one. It is published in two parts—Part I., Information; Part II., Examples of same. It costs, complete, 30s. The pitch is altered by having additional flat or sharp crooks. The reeds are softened by scraping away the thick part of the wood, about halfway between lip end and the first wire band. The cork is to make the tube air-tight. —F. D.

[52218.]—**Medical.**—Does "Assistant" feel the effects of a little pleurisy, with which congestion is often complicated? Similar effects in my own case the doctors spoke of as caused by pleuritic adhesions. Mustard or turpentine relieved me at the time; but though I only feel them occasionally now, I know they are there, and do not expect to get rid of them.—H. H.

[52218.] — **Medical.** — There are few trifling ailments the public are more uneasy about than pains in the chest walls. When unassociated with constitutional disturbance—e.g., fever, loss of appetite, malaise, &c.—they are generally due to intercostal neuralgia or intercostal rheumatism, and quickly relieved by the application of an adhesive plaster, of which perhaps belladonna is the best. —M.D.

[52218.]—**Medical.**—Assistant is evidently suffering from a little pleurisy of the right side. His means of cure are to get his system into good working order by means of plain dietary, fresh air, warm baths, and exercise. Fresh air he must get, if possible, as all lung complaints are due to want of that. For local application he can use friction with a rough towel, paint with tincture of iodine, apply mustard leaves (Rigollot's), or even a porous plaster of some kind. Deep breathing a few times a day is also a good plan, as it tends to prevent adhesion of the lung to the walls of the chest. "Assistant" must not be surprised if the pain lasts another month; but time and the above will cure it. —T. R. ALLINSON, L.R.C.P.

[52223.]—**Covering Sharp Edges of Steel.**—How would "japan" do? There is a variety that dries in a few minutes when the article is made warm. Any varnish dealer keeps it.—NUN. DOR.

[52227.]—**Vacuum Brakes, L.N.W.R.**—There is an automatic brake fixed on the middle pair of wheels on the brake vans; whilst running, the brake is kept out of gear by the driver maintaining a small vacuum. Should he fail to do this, or the train breaks loose, or the pipes disconnect, or a leakage, the brake goes on. The guard is apprised of this by the falling of a lever, which sets a bell ringing. The valve is for taking the brake off by letting in the air. There are gauges in the vans which let the guard know the amount of vacuum. I do not think it is the same as the L. and S.W.; it has been improved lately. The piston in the cylinder works with a crank instead of a ratchet wheel, and the coaches are provided with a lever to shut off the brake connection should it fail or run on a foreign line.—ROB ROY.

[52228.]—**Electro-Magnets.**—1: soften, yes; 2: horseshoe: 3: round; 4: no; 5: yes, no waste space.—C. WEST.

[52231.]—**Self-Closing Door.**—I bought at the ironmonger's a cheap contrivance which works well. Two leather straps are inclosed in a coil of strong wire, which is compressed by pulling opposite ends of straps. One end is fixed to the door itself on the inside a few inches from the hinge, and the other to the adjacent framework. A more perfect and powerful affair may be seen at work in almost any public office. Doors which close by a slant in the hinge-joints are for a private house as good as anything. "Chemicus" exclaims "No weights"; and I agree with him, having experimented, and narrowly escaped smashed toes.—ARTHUR MEE.

[52233.]—**Boiler Feed from Cistern.**—A head of water 10ft. high will feed boiler.—SABATA.

dimensions and say what kinds of wood should be used for different parts of 'cello, what thickness the pieces ought to be for back and front to allow for modelling, the knees of sides, &c.? Any information an amateur is likely to require to enable him to construct one without improvements will greatly oblige.—Edinburgh.

CHESS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 21, and unacknowledged elsewhere:—

Hennan and Froude.—R. W. Thomas and Co.—J. and H. Grace. Britannia Co. W. F. Stanley.—Lucas and Son. J. W. Queen and Co. L. and H. W. M. Ingram.—F. Grant. M. Jones.—Miranda.—A Decided Amateur. Vulcanite.—A. S. I. W. F. T. A. Dring.—Wag. Soap Boiler. B. H. M. A. Light.—Ego.—C. K. M. T. T. Ouvrier. Y. Z. E. Owen.—Amateur. Second Mortgagee. William E. Dawson.—Bow. Incognita.—Eyesight. Semaphore. Churchwarden.

Compass. Maxton's "Engineering Drawing," Lockwood and Co., Stationers' Hall-court, E.C., 4s., would be a suitable book. You will also find a very valuable series of articles on the subject in Vol. XXXIII. pp. 444, 467, 495, 566; Vol. XXXIV. pp. 32, 57, 85, 180, 489, 586.)—Fitter. (There are a variety of electric alarms in back volumes. For a simple one, see p. 561, Vol. XXVIII.; or for general directions, p. [illegible], Vol. XXXV.)—Amateur. (Voicing organ pipes is the art of the organ builder, and an amateur cannot hope to acquire even tolerable proficiency without much labour. For directions in building, see the back volumes commencing with Vol. IX.; the latest series of papers was in Vol. XXXII. pp. 25, 127, 2[illegible]1, 317, [illegible]; Vol. XXXIII. pp. 27, [illegible], 177, [illegible], 322, 431, 5[illegible]4.)—[illegible]. (Use brass spring wire. As it is doubtful if you can get that out of London, draw the ordinary wire through a hole in a steel plate that is just too small to allow it to pass without using force. Thin one end, pass it through, and then taking a firm grip, pull.)—M'Lean. (No one can tell you without making an analysis. They are mostly salts which treated with a little size or gum to protect from the atmosphere, and some are mixed with [illegible].)—Dar[illegible]. (Such a salt is not known. There are platino-cyanides of alkalis.)—F. W[illegible]. (Dab them over with a ball of putty; that is the simplest. See answer to "Questor" last week.)—M. A. P. (Napier's "Manual of Dyeing," Griffin and Co., London. Recipes for feather dyeing in back volumes.)—Isaac. Nonsense. (In going into action water would be let into the tanks so as to sink the vessel as low as would be safe, and thus offer only a small target to the enemy's shot; but that takes time, and there is no dancing up and down as you describe. By means of powerful pumps, however, the tanks can be quickly cleared, when the full amount of freeboard is required.)—Talus. (Edison's phonograph was illustrated on p. 30, No. 675; directions for making one on p. 157, No. 683.)—Donald Warren. (The carbon telephone, No. 692, p. 381, and No. 853. Chalk cylinder receiver and induction balance in No. 730; Crossley's microphone, No. 755. See also many other back numbers.)—E. J. P. (Application should be made to those who publish such statements. You will find our reference to it on p. 17[illegible], a week earlier than the date of your reference. When a really "cheap" battery for use in lighting private houses is invented, we have no doubt we shall receive early intimation; at present, inventors take their "news" where it is received without question. If you look through your back numbers—No. 948, for instance, you will probably get an idea.)—H. H. B. (See p. 456, Vol. XXXIV. Answered many times.)—Mark Wicks. (We do not care to reproduce the article, and should think you are not precluded from giving the information as a letter. Please yourself, of course; but if you care to send, it shall appear.)—B. Hardcastle. (Please send.)—J. Sutcliffe. (Enough has been said already, we think.)—G. D. A. (The insurance company in which the building is insured would probably have something to say if communicated with; but, after all, not much can be done with a landlord who has no more respect for his property than yours has—this, of course, presuming that he is bound to do repairs, and that it is not you, who, having obtained possession at a low rent, are neglecting an implied understanding to repair.)—Young Wheelwright. (The executors do not sign the will; only the testator and the two witnesses. If you apprehend any unfairness, you should advise the testator to lodge the will with his solicitor, or at his banker's, or in the hands of some respectable disinterested person. With regard to the cart-yes. Some articles on carriage painting appeared in Vol. XIV. pp. 555, 606, 659, and Vol. XV. pp. 88, 168, 218. There is also an American book entitled "The Carriage Painter's Manual," by F. B. Gardner, published by S. R. Wells, 389, Broadway, New York, which you might possibly be able to obtain through Trübner and Co., of Ludgate-hill.)—T. J. Milner. (Is it not that the movable leg being held underneath, the upper one appears to rise when the under one is allowed to fall?)—Alfred James. (Better buy it; but you can make it by dissolving an ounce and a half of shellac and a quarter of an ounce of benzoin in half a pint of rectified wood naphtha. Crush the gums, mix in a bottle, and put into a warm (not hot) place.)—Beta. (You will find the reply wanted on p. 201, Vol. XXXV.)—S. Newbury. (If you were to get a catalogue from one of the makers advertising in our pages, both questions would be answered.)—Item. (A professional would tell you in a moment, or one of the dressers. We do not think there is anything really satisfactory but shaving.)—Co. Wexford. (You will find a good deal about it in back volumes. It is better to purchase it than to attempt its manufacture. Messrs. Ihlee and Horne, of Aldermanbury, E.C., can give you all information about it.)—Guilliaumes. (See the back page of the No. for Nov. 2. A handy little book is Ellerbeck's, published by Cussons and Co., Bold-street, Liverpool; but you will find several on the shelves of any large bookseller.)—York W. R. (Both questions are answered on p. 241 of the same volume. The focus should be 6in. or less; the burner a Silber or any good device capable of consuming paraffin oil.)—F. C. Marshall. (The query is in too general terms. You can get an idea from many illustrations in back volumes, and then if any difficult point arises, ask a question about it. See p. 267, No. 922; also Nos. 530, 512, 574, 621, 695.)—James H. Halley Broomhall. (We gave a paragraph about it on p. 36, extracted from a notice in the *Times*. We are not aware that any expert has been invited to test the wonderful machine.)—Enquirer. (See p. 22, Vol. XII.; also pp. 454, 476, 501, Vol. XXXII. Any of the usual enamels or glazes will do; but the art of firing cannot be learned except by practical experience.)—J. M. (We have repeatedly pointed out that as a rule varnishes of all kinds are to be bought as cheaply as they can be made. However, dissolve half an ounce of genuine asphaltum in one ounce of Canada balsam and 10 ounces of oil of turpentine. If you cannot procure these articles of the best quality your varnish will be inferior to that sold by the dealers in photographic requisites, and if you do obtain them of good quality, they will probably cost more than the varnish ready prepared.)—Holcombe. (It is an advantage to have the dies hot; but they should be wetted too. If very large, wet thoroughly, and then pour on the wax, as if casting from a mould. By "wet" is to be understood damp all over.)—J. T. S., Southport. (Add water, and if they do not act they need taking to pieces. You will find full directions in back volumes.)—Edward Cosby. (Yes, that is it. Christmas-day is midsummer in the antipodes.)—C. (You forget that in the bottle experiment there is nothing but the original gases; in the cave there is probably a constant supply of carbonic acid from the bottom, while the mixture is swept out from the top by every breath of wind. The gases diffuse just the same, but the upper strata, say, in the wel[illegible] pumped up by the wind, and fresh air takes t[illegible] place, or, at least, mingles with them. It is only [illegible] closed, or practically closed, vessels that the gase[illegible] uniformly mixed. See any work on "Phys[illegible] under heads Endosmose, Diffusion, and Mixture [illegible] Gases.)—Pythius. (Perhaps the sal-ammoniac requ[illegible] more water. You can get suitable mangane[illegible] dealers advertising in our columns.)—Edith Wal[illegible] (Do you not think it would be advisable to procu[illegible] handbook of the art, if you intend making a bus[illegible] of it? If you do so, and become acquainted with [illegible] the rudiments, we have no doubt our readers will [illegible] you out of any difficulties; but it is too much to [illegible] for the elements. Will not the papers in the [illegible] volume help you?)—St. Mungo. (We think you [illegible] find what you meant on p. 520, No. 749. It is ma[illegible] a shellac varnish.)—J. M. Jones. (You do not w[illegible] a "book" for that. You will find several method[illegible] back volumes. See p. 467, No. 852. The usual [illegible] is to burn and fuse with carbonate of soda.)—C[illegible] Chem. S.S. (Why trouble yourself to calculate the[illegible] when you can buy a book of almost any second-[illegible] dealer. We cannot afford space to tell you h[illegible] "make" them; but you will find the method[illegible] described in most cyclopædias.)—X. Y. Z. (We do [illegible] know of any. You would find a great deal about t[illegible] engines in the technical journals, and about the sh[illegible] in the *Transactions* of the Institution of Naval Arc[illegible] tects; but you do not indicate the nature of the info[illegible] mation needed.)—Donald Crottach. (Queries ar[illegible] the class known as advertisements, because the repli[illegible] would necessarily advertise some firm. Try some [illegible] the artists' colourmen.)—Ebor. (Not of sufficient in[illegible] terest. We should hunt up the photographic stores i[illegible] any of the large towns.)—Dumo. (It is entirely a loca[illegible] question, and one probably which would have to b[illegible] argued, before a satisfactory decision could be obtained [illegible] and we really cannot spare half a column for the quer[illegible] and extracts.)—Edward M. Richards. (Too theolo[illegible] gical; there is no doubt the Canon was settled in som[illegible] way at that council.)—F. W. B. (Not illegal in smal[illegible] quantities, and for own use.)—J. C. H., R. A. [illegible] Bennett. (In type.)

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are re[illegible] quested to observe that the last number of the term for whic[illegible] their subscription is paid will be forwarded to them in a Pi[illegible] Wrapper, as an intimation that a fresh remittance is necessary, [illegible] it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight Words	0	3

*** It must be borne in mind that no Displayed advertisement[illegible] can appear in the "Sixpenny Sale Column." All advertisement[illegible] must be prepaid; no reduction is made on repeated insertions[illegible] and in cases where the amount sent exceeds One Shilling, th[illegible] publisher would be grateful if a P.O.O. could be sent, and no[illegible] stamps. Stamps, however (preferably halfpenny stamps), ma[illegible] be sent where it is inconvenient to obtain P.O.O's.

The address is included as part of the advertisement, and charge[illegible] for.

Advertisements must reach the office by 1 p.m. on Wednesda[illegible] to insure insertion in the following Friday's number.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free [illegible] any part of the United Kingdom. For the United States, 13s., [illegible] 3 dols. 25c. gold; to France or Belgium, 13s., or 16f. 5oc.; to Ind[illegible] (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the We[illegible] Indies, Canada, Nova Scotia, Natal, or any of the Austra[illegible] Colonies, 13s.

The remittance should be made by Post-office order. Ba[illegible] numbers cannot be sent out of the United Kingdom by [illegible] ordinary newspaper post, but must be remitted for at the rate [illegible] 1d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Phi[illegible] delphia, are authorised to receive subscriptions for the Uni[illegible] States for the ENGLISH MECHANIC, at the rate of 3 do[illegible] 25c. gold, or Thirteen Shillings per annum, post-free. The cop[illegible] will be forwarded direct by mail from the publishing office [illegible] London. All subscriptions will commence with the number [illegible] issued after the receipt of the subscription. If back numbers [illegible] required to complete volumes, they must be paid for at the rate [illegible] 1d. each copy, to cover extra postage.

Vols. XXIV., XXVII., XXVIII., XXX., XXXI., XXX[illegible] XXXIII., XXXIV., XXXV., XXXVI., and XXXVII. bou[illegible] in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscrib[illegible] would do well to order volumes as soon as possible after the co[illegible] clusion of each half-yearly volume in March and September. [illegible] only a limited number are bound up, and these soon run ou[illegible] print. Most of our back numbers can be had singly, price [illegible] each, through any bookseller or newsagent, or 2½d. each, post-f[illegible] from the office (except index numbers, which are 3d. each, [illegible] post-free, 3½d.)

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. P[illegible] free 2½d. each. Indexes to Vol. XI. and to subsequent vols. [illegible] each, or post free, 3½d. Cases for binding, 1s. 6d. each.

Throat Irritation and Cough.—Soreness a[illegible] dryness, tickling and irritation, inducing cough, and affecting [illegible] voice. For these symptoms use Epps's Glycerine Jujubes. [illegible] contact with the glands at the moment they are excited by [illegible] act of sucking, the Glycerine in these agreeable confect[illegible] becomes actively healing. Sold only in boxes 7½d., tins 1s. 1½d. labelled "James Epps and Co., Homœopathic Chemists, Lond[illegible] A letter received: "Gentlemen,—It may, perhaps, interest y[illegible] to know that, after an extended trial, I have found y[illegible] Glycerine Jujubes of considerable benefit (with or wi[illegible] medical treatment) in almost all forms of throat disease. Th[illegible] soften and clear the voice.—Yours faithfully, Gordon Hol[illegible] M.D., Senior Physician to the Municipal Throat and E[illegible] Infirmary."

Holloway's Pills have many competitors, [illegible] no equals, for supplying the young and delicate with a [illegible] strengthening, and purifying aperient. These Pills, composed [illegible] the finest balsams, are particularly adapted for all complai[illegible] peculiar to females, and are most serviceable at the criti[illegible] periods of early and mature years.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, NOVEMBER 30, 1883.

M. CAILLOT'S REST.

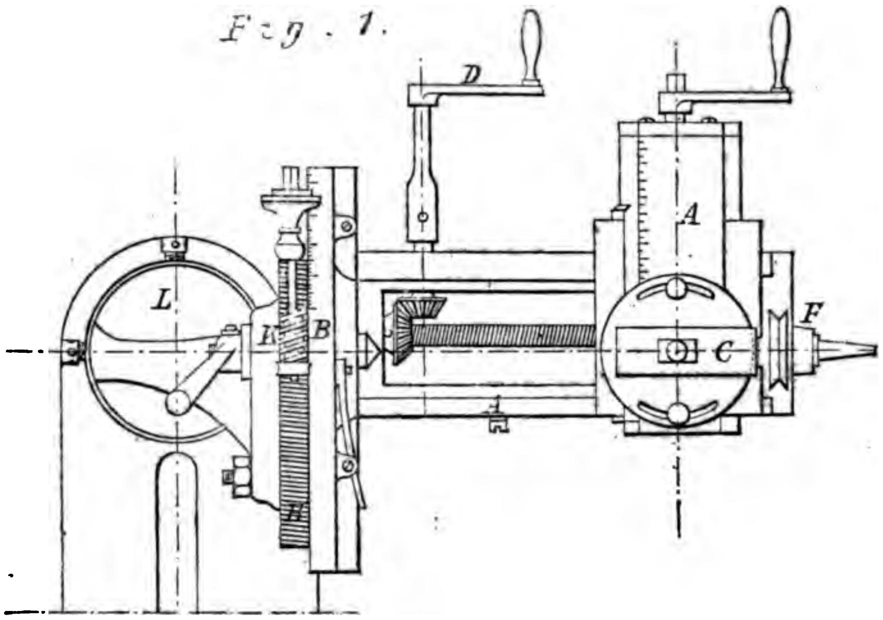

Fig. 1.

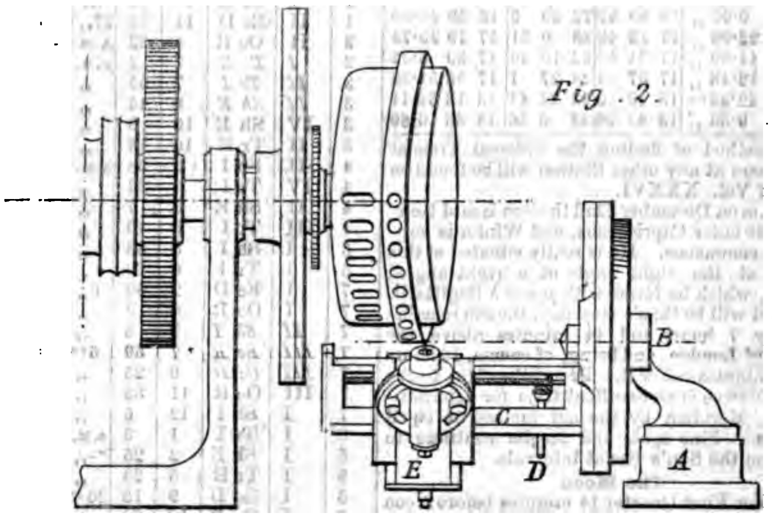

Fig. 2.

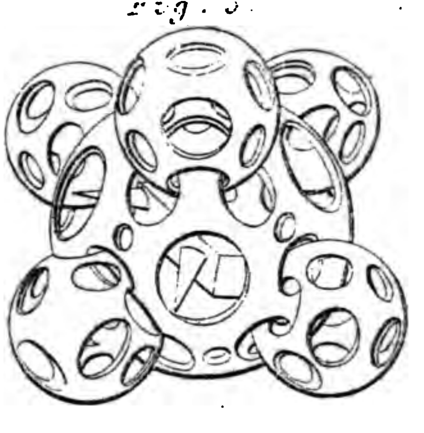
THE two figures annexed to this paper will, I think, be sufficient to show the general features of the rest suggested in M Caillot's pamphlet. The present form is an improvement on a more complicated design, originally devised by the inventor. It may be as well to state that the rest is not a mere theoretical arrangement, but is one in actual use, and proves equal to the work for which it is designed—viz., the placing ornamental drills and cutters in a proper position for the ornamentation of ellipses. Fig. 2, I think, will best illustrate the plan; but the elliptic chuck represented is not like that ordinarily used, and is probably one like that described by Bergeron. Into this, however, I need not enter. A, is a cast-iron support clamped to the lathe bed, and needs to be substantial, as it has to carry the whole slide-rest which pivots upon it. To my own mind, this is the weak point of the invention, as the rest is a heavy affair to overhang as it does here, with no support except at one end; but as the inventor is the better judge, and finds the arrangement a practically good one, I am scarcely justified in denouncing it. The rest is not pivoted direct to the support, as will be seen by referring to Fig. 1, which is a reduced drawing, quarter size. The plate B, which is circular, carries the rest attached to it by a slide moving in V's to allow it to be adjusted nearer to or further from the work. (There are two other drawings in the pamphlet showing the slide which I think will, however, be sufficiently understood without them.)

The front disc, to which the rest is thus clamped securely, turns upon a centre pin in a second circular plate, against the face of which it beds fairly. This back-plate is lettered H in Fig. 1. The plate H has a racked edge in which works the tangent screw which is fixed to the front plate, so that a circular motion is thus given to the plate carrying the rest; whereby the latter may be accurately placed at any desired angle, causing a tool in the holder to assume a radial position. As the rest is often so situated as to prevent the use of the ordinary handle to turn its leading screw, the latter is fitted with a bevel wheel to gear with one working at right angles to the screw, to which a handle may be applied when necessary. I have sent these drawings and brief description for the sake of the few who are in the habit of doing elliptic work, and who can judge of the merits of the invention better than I can myself. There are certain calculations necessary in order to determine the exact amount by which the worm wheel is to advance after each bead or device has been cut; but in order to explain these it would be necessary to copy some elaborate illustrations, and I think that if any one feels inclined to go into the matter, he had better procure a copy of the pamphlet. It is called "L'Art du Tourneur-Tabletier," and is published at Nantes by M. Th. Veloppe, à la Libraire Rue Jean-Jacques-Rousseau; and at Paris by M. Baudry, Libraire Polytechnique, 15, Rue des Saint Péres. The price, 2s. 6d.

The author invites correspondence, and indeed suggests the advisability of more intercourse between amateur turners. Possibly he would like to join the Amateur Mechanical Society. His address is 9 Rue Cambronne, Nantes. In the early pages of the pamphlet is such a specimen of interlaced ball turning as I never before saw, and full details are given for executing a similar one. M. Caillot has himself completed such a ball, which, as I cannot copy, I will describe. It consists of a hollow shell of ivory, inside which is a star of six rays, upon a cube cut out of the same solid as the ball. This, as any one knows who has tried it, is work enough for a man of ordinary patience and extraordinary skill; but this is not one half of the puzzle, for there are hanging about the big ball and linked into it six other similar shells, forming I think altogether the most marvellous specimen of a turner's skill ever executed. The ordinary Chinese balls are nowhere beside such a specimen as this. Of course tools and templets and plugs of various forms are needed, all of which were made as required, and, I may add, M. Caillot discovered for himself the way in which to cut out these balls from an inspection of one of the simpler ones in a turner's shop window. Even if the gentleman in question were a professional turner, the execution of such a work would have placed him in the front rank; but being engaged in business which leaves him little time for lathework, his skill is the more wonderful. If this ball were exhibited at the Mansion House this winter, it could hardly fail to bring due honour to the workman, and the introduction of a Foreign member would be a graceful act on the part of the Amateur Mechanical Society.

Fig. 3.



But if I were personally asked to attempt a similar piece of lathework, and had the requisite skill and appliances, neither of which I have, I should most certainly decline with thanks. It is the sort of job to be executed once in a lifetime as a guarantee of capability, and not to be repeated—a job for someone who has *too* much leisure, which I suppose is a disease not many of us are afflicted with. There were, I remember, some of these "boules agrafées" in Bergeron's volumes, very cleverly executed, but not as complicated as those now described. There was, however, one particular detail which I certainly have never seen in reality—viz., a sort of star with all its points or rays reversed—pointing inwards to a common centre. These, too, were the offspring of some Frenchman's skill—probably Bergeron's own; but I never read up the modus operandi, and verily it seems the nearest to an impossibility of any lathe puzzle. After all, though patience is not exactly a virtue of mine, I think I must set to work to copy M. [illegible]'s drawing. It will be an exercise at all events not without its own advantages. I only hope I may be fairly successful (Fig. 5), as I should like the readers of the ENGLISH MECHANIC to see what they can do over the water—not at Paris either, but at Nantes, where, by the bye, are some notable lathe makers. **O. J. L.**

ASTRONOMICAL NOTES FOR DECEMBER, 1883.

The Sun.

Day of Month.	Souths.			At Greenwich Mean Noon. Right Ascension.			Declination South.			Sidereal Time.

31	0	3	9·56 ..	18	41	26	23	6	30	18	38	16·89

The method of finding the Sidereal Time at Mean Noon at any other Station will be found on p. 573 of Vol. XXXVI.

At 4 a.m. on December 22nd the Sun is said technically to enter Capricornus, and Winter is supposed to commence. He is really situated at this instant at the right angle of a right-angled triangle, which he forms with μ and λ Sagittarii. The 22nd will be the shortest day, the sun remaining only 7 hours and 44 minutes above the horizon of London, and being, of course, 16 hours and 16 minutes below it. From the 21st to the 23rd inclusive is an excellent time for determining the Meridian by the old method of equal altitudes. Fine spots and faculæ continue to appear on the Sun's disc at intervals.

The Moon

Enters her First Quarter 14 minutes before Noon on December 7th, and is Full at 5h. 25·3m. a.m. on the 14th. She will enter her Last Quarter at [illegible] a.m. in the morning of the 21st, and be New at 59·7m. after Noon on the 29th.

Day of Month.	Moon's Age at Noon.	Souths.		
	Days.	h.	m.	
1	1·7	1	14·0	p.m.
6	6·7	5	19·2	,,

21	21·7	5	50·4	,,
26	26·7	9	31·7	,,
31	2·0	1	39·3	p.m.

The Moon will be in conjunction with Venus at 10 a.m. on the 1st; with Saturn at 1 a.m. on the 13th; with Jupiter at 3 a.m. on the 17th; with Mars at 2 p.m. on the 15th; with Mercury at 6 a.m. on the 31st; and with Venus at 8 o'clock the same evening.

Mercury

Is an Evening Star during the whole of December, but especially towards the middle of the month is as badly placed as he possibly can be for the observer owing to his very great South Declination. His angular diameter increases from 4·6″ on December 1st to 6·2″ on the 31st.

The printing of a phenomenon in *italics* indicates that its visibility is rendered doubtful, either by the brightness of the twilight or by Jupiter's proximity to the horizon.

Mercury.

From this it will be seen that Mercury will start from the South Western extremity of Ophiuchus, cross the whole width of Sagittarius, and be found by the end of the month in Capricornus. He will not approach any conspicuous Star.

Jupiter

Still Souths after midnight, but is visible for the observer's purpose during the greater part of the night. His angular diameter increases steadily from 39·7″ on December 1st to 42·5″ by the 31st, and he is now the most brilliant and conspicuous object in the night sky.

Jupiter hence describes a short retrograde arc in Cancer.

Venus

Is an Evening Star, too, but is, practically, as badly placed for the observer as Mercury, and for the same reason. Her angular diameter increases from 10·4″ at the beginning of the month to 11·2″ by the end of it. She has now lost her perfectly circular outline, too, and is beginning to be gibbous.

Day of Month.	Right Ascension.		Declination South.		Souths.		
	h.	m.	°	′	h.	m.	
1	17	47·2	24	20·0	1	7·0	p.m.
6	18	14·7	24	29·9	1	14·7	,,
11	18	42·1	24	20·9	1	22·5	,,
16	19	9·4	23	53·1	1	30·1	,,
21	19	36·5	23	7·1	1	37·4	,,
26	20	3·1	22	3·7	1	44·3	,,
31	20	29·3	20	43·9	1	50·7	,,

The path indicated by the above Ephemeris begins in Sagittarius, extends, as in the case of that of Mercury, right across that constellation, and also terminates in Capricornus.

Mars,

Viewed with reference to his time of Southing, is still a Morning Star; but as he rises soon after 9 p.m. at the beginning of December, and at about 7h. 20m. in the evening at the end of it, he may now be fairly observed during all the later working hours of the night. His angular diameter increases from 11·3″ on the 1st of the month to 14·5″ by the 31st. Even with the latter angular subtense, though, he presents but a relatively small disc; and the student will note that he is still gibbous.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	9 29·3	17 28·2	4 50·4 a.m.
6	9 33·9	17 17·7	4 35·4 ,,
11	9 37·5	17 12·1	4 19·3 ,,
16	9 40·1	17 12·0	4 2·3 ,,
21	9 41·6	17 17·9	3 44·1 ,,
26	9 41·7	17 30·1	3 24·5 ,,
31	9 40·6	17 48·8	3 3·8 ,,

The arc thus described by Mars lies in that very blank region of the sky to the West of the Constellation Leo.

Saturn

Is visible all night long, and is excellently placed for the observer. His angular diameter decreases insensibly from 18·4″ at the beginning of December to 18·0″ by the end of it. No difference in the opening of his ring system is now perceptible.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	4 19·7	19 24·8	11 37·8 p.m.
6	4 18·0	19 21·2	11 16·4 ,,
11	4 16·3	19 17·7	10 55·1 ,,
16	4 14·7	19 14·4	10 33·8 ,,
21	4 13·2	19 11·4	10 12·7 ,,
26	4 11·8	19 8·7	9 51·6 ,,
31	4 10·5	19 6·3	9 30·6 ,,

So that Saturn will travel in a westerly direction from ε Tauri, the most northerly star in the Hyades.

Uranus

Will be in quadrature with the Sun at 7 a.m. on the 20th, but does not yet rise soon enough to be observed with any advantage.

Neptune,

Though, is visible during the entire night, and is in a very good position for observation by the possessor of adequate optical means.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 8·8	15 46·3	10 27·0 p.m.
6	3 8·3	15 44·4	10 6·9 ,,
11	3 7·8	15 42·6	9 46·7 ,,
16	3 7·3	15 40·9	9 26·7 ,,
21	3 6·9	15 39·4	9 6·6 ,,
26	3 6·5	15 38·1	8 46·5 ,,
31	3 6·2	15 37·0	8 26·5 ,,

From this Ephemeris it will be noted that Neptune travels into a position almost south of δ Arietis and some 3° or 4° from that Star.

Shooting Stars

Are less numerous than they were last month. The most probable periods at which their apparition may be expected are from the 11th to the 13th, and again on the 24th.

The Pons-Brooks Comet.

The Comet originally discovered by Pons on July 20, 1812, and detected on its return on Sept. 2nd of the present year by Brooks in the United States ("Scientific News," p. 35), is now nightly becoming more visible with but small optical aid. In fact, it may now be seen with a good opera-glass. We append the approximate co-ordinates of its position for every fifth day at Greenwich Mean Midnight, whence it will be found without difficulty.

Day of Month.	Right Ascension.	Declination North.
	h. m. s.	° ′
1	18 35 51	46 25·0
6	18 59 16	44 46·9
11	19 25 47	42 41·5
16	19 55 29	39 48·3
21	20 28 9	35 57·8
26	21 3 4	30 39·6
31	21 39 4	23 54·9

It will be seen from the above Ephemeris that the Comet will start from a point in that empty region some 8° North of Vega, and will travel in a South Easterly direction across the Northern half of Lyra, passing into Cygnus between the nights of the 9th and 10th. During the rest of December it will be travelling through that great constellation; and after the 11th, will be superposed on part of the Milky way; a very remarkable and unusual spectacle.

Greenwich Mean Time of Southing of Sixteen of the Principal Fixed Stars on the Night of December 1st, 1883.

Star.	Souths. h. m. s.
α Aquarii	5 18 56·83 p.m.

α Andromedæ	7 21 11·92 ,,
α Cassiopeiæ	7 52 40·12 ,,
Polaris	8 35 39·00 ,,
α Arietis	9 19 7·60 ,,
α Ceti	10 14 33·24 ,,
α Persei	10 34 20·96 ,,
γ¹ Eridani	11 10 48·07 ,,
Aldebaran	11 47 21·23 ,,
Capella	12 26 6·89 ,,
Rigel	12 26 56·43 ,,
α Leporis	12 45 32·48 ,,
α Columbæ	12 53 21·46 ,,

The Method of determining the Greenwich Mean Time of Southing of either of the Stars in the above List for any other night in December, as also that of determining the Local Instant of its Transit over the Meridian at any other Station, will be found on p. 375 of Vol. XXXVI. The rules given, however (loc. cit.), are not rigidly accurate when applied to Polaris or to any close circumpolar star.

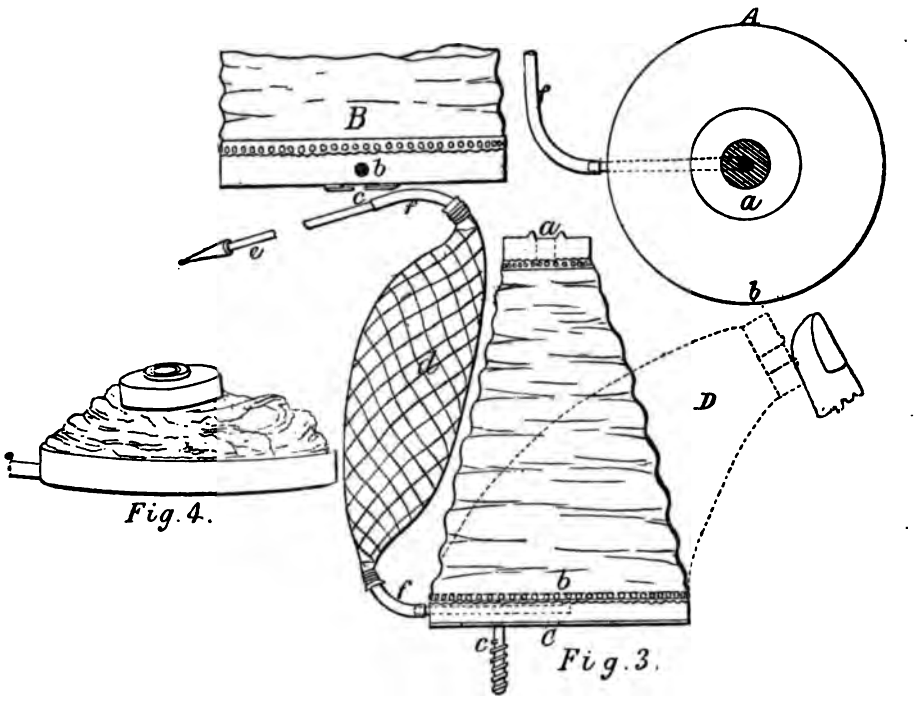

Fig. 4.

Fig. 3.

A NEW PATTERN HAND-BLOWER FOR BLOWPIPE ANALYSIS, WITHOUT VALVE OR SPRING.

By Lieut.-Col. W. A. Ross, F.G.S., late R.A.,
Member of the German Chemical Society.

A IS a plan of the two wooden circular frames belonging to this blower, *a* being the smaller frame, and *b* the larger one; the larger shaded circle is a hole cut in the upper smaller frame; the small shaded circle, a hole in the under larger frame. B is a front elevation of *b*, showing a section of the windpipe as a dark-shaded circle, with an iron slot *c* underneath, for the head of a screw or nail fastened into the table, to keep the blower down when pulled upwards. C is a stereographic sketch of the hand-blower in position, *a* and *b* being the two wooden frames, with *d* an elastic air-reservoir covered by a hair-net, and *e* a blast-pipe with nozzle, which can, of course, be made any length convenient to the operator; *c* is the table screw fitted into the slot above described, which Mr. J. T. Letcher thinks might be done away with, by weighting the inner side of the large wooden frame A with two pieces of lead: or the whole of its inner surface might be covered with a circular sheet of lead. This arrangement would not injure the table in any way, and would, I think, be sufficient to hold the blower down, making it a *little* heavier; but that is not of much consequence. *f*, *f*, *f* are pieces of elastic tubing, placed where convenient.

To use the machine, the smaller wooden frame is taken between the operator's thumb and second and third fingers; when the soft leather bag has been thus pulled out to the utmost extent, as shown in Fig. 3, the hole *a* is stopped air-tightly by the *first* finger, and the bag pressed firmly down, which motion has the effect of driving its contained air into the reservoir *d*, which is at once expanded, and exerts an amount of air-pressure upon the lamp-flame proportioned to its expansion. In pulling up the blower in order to renew the downwards stroke, of course the forefinger is raised from the hole *a*, thus acting as *the valve*, whilst the extremely slight muscular force of the arm required to pull up the soft leather bag, acts instead of the *steel spring*, which constitutes the chief expense of leather hand-blowers.

Mr. J. T. Letcher, of Truro, Cornwall, has been so kind as to make, at my request, a temporary but working specimen from the above sketch and description, of the cheapest possible materials; the air-reservoir and tube, *d*, *f*, Fig. 3, being made of one of those squeaking, elastic air-bladders sold in toyshops for one halfpenny each. He will, no doubt, make others more complete, and stronger than this, to any orders; and I am quite certain, from what I have seen of his work, the purchasers will be thoroughly satisfied with as being far more moderate in price, and [illegible] as well finished as that of the best Freiberg makers. I [illegible] constituted him sole trade maker of this [illegible] blower, which would appear to be the cheapest leather one in existence, as well as of the whole of my pyrological apparatus.

The dotted lines surrounding D show another form of wind-bag, which, I think, would be an improvement, and not increase the price at all. Fig. [illegible] is a rough sketch of the blower made by Mr. Letcher, closed for packing. All Figs. are half the natural size.

DR. MELDON'S ELECTRIC MOTOR.

AN improved electric motor has been devised by Dr. Austin Meldon, of 15, Merrion-square, Dublin, which not only does away with the manifold disadvantages and drawbacks attendant on the employment of dynamos, but also creates the largest amount of driving power with the least expenditure of electrical force. Dr. Meldon, in his first attempt at motor construction, made use of twelve magnets, but when the machine was tested it was found that although each of the magnets would lift half a cwt., or attract a heavy iron bar from 1in., yet the whole 12 when bound together would only lift or attract exactly the same weight. Seeing that something was evidently wrong, he sought information as to the cause of so singular a circumstance, but, although he received a very large number of suggestions, not one of his correspondents hit upon a solution. Nothing discouraged, Dr. Meldon persevered in his investigation, with the gratifying result that after some trouble he found that the inertness of the magnets was due to neutralisation, and that by magnetically insulating the bars with copper instead of iron bolts, and putting a few layers of guttapercha between the bars and the rims of the wheels, he could develop full power—a fact which seems to have been hitherto unknown. The armature of the new machine is formed by joining together two [illegible]in. solid pulley wheels with seven flat bars of iron, each bar being [illegible] long by 1in. wide and 1¼in. thick, and, as has been observed, the bars are laid upon guttapercha, copper bolts being used to fasten them to the wheels. A shaft of 1¼in. steel passes through the centre, and the whole is supported by a hard-wood frame, stayed with iron. Each side of the frame where the shaft emerges therefrom is supplied with an ivory commutator, the one on the right having three, and the other four, brushes, each of which communicates with a magnet. Attached to the frame are seven electro-magnets; the three larger ones being made of [illegible]in. soft iron, and wound with [illegible] wire without bobbins, and the other four of [illegible] iron, and wound with No. [illegible] wire. The total weight, as at present constructed, is a little over [illegible]. The first trial of the motor took place in [illegible] last, in a boat [illegible]ft. long and 5ft. beam; and the battery used on the occasion consisted of [illegible] cells of bichromate of calcium, with zincs [illegible] by [illegible]in. and carbons [illegible]in. by [illegible]in. Half of the current passed through a commutator into one set of magnets, the whole charge going into one magnet at a time, and the remainder of the current through the other commutator into the second set. The great utility of this arrangement was experienced during the trip, as when all the cells were made use of the boat went at full speed, but when only one commutator was employed half speed was obtained, and on a long trip the second battery could be [illegible] in reserve. The motor is capable of [illegible], but this is [illegible] was [illegible], when the boat [illegible] a little more than [illegible] [illegible]. It is [illegible] small size of the [illegible] battery, which was placed in the forward part of the boat [illegible] arranged [illegible] that there was only [illegible] with any degree of [illegible] was obliged to [illegible] with a battery [illegible].

[illegible] Dr. Meldon's [illegible] minutes, and it should be noted that the battery was nearly exhausted when this trial took place.

Dr. Meldon's object in consenting to the publication of these details of the motor is two-fold.—First, to place upon record an account of his original experiments for the benefit of those who are interested in the subject of electricity as a motive power: and, secondly, to receive any practical suggestions which the reader of this brief description of his invention may be disposed to send to him.

THE USE AND ABUSE OF THE MACKINTOSH.

THE season has set in for wearing mackintoshes. A caution may be therefore not unnecessary, and let us hope, not unheeded, as to the use and abuse of this serviceable, but, when improperly employed, dangerous, article of clothing. When once a mackintosh is put on to defend the body from wet, it should on no account be taken off until the wearer has not only taken shelter, but is in a position to change his clothes. What a covering of oiled skin does for a wet rag in the surgery—viz., convert it into a poultice—the mackintosh does for the clothes of its wearer. The insensible perspiration which finds a way of escape through ordinary clothing is kept in by the waterproof, and the clothes are saturated with moisture. A very few minutes will suffice to render the under-clothing "damp" under a mackintosh, particularly if either the wearer perspires freely, or the weather be what is called "muggy" as well as wet. When, therefore, the wearer of a mackintosh takes off that article of clothing because it has ceased to rain, he is in the position of a person who has damp clothes on, and if he sits in the saddle, or walks home, or rides in an open trap, he is more likely to take cold than if he had not used the mackintosh at all. If therefore, we say, a mackintosh is once put on, it should on no account be removed until the clothes can be changed or dried by a fire without reduction of bodily temperature. The use of a mackintosh is to protect a man from a severe storm of rain. His clothes *must* be damp if he wears one of these protectors. The sole gain from using it is to render the moisture warm instead of cold, and to prevent loss of heat by evaporation. If the mackintosh be removed, evaporation commences immediately, with all the consequent risks of that process.—*Lancet.*

USEFUL AND SCIENTIFIC NOTES.

Fluid of High Refractive and Dispersive Power.—Herr C. Rohrbach, of Leipsic, has lately described a method of procuring a fluid having extraordinarily high refractive and dispersive powers. 100 parts of iodide of barium are mixed with 130 parts of scarlet biniodide of mercury. About 20cc. of distilled water are added to the powders, and they are then stirred up with a glass rod while heated in a test tube plunged into an oil bath previously warmed to 150° or 200° C. A fluid double iodide of mercury and barium is formed, which is then poured into a shallow porcelain dish and evaporated down until it acquires a density so great that a crystal of epidote no longer sinks in it. When cold, even topaz will float in it. It is then filtered through glass-wool. The fluid so prepared has a density of 3·575—3·588, boils at about 145°, and is of a yellow colour. Its refractive index is 1·7755 for the C line, and 1·8265 for the E line of the spectrum. For the two D lines of sodium the refractive indices are 1·7931 and 1·7933 respectively. So great is the dispersion that, using a single hollow prism with a refracting power of 60°, the dispersion between the two D lines is almost exactly 2′ of angle.

Letts' Diaries.—First in the field, and certainly *primus inter pares*, are Letts, Son, and Co., of London-bridge, with their varied assortment of diaries for 1884. If only this firm had existed two centuries back, how many more finds like Evelyn and Pepys's diaries might posterity have had to rejoice over, such facilities do their numerous volumes furnish for every record with the slightest claim to preservation. Housekeeper and parson, business man and lawyer, man of fashion and fine lady, all alike are catered for, from the daintiest volume for the pocket to the rough scribbling diary for the desk, and all alike of the best.

Catalogues.—We have received the new catalogue and price list of the Anglo-American Brush Electric Light Corporation, which is a useful publication, showing the public what apparatus they can now have for arc and incandescence lighting, and the prices of the machines and accessories.—The "Amateur Catalogue" of Churchill and Co., [illegible]-street, Finsbury, is a reproduction, by the aid of photography, of their large catalogue of American machinery, &c., which we noticed on p. 12[illegible].

SCIENTIFIC SOCIETIES.

◆

ROYAL METEOROLOGICAL SOCIETY.

THE first meeting of the present session was held at the Institution of Civil Engineers, Mr. J. K. Laughton, M.A., F.R.A.S., President, in the chair.

The following papers were read:—

(1.) "Report on Temperatures in two different patterns of Stevenson Screens," by E. Mawley, F.R.Met.Soc. The screens employed were an ordinary Stevenson screen obtained from Casella, and a new Stevenson screen made in accordance with the recommendations of a Committee appointed by the Council of the Society. The new screen is 2in. wider and deeper than the old screen. It has also an upper sloping roof, and at a little distance below a flat inner roof pierced with holes for ventilation; while the old screen has a single flat roof with only a narrow slit beneath on each side for ventilation. Observations were made during the three months July to September, and the results are given in the paper. From these it appears that the new screen is, of the two, slightly cooler and better ventilated and retains the heat of the sun for a less time than the old screen; also, having a double roof and over-lapping boards below, it is better suited for extreme climates.

(2.) "On the Storm which crossed the British Islands between September 1st and 3rd, 1883, and its track over the North Atlantic," by C. Harding, F.R.Met.Soc., of the Meteorological Office. This storm caused considerable havoc in the south-west and south of England owing not only to its exceptional violence, but also to its occurrence before the completion of the harvest. The storm is traceable in the first instance to two centres of disturbance, one being first shown at about 450 miles to the south of Bermuda on the 26th of August, and the other to the east of the Rocky Mountains on the 27th; these two disturbances afterwards merged on the 29th at about 300 miles to the north of Bermuda and formed one great and destructive gale, which continued to grow in violence as it crossed the Atlantic until it reached the coasts of the British Islands. The average speed at which this storm crossed the Atlantic was fully 40 miles an hour, which is more than double the usual speed of storms which traverse that ocean.

(3.) "On the Influence of the Moon on the Height of the Barometer within the Tropics," by Robert Lawson, Inspector General of Hospitals.

(4.) "The Great Ice Storm of July 3rd, 1883, in North Lincolnshire," by J. Cordeaux. The direction of the storm was nearly south-east to north-west, and travelled from Caistor along the higher ridges of the hills to Barton-on-Humber. The storm commenced at about 9.20 p.m. with heavy drops of rain, increasing to a downpour, speedily followed, amidst the blaze of lightning and the constant roll of thunder, by the rush of hail, or rather lumps of ice. An eye-witness remarked that they were not like hailstones but "salt-cellars," another that they resembled "ducks' eggs"; in fact they were solid lumps of ice of every shape and size, weighing from 2oz. to 6oz., and some measured 6in. in circumference. The injury done to the growing crops cannot be estimated at less than £20,000.

Weights and Measures.—In a Board of Trade "Report of Proceedings under the Weights and Measures Act, 1878," just issued, Mr. H. J. Chaney remarks on his visit to the Paris Bureau, that "there can be no doubt that, in the construction and arrangement of the comparing rooms, and in the design and use of the comparing apparatus, the office at Sèvres has made important advances towards that high accuracy of work which science now demands. With the means there provided it is possible, for instance, to ascertain a difference between two kilogram weights so small as 0·0000003 kilog., or less than a three hundred millionth part of the whole weight. In the comparison of two metres, a difference so small as 0·1 micron (0·0001mm., or 0·0000039in.) could be determined. At the Standards Office, which is perhaps as well equipped as the best offices of other Governments, it is at present not possible, with the microscopic apparatus alone, to ascertain differences in kilogram weights smaller than 0·0000005 kilog., or the twenty millionth of the whole quantity weighed; or the difference between two measures of length to less than 0·000095in."

Temperance in Middlesex.—We have been asked more than once for addresses of societies and notes of coming events in connection with the temperance cause in the metropolis. Mr. F. A. Edwards, of 321, High Holborn, has sent us the first number of a quarterly record of Band of Hope and Temperance work in Middlesex, with a directory of societies and list of coming meetings. The price is only a penny, and the *Middlesex Temperance Chronicle* is well edited, and will be found very useful.

look exactly like small ink spots, the terminator being on the W. border of Stoffler. I have never seen them appear so again, even with the terminator so close as Landslaeg. I have seen Mr. Neison's parallel clefts between Cavendish *a* and *d*, but not those Mr. Gaudibert mentions crossing them N. and S. Some others I have seen, which are not shown by Mr. Neison. One joining Cavendish with Mersenius, starting N. of Cavendish A, and reaching Mersenius at a small crater which lies N. of the principal crater on the E. wall. It lies at the foot of some mountains which run parallel with it. Mr. Neison's cleft ψ reaches it about halfway along its course. Is there not a well-marked cleft crossing the entire length of Cavendish itself, from N. to S., which is not shown on the map? Crossing from east to west B and C casts of Cavendish, and an imperfect ring S. of C, I have seen light streaks which might, at another illumination, prove to be clefts. **M. A.**

SELENOGRAPHICAL.

[22073.]—Mr. Maitland Baird Gemmill makes some remarks on this subject, which show, as it appears to me, that he has a mistaken idea of selenographical work. It is not necessary, as he imagines, to possess all the works of the great Selenographers in order to do useful lunar work; some map is requisite, and Mr. Neison's alone would be sufficient. Then Mr. Gemmill complains that what is published is so technical; but this *must* be the case, and the same is true of any other branch of astronomy. If he means that it is too technical to be grasped easily, I think he is mistaken. He certainly has a mistaken idea of the use of the District Catalogues to which he refers. He seems to think that they and other things published can only be utilised by those learned in the science, and that "observers less ambitious or having smaller instruments, or less time, are not provided for; and that there is a want of readily accessible direction as to what should be done."

The catalogues can be used quite easily by beginners, and though they may look very technical on paper, they will be found to simplify lunar work considerably. All that is necessary is to obtain the key plan of the district, and then set to work with the list. It will be found a great help to have the leading known objects mapped and lettered, instead of being bewildered at the outset with the multitude of objects in a district, which must be mapped before anything can be done. A note appended to the catalogues asks for observations, therefore, I do not think anyone can complain of not knowing what to do. Catalogues are necessary as a foundation for work. Order and method there must be if anything is to be accomplished. Without some such lists, if several persons were to observe a formation, say only three, and each were to number the objects after his own private judgment, would not the confusion be great, and how could the necessary work of generalisation be done which Mr. Gemmill urges, and comparison of the observations in order to deduce results? Mr. Gemmill also laments the want of papers like some of those published in past days; but he forgets that if more observations of the moon were made, there would be more material for such papers.

I cannot answer Mr. Gemmill's question whether A in his sketch of Plato is a valley or cleft; but I have seen (1880) a valley or steep cliff in that position and extending some way northward. In 1878 I also saw two craters south of this spot, and three or four small ones north of it, with a projecting rock from one. B may be Schröter's χ, but if so, it seems to be too far east on the sketch. A line passing through χ and the east wall of Plato also touches two craters north of χ, one being on the edge of the white ground. The ridges B on his sketch, between Picard and Pierce, may be the same as that mentioned in "Lunar Work" in the "Astro. Register" for February, 1883.

With regard to lunar work generally, which seems to be alternately taken up and given up, if I may say my own idea, it is this: without intending to reflect on those who through circumstances have been unable to go on with it, I think what is needed is observers who will take it up and *stick to it*; not taking it up for a time and then tiring of it, but deliberating first and then doing it—for ever; remembering that as J. Ingelow teaches us:

"Here, as in other fields, the most he gleans
Who works, and *never* swerves." **M. A.**

TELESCOPE POWERS FOR JUPITER AND SATURN.

[22074.]—Amongst the readers of "ours" are possessors of telescopes of such almost infinite variety, that I think the point raised by Mr. Franks and "F.R.A.S.," concerning the relative powers that Jupiter and Saturn will bear, might be investigated, with a great probability of the reason of the apparent inconsistency being arrived at. If it is a fact that Saturn will bear *higher magnification than Jupiter, when the telescope used is practically free from imperfections, and the atmospheric conditions* are impartial, I am inclined to think that the reason will be found to be connected with the comparative definiteness of the details looked for in Saturn—the ring's shadows, and even the divisions in rings, being of a more uniform and decided character than anything to be seen on the average disc of Jupiter. The instruments I have at command are not of the necessary perfection to enable me to assist in the investigation; but I hope all of our astronomical friends who are in a position to do so will unite in the search for more light on a matter of interest to so many. **Makeshift.**

ADJUSTMENT OF REFLECTING TELESCOPES.

[22075.]—A correspondent writing upon this subject says, instead of making a dot in centre of his mirror, he uses a stop, just a little larger than his flat, so as to show a ring of light round the black shadow. This plan appears to me to require extreme care in placing the stop, as otherwise it would be sure to be wrong. As I remove my flat every time I use it, I have to adjust anew every time also; therefore, I have acquired much facility in adjustment. As there seems to me an unnecessary amount of trouble in nearly all the directions given, and my way is simplicity itself, I have ventured to describe it in the hope it may be useful to others. In the centre of my mirror cover is a small button for lifting cover off and on. This is placed in the tube as near the centre as I can judge, and there is no need to be to a hair-breadth. Next I place the flat in, seeing that it is somewhere near its place. In one end of drawtube I place a short piece of tube (mine is made of paper), with two fine pins or needles crossing each the other at right angles. The point of crossing is the centre of tube. At the other end (the eye end) another short piece of tube holds a penny piece, with a hole about the one-twentieth of an inch in the centre. Looking through this, the crosswires at the other end are visible, and the reflection of the button on speculum cover is seen in flat. Now I bring the centre of the button apparently in a straight line with aperture and wires by altering the flat until it is so. When once the cross point of the wires is perfectly central over button of speculum cover, the flat is in perfect adjustment. Then I uncover the speculum, and if the reflection of flat is not central, I put one hand on open end of tube so as to see which side I see too much of, and use the adjusting screws under speculum to bring it right. The image of speculum reflected in flat, if the least wider one side than the other, is immediately visible, and the wide side is the part requires screwing up to bring matters right. The whole adjustment of a 9in. reflector occupies me about two minutes, and I always have both mirrors to adjust.

Mr. Herbert Sadler has been kind enough to inform me that the double star following Σ 385 is not in any double-star catalogue. He says it is "Arg. (+ 59°) 661, the place of which for 1880 is IIIh. 19m. 55·5s.; + 59° 29·9′. It is 9th mag. in Arg., and follows Σ 385 41·7s. and is 1·4′ to the south of that pair."

Both "F.R.A.S" and Mr. Franks have made some remarks upon Saturn bearing more magnifying than Jupiter. I should like to know their experience of Mars. I always find Mars worse than either Jupiter or Saturn. His limb is less sharp and far more unsteady. In fact, he is always a more difficult object than Uranus even.

Edwin Holmes.

MICROSCOPIC TEST OBJECTS.

[22076.]—Those readers of the "E. M." who are interested in the resolution of the more finely marked diatoms, and who have seen or heard of the magnificent image of *Surirella gemma*, mounted in phosphorus, shown by Mr. J. W. Stephenson at the R.M.S. meetings and conversazioni, with a Zeiss' oil immersion $\frac{1}{8}$th objective, and his own catoptric illuminator, will be glad to learn that Möller now supplies some of the more difficult test objects mounted in highly refractive media. Having recently purchased a slide of *Amphipleura pellucida* mounted in phosphorus, and one of *Surirella gemma* mounted in monobromide of naphthaline, I will give the result of my examination of them. The resolution of the hemispherules on the latter was not remarkable, being much the same as that obtained on a slide of the object mounted dry. The resolution of the former, however, was all that could be desired with the means at my command, and contrasted favourably with anything I had seen before. Previously, with a Powell and Lealand's water immersion $\frac{1}{8}$th objective, and Wenham's disc illuminator, I had seen the striæ very faintly shown on a balsam-mounted slide. Much better resolution had been effected on a dry mount by a P. and L. oil immersion $\frac{1}{25}$th objective, and their achromatic condenser. But even this result was not to be compared with that obtained on the phosphorus mount above alluded to. Using P. and L.'s oil immersion $\frac{1}{12}$th objective (N.A. 1·43), and their oil immersion condenser, the striæ came out remarkably clear and sharp, and, though not distinctly broken up into dots, gave apparent in cations of a want of continuity. It would be teresting if other observers who possess la angled object glasses, and corresponding means illumination, would give their experience in rega to the new slides of these difficult but fascinati objects. **Edmund Carr.**

Holbrooke Hall, near Derby.

BICYCLES AND TRICYCLES.

[22077.]—I was on the point of writing a lett to the "E. M." asking riders of different machines to give their season's experiences, so as to complet the series of letters which in the spring mainly dealt with theory. But I am pleased to see that "Y. B." has already done so.

In reply to "Y. B.'s" second question, which is the only one on tricycles which I care to answer, I must say that I do not believe in gears. It seems absurd to be always carrying about a lot of wheels, which, even though they only work together when set for power, are always a dead weight, and then do not give the theoretical increase because of the new friction involved. For other reasons, too, I do not believe in them, for I think slow riding up hills a mistake, as every stone, every little obstruction is separately felt; whereas, by going faster, the momentum carries the machine over them. It is, of course, clear that more force will be required to go faster; but then it lasts over a shorter time, and the labour of fighting individual obstructions is avoided.

Again, we who are riders of the Otto never dream of riding less than 54in.—most ride 56in.; 60in. and 65in. speeding I have tried, and found delightful. Everyone knows that the Otto does not keep tricycles, or even bicycles, waiting up hills. Having this ample power for hill-riding with our high wheels, we naturally wonder at the fuss that is made by people over 30in. and 40in. gears.

"Y. B.'s" difficulty on hills is most natural: till the rider of the Otto has sufficient confidence in himself and in his machine to lean well forward at each tread, swaying back for the dead points, he cannot get up hills at all. So soon as "Y. B." has acquired this knack, so soon will he look forward to a hill as a pleasant change from the level.

If "Y. B." has already learnt the art of riding down hills, he may safely reckon on soon being able to ride up. Most people find they can ride up first.

I do not understand the spinning round of the Otto to which "Y. B." refers. He probably does not mean the apparently reversed steering, which beginners invariably imagine to be necessary down hills. It may be that, when nervous, he tries to back treadle and steer at the same time, which, of course, is wrong; the new brake gives ample stopping power. Or it may be that his machine is not kept in proper condition. When the handle is turned outwards, does it spring back quite freely? If not, oil or clean the stiff place till it does.

So little fear have I of ever breaking a driving-band, that when I started for my autumn's tour of about 1,300 miles I did not think it worth while to take a spare band with me, though one weighs nothing, and will go into my pocket. If a band did break, which could only happen when labouring up a very steep hill, the rider would merely step on to the ground; no harm could happen to him or his machine.

I am glad to say that my autumn's experience bears out everything I said of the Otto in my four previous letters. In the country between Lincolnshire, Norfolk, London, Southampton, Devonshire, and Cheltenham I have this autumn met with roads of every kind—from the most perfect to the worst that can be imagined, from impossible hills to a dead level. Nowhere had I the slightest difficulty in shooting past the few tricycles which I saw about, and with some of which I rode a little way. I found that about 70 miles made a comfortable day's run, though on some occasions it was convenient to do much more than this, and on others less. I have experienced no difficulty whatever down the hills. The steepest which I had occasion to ride down was the main street in Lyme-Regis, going east. This at the bottom is rather a severe trial, and I should recommend beginners not to practise there. I did not ride down some few of the hills in Devonshire, where many loose stones made them really dangerous; it would have been absurd to have done so.

I carried all my luggage in a home-made satchel 20in. long and 5½in. in diameter, hung under the axle and tail by three spring hooks. I had no lamp.

Of course I am a member of the C.T.C. Let me, therefore, acknowledge the uniform attention which I received at the headquarters in all parts.

An Ottoman.

TRICYCLES.

[22078.]—The following experience may be of service to "Y. B." and others seeking information. I have used [illegible]

[illegible] science of mechanical [illegible]

[illegible] grammar, and naturally [illegible] cases usually [illegible] grasp, and won't [illegible] mysterious letters that give a [illegible] the facts they have [illegible] they are even annoyed at [illegible] delighted when the amateur [illegible] want of manual dexterity [illegible] exceptions. Let them rest [illegible] skill and dexterity can never be [illegible] of practice, and so far the [illegible] will always hold his own and be [illegible] the more machinery is brought into use, and the [illegible] dexterity and skill are necessary [illegible] brains and reason be a match [illegible] observation.

The remarks in the last paragraph were suggested by an article in Vol. XXV. p. 405. Everyone must have the greatest respect for Mr. Rose's [illegible], but I cannot help thinking that it would have been better to have tried to reduce the various modifying influences to something like order, and shown (supposing theory to be right in the main) how these general rules required modifying to meet various cases, than to assert the impossibility of ever doing away with the so-called rule of thumb. Mr. Rose may not be able to do it, but done it will be some day, to a very large extent. Take the case of which an illustration is given, where the writer argues that it is no use giving rules for the clearance, or "angle of relief," because it must vary with the feed. To which the answer is: Show how it varies with the feed then. The feed makes no difference to the clearance of the front face: but as regards the side cutting the shoulder, a [illegible] feed does take off some of the clearance, for the [illegible] edge is now planing down a slope, and the effect is like what would be produced in a planing machine by sloping the standards carrying the tool the way the table travels: and, of course, if the tool have [illegible] clearance, sloping the standards with respect to the table reduces that clearance by the same amount. Roughly speaking, for lathe work the feed in eighteenths, divided by the diameter of the work in inches, gives this slope or angle taken off clearance. Feed in eighteenths [illegible] small angles, and the [illegible] for pitch of the screws. [illegible] for facing a surface [illegible] with continuous feed. [illegible] must be greater, the amount [illegible] with [illegible] feed on [illegible] take the place of [illegible] think the [illegible] and [illegible]

[illegible]

Bow.

[illegible] LIGHT

[illegible] closed [illegible] the same [illegible] also [illegible] intense as [illegible] Huxley perceived [illegible] peacock's tail, sur- [illegible] I cannot, for all is as [illegible] I remember, when a boy, [illegible] boy's head, each [illegible] a dark passage, [illegible] and presented [illegible] Also on passing [illegible] with a chain band [illegible] closed eyes, I saw a [illegible] I may presume, and I [illegible] that the sunlight I [illegible] phorus, forming so [illegible] per cent. according [illegible] situated in this [illegible] the motion, that [illegible] spot was [illegible] minute atoms [illegible] radiating from it [illegible] It was as a fountain reversed [illegible] and every particle dissolved itself into this centre light. Perhaps I saw an image of the back of the eye, and afterwards an image of the multifarious brain; but how to account for the motion I know not.

The impressions of light on the retina (with the eye open), according to Dr. Roget, is "compared to the revolution of a wheel made to revolve behind a series of perpendicular bars which change in appearance from radial spokes to curved lines." But I saw no lines and no radius, only a continuous outward movement, which was in reality an inward impression. As I know of no motion in nature like this, I shall be glad to be informed of a probable cause and origin, for perhaps the brain has this sensational movement at all times as an involuntary condition.

Fiddler.

CONTINUOUS BRAKES.

[22082.]—Your correspondent "Imprimatur" (letter 22061, p. 265) must have a very small idea of the intelligence of the readers of the English Mechanic if he imagines they cannot see through his letter—especially when the same statements have long ago been paraded before them, and their true value exposed. "Imprimatur" carefully sets out the number of miles run with the respective brakes and the "failures" recorded; but he does not take the trouble to explain what the word "failures" means. Given a brake which always indicates when it is not in a condition for working, it is obvious that more "failures" will be reported with that, than in the case of a brake which gives no indication that it is out of order, and which too often fails when it is most wanted. Your correspondent either knows this fact or he does not; if the latter, he should not write upon what he does not understand; if the former, he has to answer the charge of deliberately suppressing the truth. So far from the returns showing "unfavourable results" for the Westinghouse brake, anyone who will take the trouble to examine them in a manner which will lead to their comprehension, will discover, as all disinterested engineers have, that the Westinghouse automatic brake is the only really trustworthy appliance in existence. The child-like innocence with which "Imprimatur" descants on the merits of the mechanical brake which he has apparently taken under his special protection, is amusing; but he should favour the daily papers with his encomiums—they will not wash in these columns. By way of a parting shot, let me ask "Imprimatur" if he can give the details of any instance when one of his "failures" of the Westinghouse brake was the cause of an accident? What does he mean when he says (p. 266), that "it is known to all that it is the continuous brake that frequently produces the catastrophe"? That must be one of the "failures"—probably one not recorded.

Nun. Dor.

[illegible]—Your correspondent "Imprimatur," [illegible], furnishes a long and perfectly misleading statement relating to the brake failures, and remarks that as it is from the *Railway Engineer* the accuracy can hardly be questioned.

I think it may not be known to all your readers that this paper has for a long time made false statements with regard to the Westinghouse brake, and in May last the editor published a public apology in which he regretted having written statements all which he thereby acknowledged to be unfounded, and he was advised they were libellous. An action for libel was brought a few months ago, and damages were awarded by the jury.

With such facts as these before us, I do not think the readers of the "E. M." will think the *Railway Engineer* an impartial authority.

The Board of Trade requires that the failures should be given under the three following heads:—

(1.) Failure or partial failure of the continuous brakes to act when required in case of an accident to a train, or a collision between trains being imminent.

(2.) Failure or partial failure of the continuous brakes to act under ordinary circumstances to stop a train when required.

(3.) Delay in the working of trains in consequence of defects in, or improper action of, the brakes, distinguishing whether they arose from neglect or inexperience of servants or failure of machinery or material.

It will be seen that the importance of a "failure" depends upon which class it comes under. No. 1 is very serious indeed. No. 2 shows that no accident took place because, fortunately, there was no obstruction in the way. No. 3 is of very little importance, as simply a few minutes' delay took place.

Now, the list given by "Imprimatur" is artfully drawn up so as not to show to which class a "failure" belongs: it simply give a total number of cases and total miles run. An accident caused by the failure of a vacuum brake counts *one*, and of course a delay of a minute to the Westinghouse brake also counts *one*; but surely there is a wide difference between an actual collision and a few minutes' delay. Will "Imprimatur" be good enough next week to furnish another list, showing the failures placed under the three heads as required by the Board of Trade?

As I pointed out in my pamphlet (Railway Accidents), to draw up a proportion of failures to miles run is absurd, as some trains with one brake run a hundred miles without stopping, and others having another brake perhaps stop a hundred times in running the same distance; therefore, a fair comparison cannot possibly be made unless further information be given.

The chain brake on the L. and N.W. shows a very large mileage and few faults. This brake is used in "emergencies," it is therefore *carried* over a number of miles, but is not regularly worked; a comparison therefore is useless.

The "two-minute vacuum" on the Midland shows a large mileage, but few faults. There have been cases of running into buffer stops (which should come under class 1), and very many runs past stations (class 2), yet none of these instances are reported by the company to the Board of Trade; the returns, therefore, are rendered practically useless.

"Imprimatur" expresses a strong opinion in favour of mechanical brakes, and considers them superior to fluid systems. He is perfectly justified in holding his own opinions, but I wish he would give some facts in support of them.

Is any company at the present day adopting or thinking of adopting mechanical brakes? On the other hand, are not many lines removing them?

The London and North Western has had great experience with "mechanical" systems on its own line, and its officials have inspected all those used on every line in all parts of the world, yet the result is that mechanical systems cannot be made satisfactorily. After the chain brake had been adopted at great cost, we may rest assured that its removal would not have been ordered so long as there was any chance of improving it. I have been informed by an official that if the company had considered the Parker-Smith system likely to be efficient it would have been tried with a view to its adoption in connection with the chain brake gear.

The battle of the brakes has for a long time been settled, so far as discovering which is the *best brake*; the difficulty now is to remove obstruction caused by private interest. As long as the companies can continue to do nothing, or very little, so long will the brake question remain in the present dangerous state. If Parliament were to pass an Act (as I trust it will do next year) compelling companies to adopt brakes which fulfil the Board of Trade conditions, private interest would have to give way, efficient brakes would be adopted, and the safety of the public provided for.

Clement E. Stretton.

Saxe Coburg-street, Leicester, Nov. 24.

LONDON AND MANCHESTER TRAINS.

[22084.]—As I notice that a correspondent asks for particulars of these trains, I give a list of the fastest by each of the three routes, taken from the time-tables of this month. Below are the trains which take less than 4h. 40m.:—

Midland Route—distance 186¾ miles.—The fastest trains by this route are the 3.30 p.m. from St. Pancras and the 3.45 p.m. from Manchester. Both of these trains take 4h. 35m.; one makes three and the other six intermediate stops, including Kentish Town; they are drawn by 7ft. coupled bogie engines.

London and North-Western Route—(I am not sure of the exact distance, but it is nearly the same as the Midland). There are two trains by this route which take 4h. 30m.—namely, the 10.10 a.m. from Euston, and the 4.15 p.m. from Manchester; another train, the 11.15 a.m. from Manchester, takes 4h. 35m. These trains make seven, four, and five intermediate stops respectively, including Willesden, and are drawn by 6ft. 6in. coupled engines.

Great Northern Route—distance 203 miles.—These trains are G.N.R. and M.S. and L. joint. There are four, the 2 p.m. and 6.15 p.m. from King's-cross and the 11 a.m. and 2 p.m. from Manchester, all taking 4h. 30m. and making two intermediate stops. They consist of only five carriages, and are drawn to Grantham by G.N. 8ft. bogie engines, and thence to Manchester by M.S. and L. 7ft. 6in. single engines. (Perhaps "R. N. H." will give the other dimensions of these engines.) Though the distance is much greater by this last route than by the other two, no difficulty is found in keeping time, as the following extract from a local paper will show:—

The New Fast Trains to London.—On Monday the Manchester, Sheffield, and Lincolnshire Railway Company commenced running new express trains between Sheffield and London, at the times and under the conditions of speed already mentioned in these columns. The journeys were practically "trial trips," and they proved most successful ones. The first train leaving Manchester at 11 a.m. reached Sheffield at 11.53, or 8 minutes before time, being due in at 12.1. At 12.5 it proceeded on its journey, [illegible] of the forefinger of the left hand. [illegible] toward direction at which the [illegible] to be changed, the whole position [illegible] will have to be altered. At the [illegible] of the cut, the edge of the razor should [illegible] beyond the thumb or finger nail, as the [illegible], and it is well for the two hands to [illegible], as the mere fact of doing so seems to steady [illegible] and to make any change of position more [illegible] perceptible. The elbows may be rested on [illegible]ble, and while the section cutting is going on inadvisable to lay the razor or the object [illegible] and take them up again oftener than be helped, since the direction of the cuts [illegible] thus almost inevitably be changed, so the under surface of the section would not rallel to the upper. Having made a first cut tain an even surface, wet the razor well by ing the point into water or spirit and slanting lade so that it runs toward the heel; wet the ce of the object also. Pressing somewhat lightly with the blade on the edge of the b or finger nail (which will give the thickness e section), make a second cut, preserving as s possible the precise direction of the first. A or less perfect section will then be left on the e, and may, if thought good enough, be ed off into a mounting pot (*e.g.*, a toothpaste as previously described), three parts full of r, glycerine and water (which may also be for moistening the razor), spirit, or staining, according to circumstances. To float it off, ; the razor from heel to point, so that its point neath the surface of the liquid. Wetting a l's hair pencil from the liquid, touch the blade it behind the section. The latter will then down in the little stream thus created, and be assisted by the pencil in doing so. The point that remains to be noticed (besides the of carefulness not to cut the thumb, or, as it be, the finger of the left hand, against which razor comes when it has finished cutting the t), is that thin sections are liable to double in bing up (as it were) the razor blade from edge ck, or to be torn on account of the diagonal on. To prevent this, first, use plenty of liquid e razor; second, slant it somewhat, so that it upward, and the section falls by its own ht; third, get a second person to "doctor" or the section along with a wet camel's hair il. Two can always cut sections better together than one by himself. If the object has a ate side, cut beginning from that side.

fore speculating in a microtome, it is best, I k, to practise hand cutting. For instance, cut piece from a raw potato with a knife. It is use cutting a piece with a larger cross section can be placed under a covering-glass, with a margin at the sides. With this try the above tions. There will probably, at first especially, any imperfect sections. Wave these with the [illegible] fingers in a glass of clear water. A fine [illegible] will come from them, and settle at the [illegible]. This is potato-starch. A little of it may ken up in a tube, transferred to a glass slip, ted, and inspected with a polariscope. The h granules will show like little packages tied a black string, and may easily be mounted. [illegible], pour the sediment into a test tube, filling with fresh water and allowing the opalescent d partially to settle, when the larger and [illegible] particles will come to the bottom first, and [illegible] may be poured off. This way of separating from light is called elutriation; it is of considerable use [illegible] in mounting diatoms; and this ample example of it. The tube being nearly, not quite, dry, half fill with methylated spirit, repeat the process after a little time. When [illegible] of the emptied spirit are nearly dry in [illegible] pour in a drachm or so of chloroform. Give it to penetrate, and then, with a tube, put a drop starch containing chloroform on a slip, whereupon when the chloroform is nearly dry, put a drop [illegible] and Canada balsam, and cover with a ing glass. Other kinds of starch (*e.g.*, that h falls out of a [illegible] stock of celery) may be [illegible] in the same way. Meanwhile, as the dry[illegible] is going on, other sections may be cut. [illegible] of them should be examined fresh; and the [illegible] at least the best ones.

[illegible] staining is either single or double [illegible], of which the second is, naturally, more [illegible]. A multitude of staining fluids are in [illegible] but for the present, as anyone who has cut [illegible] will [illegible] of staining and mounting [illegible], I will give a simple way of using extract of [illegible], [illegible] logwood, by which almost anything [illegible] be stained. Take [illegible] hæmatoxylin, thirty grains, alum, three [illegible]. Break the hæmatoxylin small pieces, and add a few teaspoonfuls of [illegible] with which it will form a semi-fluid mass. with the [illegible] and a half of boiling water, [illegible] which it will form a turbid solution, and add [illegible] the alum dissolved in rather less than two [illegible] of boiling water. Mix the two solutions, through blotting paper, or Swedish paper. [illegible] of spirit, fill up to [illegible] with water, and keep in a (corked will do) bottle, the composition of the logwood staining fluid being written on the label. When wanted, take a sufficient quantity of the fluid, add about eight times the amount of water, and therein leave the sections or other objects till sufficiently stained. Then transfer to methylated spirit, then to benzol, turpentine, or oil of cloves, and mount resinously, as previously described.

IV. *Various Practical Details.*—To use a dipping tube, which ought to be made almost capillary at one end and left open at the other, dip the tube into the liquid of which it is desired to take a small portion for examination. Close the open top of the tube with the thumb, and on removing the tube the liquid will not escape. By cautiously and partially removing the thumb, it will flow out; or a little will do so on warming the tube—e.g., by the heat of the hand. Small objects may also be made to enter the tube, if its lower and narrower opening is made a little larger. For changing liquids in which objects are immersed, a tube with a finer ending may be used (the finer the ending, the less the objects are disturbed), part of the liquid being sucked up, squirted out again, and the process repeated. This is much more cleanly than a syringe, as the thread round the piston of a syringe inevitably becomes soiled, however great care be taken to prevent the liquid from touching it. There is but little danger, after a few trials, of the liquid entering the mouth, if the suction is effected, not by drawing in air into the chest; but by closing the back of the mouth, as in saying the ck of the word back and sucking, by making a cavity between the top of the tongue and the roof of the mouth, placing the tip of the tongue against the tube when this space is filled with air, and repeating the operation till no more liquid can be drawn in this way from the mounting pot, or pot containing the objects. The mounting pot may then be placed on its side to drain; and the next fluid afterwards cautiously poured in without incurring the danger of breaking involved in shifting thin section, &c., from one pot to another, which is, however, the most cleanly way for the sections. It is best immediately to move them about in a new fluid, as otherwise—e.g., in turpentine after spirit, they may cling to the bottom or sides; they are best moved by creating a current in their neighbourhood, or they may be lifted from one pot to another containing the new fluid, by a piece of fine gauze wirework, or by inserting the blade or handle of a scalpel into the liquid, and coaxing them on it with a camel's hair pencil. To clean sections, they may be gently brushed as they lie on a slip, with the turpentine, &c., in which they have previously been immersed. A drop of clean turpentine may be poured on them: it will spread over the slip, washing the dirt before it. The dirty turpentine surrounding the section may then be removed with a handkerchief, and the same thing done again. Some objects, again, will bear rougher treatment than others—e.g., they may be taken up by the forceps (holding them, preferably, by some part which it is not desired to mount), and waved in the fluid, and any visible dirt may be removed with with a stiff hair from a badger brush, fastened to a penholder by tying round with thread. This searches into nooks and crannies.

F. Grant.

ERRATUM.—**Humidity and Chronometers.**—With reference to this question (see pp. 237, 266), Mr. Crisp writes to say that the name of the station, the temperature, &c., are *not* given in the communications referred to.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51656.]—**A Three-Cell Battery.**—In respect to "No Sig.," as to size of cells, carbons, and zincs, are as follows:—Size of outer jar, 10in. by [illegible]in.; porous cells, 11in. by 2¾in.; carbon plates, 9½in. by 2¼in. by ½in. Zincs in the shape of a tube and open down the middle (being much better than the rods) 11in. long by 2in. diameter. I notice the light becomes fainter after the battery has been in action for about four hours together. Then the action should be stopped for some hours on purpose for it to recover its strength again. For other information I refer our reader to replies of the [illegible]th September and 26th October, under the above heading.—ELECTRICIAN.

[51792.]—**Cancer in the Mouth.**—I am extremely sorry that I have been unable sooner to answer Dr. Allinson's question, [illegible] epidemic of typhoid which has kept me [illegible] employed. The cases to which I [illegible] almost entirely amongst hospital patients [illegible] have no detailed notes of most of them [illegible] safely say that nearly all of them smoked [illegible] pipes—many to an immoderate extent. [illegible] call to mind one who [illegible] smoked cigars or cigarettes [illegible] impression is that [illegible] many of my medical acquaintances [illegible] irritation of the porous clay is at least the exciting cause of this complaint.—ST. BART'S.

[51961.] — **Cementing Object Glasses.**—Will you kindly permit me to state briefly the result of my experiment with castor oil as a cement for object glasses. After no little trouble and messing, I obtained what appeared to be a perfect film between the glasses, and, when now examined the transparency and clearness of the lenses were most pleasing. Upon trial, I found the focus shortened by nearly 2in. The light was certainly improved. A small satellite of Saturn—which an hour before was only suspected under almost identical conditions of light—was now held steadily, and what was also very striking was the comparative blackness of the surrounding field. On examining the planet, however, for definition, I was grievously disappointed. It would not focus sharply, and there was a most unmistakable fringe of blue. Perhaps there was too much oil between the lenses, as a good deal exuded after screwing up. In their normal condition the surfaces are in perfect contact. If the defective definition and colour could be overcome, then the improvement otherwise would well repay the trouble of occasionally renewing the oil.—ACHROMATIC.

[52003.]—**Defective Coil in Galvanic Battery.**—If "J. D." expects an answer to this query he must say what it is he really wants to know. To enable him to do that he may be safely referred to back volumes, when, by diligent reading, he will probably find what he requires to know. At present, his query is a bit of a puzzle.—NUX. DOR.

[52010.]—**Lifting Water.**—This querist should try what can be done with a hydraulic ram, which, I fancy, would give more satisfactory results than a turbine, considering that the fall is only 5ft. He will find a great deal of information in Mr. Davies's articles and recent letters on rams.—ESSAR.

[52014.]—**Sawmill Waste.**—"Sawyer" should advertise his "waste," giving particulars, as much of it would evidently do for hammer and other tool handles, and for general turner's work.—ESSAR.

[52017.]—**Heating Water.**—Cannot "Bernard" take the lime out of the water, and then heat the latter in the ordinary way?—ESSAR.

[52022.]—**Light-waves.**—Does not "No Sig." see that if we could see and measure what he calls the altitude of light-waves, it would settle beyond all possibility of doubt any dispute as to the undulatory theory? Just as the intensity of a sound is due to the amplitude of the sound-wave, so presumably is the intensity of light due to the amplitude of the light-wave. The querist should refer to some textbook of physics.—NUX. DOR.

[52025.]—**Afterludes.**—I suppose this querist would find something to suit him in the catalogues of Novello and Co. and the other music publishers.—DIAPASON.

[52026.]—**American Clocks.**—So far as all the information conveyed by this query is concerned, it is only possible to guess that the clocks want regulating, or else are worn out. Better try another "clocksmith," unless you can persuade a real "horologist" to undertake the work: but I warn you, he will probably consider his time wasted on such clocks.—NUX. DOR.

[52027.] — **American Egg - Boilers.** — If "Dux," with his egg-boilers before him, cannot discover why they stop running, how can anyone who has not seen them? Perhaps the sand is too large in the grain.—NUX. DOR.

[5203[illegible].] — **Street Medical Coil.**—Put your bundle of wires forming the core and the brass tube into a paper tube made on a mandrel just large enough to allow the brass tube to fit loosely. Wind your wire on the paper tube. If you mean the description given on p. 23, Vol. XIX., it is plain enough if you think it over with a knowledge of the principles.—NUX. DOR.

[illegible]—**Valve-Spindles.**—Querist does not state what valve-spindles, but I do not think rubber can be used as packing unless there is a coat of asbestos fibre between the rubber and the spindle. If for a steam engine, the heat will surely affect the rubber before long.—ESSAR.

[illegible]—**Punching Machine.**—My answer to "[illegible]" was as plain as I could put it. What is your difficulty? All you require is to multiply the circumference of the hole by the thickness of the plate in inches and by the shearing strength of the plate in tons per sq. inch for an answer. As you have altered the thickness from 2in. to 2[illegible]in., and the shearing strength from [illegible] to 34 tons per square inch the answer will be—3·1416 × 2 × 2·0625 × [illegible] tons. I have not taken the taper of the hole into consideration in the above.—S. NICHOLLS.

[illegible]—**Engine.**—As I asked the Editor's permission, [illegible] not having been granted, I had [illegible] of sending my letter on the [illegible] "Essar" wishes it, and [illegible] permission, I will send; but at the same time I have no intention of opening out a controversy in the "E. M." (especially such as that on "Thought Reading," from which I think very few have derived benefit), neither should I persist in my method of calculation if it was clearly shown that I was in the wrong. "Essar" is good enough to warn me to take care, otherwise I may lose myself. This is quite possible, yet I think I am aware of some of the practical advantages of the compound over the single-cylinder engine; but I should like to ask "Essar" if ever he obtained a greater theoretical power from a compound than from a single-cylinder engine with the same number of expansions and measurement of steam. If so, how?—Engineer, Dewsbury.

[Please send.—Ed.]

[52118.]—**Tarring Posts.**—The querist must get his timber as dry as practicable from sap, &c. The parts inserted in ground should first be charred, and afterwards well soaked with a composition of ¾ tar and ¼ pitch, well boiled, into which a sprinkling of quicklime is stirred. The rails above ground having two coats of this will be proof against all kinds of weather.—E. Owen.

[52128.]—**M. S. and L. Engines.** — The M. S. and L. engines in question (Nos. 500-509) were built at the company's works at Gorton this year. They have outside cylinders 18in. by 26in., and single driving wheels 7ft. 6in. diameter. The boiler is not so large as in the general types of M. S. and L. engines, and the firebox is raised. The leading and trailing wheels have outside frames, this outside frame being carried on over the driving wheel, but not connected with it. The connecting-rod is nearly hidden by the framing. The engines are somewhat similar to No. 399 (1882); but 399 has plain splashers, the new ones having a pattern of ovals in the driving splashers. The expresses between Manchester and Grantham run by these engines do not average above five or six carriages.—Meteor.

[52207.]—**Boring Cylinder.**—Granting what you have stated correct, in my opinion, as an old hand, you were not in error with the job; but in the first place, I should like to know how the line was obtained with the rough casting, and also would the 1/16 bare, as shown by the foreman's gauge, materially signify, and were the lathe shears true? He reported you as confident and not so good at explaining. Now, in my opinion, here the magnitude of fault occurred.—W. Mc.

[52210].—**Stereoscopic Camera.** — Originally the size of stereoplate was 5¼in. by 3¼in., the distance from centre to centre being, of course, 2¾in. This was subsequently increased to 6¾in. by 3¼in., the distance from centre to centre being 3⅜in. Decide what sizes you will adopt, and fix your lenses accordingly; or what is still better, have the front of camera so made that the lenses can be separated or brought closer together as required. Lenses of 6in. focus are about the best for general purposes. The prints should be trimmed and mounted, and the separation of the stereoscope lenses arranged to correspond; but as to the focus of the latter, that is mainly a matter of individual idiosyncrasy.—W. Robinson, Jun.

[52211.]—**Electric Formula.**—To find the potential due to a solenoid at an external point P: Let V_P be the required potential, and let $+m$ and $-m$ be the powers exerted by the poles of the solenoid (taking the south-seeking pole as negative), and r_1 and r_2 the respective distances of the said poles from the point P; then $V_P = m\left\{\frac{1}{r_1} - \frac{1}{r_2}\right\}$. J. Crocker will probably find an answer to the first query in "Electricity and Magnetism," by Silvanus P. Thompson, published by Macmillan and Co.—A. R. D., Hale, Lancashire.

[52218.]—**Medical.**—"Assistant" is still suffering from the cold which caused the congestion of the left lung. He would do well to put 5 globules of thuja, 5 globules of verbena, 5 globules of bursa in a pint of water, or a little more, and drink it in small quantities at a time. Wet a piece of flannel in the same water, and put it cold on the skin over the place where the pain is. He has no need to fear these remedies, as they are extracts of herbs not poisonous.—Etheropathy.

[52220.]—**Collotype Printing.**—I experienced some difficulty in my earlier experiments in collotypic printing, as the film would not adhere to the glass; but directions as to the method adopted by Herr Albert, of Munich, which I found in "Pritchard's Studios of Europe," enabled me to work the method with success. I obtained the book at the office of the *Photographic News* in Castle-street, Holborn.—James Bradford.

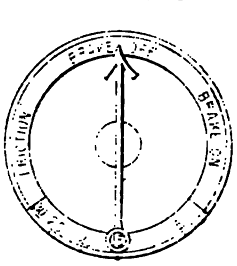
[52220.]—**Collotype Printing.** — Most likely owing to the use of too soft a gelatine, or too stiff an ink. I am not aware of any work on the subject in English, but there is a French book by Geymet, entitled "Traité pratique de Photolithographie et de Phototypie," published by Gauthier-Villars, 55, Quai des Augustins, Paris, price 5fr., which would probably contain all necessary information. There is also a series of articles by Mr. Bolas in the "British Journal of Photography," 1878-9.—W. Robinson, Jun.

[52219.] — **Geometrical Problem.** — Taking the centre of the larger circle as origin, and the line joining both centres as axis of x, the equations to the circles are — $x^2 + y^2 - R^2 = 0$, and $x^2 - 2rx + y^2 = 0$. ∴ they cut at the point $x = \frac{R^2}{2r}$. From equations above, we have $y = \sqrt{R^2 - x^2}$ and $y = \sqrt{2rx - x^2}$ ∴ area common to both circles is $\frac{\pi R^2}{2} - 2\int^{\frac{R^2}{2r}} (\sqrt{R^2 - x^2} - \sqrt{2rx - x^2})\,dx$.

$$\therefore \frac{\pi R^2}{2} - \frac{R^2}{2r}\sqrt{R^2 - \frac{R^4}{4r^2}} - R^2 \sin.^{-1}\frac{R}{2r} + \frac{2r^2}{2}\cos.^{-1}\frac{2r^2 - R^2}{2r^2} - \frac{(2r^2 - R^2)R}{4r^2}\sqrt{(4r^2 - R^2)} = \frac{\pi r^2}{2}. \quad \therefore R^2 \cos.^{-1}\frac{R}{2r} - \frac{R^3}{4r^2}\sqrt{4r^2 - R^2} + r^2\cos.^{-1}\frac{2r^2 - R^2}{2r^2} - \frac{(2r^2 - R^2)R}{4r^2}\sqrt{4r^2 - R^2} = \frac{\pi r^2}{2}.$$

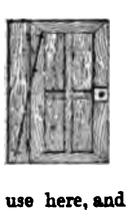
We may obtain this result also by mensuration, thus.—Join the common points; this chord divides the part common to both circles into two segments. Calling x the perpendicular distance of the centre of the larger circle from this common chord, we have (3·36) $R^2 - x^2 = x(2r - x)$. ∴ $x = \frac{R^2}{2r}$ in area of segments $= R^2\cos.^{-1}\frac{R}{2r} - \frac{R^3}{4r^2}\sqrt{4r^2 - R^2}$ and $r^2\cos.^{-1}\frac{2r^2 - R^2}{2r^2} - \frac{(2r^2 - R^2)R}{4r^2}\sqrt{4r^2 - R^2}$. The sum of these $= \frac{\pi}{2}\cdot r^2$. Cancelling, we obtain $R^2\cos.^{-1}\frac{R}{2r} - \frac{R}{2}\sqrt{4r^2 - R^2} = r^2\sin.^{-1}\frac{2r^2 - R^2}{2r^2}$. This equation gives the relation between R and r, but the solution of it is rather abstruse.—C. Relle, Devonport.

[52227.]—**L. and N.W.R Vacuum Brake.**—In reply to H. W. Hudson, as has already been stated in the "E. M.," the Webb brake, recently adopted by the above company, is not automatic except on the guard's van. Each van has, besides the vacuum apparatus, an automatic friction brake, which, while the train is running, is kept out of gear by a slight amount of vacuum, maintained by a small ejector throughout the train. The vacuum brake is applied by the driver using the large ejector, and if the train divides, the entire vacuum is destroyed, and so the friction brake goes on. Inclosed is a rough sketch of the gauge used. Before



coupling up the train, the needle points to the left. When the train is ready to start, the small ejector is taken off the friction brake and brings the needle into the position shown. When the large ejector is applied, it flies to the right and indicates how much vacuum is obtained. This is not the same as the brake used on the L. and S.W.R., which was illustrated in the "E. M." some six months ago.—W. Thompson, Rugby.

[52231.]—**Spring for Door.**—Attach a steel rod about 5ft. or 6ft. in length and ¾in. in diameter behind the door as shown in sketch. We have a



great many such in use here, and they answer admirably.—F. R.

[52231.]—**Self-closing Doors.**—I beg to recommend to "Chemicus" the "Premium Door and Gate Spring," which is the most simple and effective arrangement for closing doors I have met with. The spring is easily fixed, and can be taken off should the door at any time be required to be left open without removing any fixtures, the spring having merely to be slipped off the pivots.—G. Fowler.

[52236.]—**Combining Weights of Tartaric Acid and Bicarbonate of Soda.**—These may be calculated by adding the combining weights of their components together thus, $NaHO_3$:—

$$\begin{aligned} Na &= 23 \\ H &= 1 \\ C &= 12 \\ O_3 &= 48 \\ \hline \therefore NaHCO_3 &= 84 \end{aligned}$$

Also $H_2C_4H_4O_6$, or $C_4H_6O_6$:—

$$\begin{aligned} C_4 &= 48 \\ H_6 &= 6 \\ O_6 &= 96 \\ \hline \therefore H_2C_4H_4O_6 &= 150 \end{aligned}$$

The combining weight may also be determined from the specific heat: because combining weight × specific heat = a constant. This constant is found thus:—

	Specific Heat.		Atomic W.		Constant.
S........	0·2026	×	32	=	6·48
P	0·2120	×	31	=	6·57
As	0·0814	×	75	=	6·11
Fe	0·1138	×	56	=	6·37
Pb	0·0314	×	207	=	6·50
Ag......	0·0570	×	108	=	6·16
Li	0·9408	×	7	=	6·59
				Mean,	6·40

—A. R. D., Hale, Lancashire.

[52237.]—**Jointing Material to withstand the Action of Soap Lees.**—"C. J. R." will find that if he uses fireclay moistened with weak muriatic acid upon the threads of the screws, he will have no more leakage. Lead in any shape is utterly useless with caustic alkali. As to the leakage in steam pipe, I take it that he only uses a small quantity of lye to correct hardness of water in the steam boiler. This would not cause the pipes to leak; it is caused by the water resting at the depressed part of the pipe. A small cock inserted there to let off the water at night, or a self-acting small valve, will remedy this.—Soap Boiler.

[52238.]—**Induction Coil.**—In this case the two sides of the condenser probably communicate. Let the querist attach a battery cell to the condenser, coupling up a galvanometer in circuit; and, if the sides communicate, there will be an instant deflection. —B. H.

[52243.]—**Lifeboat.**—If "Grace Darling" feels interested in the lifeboat, he can see a small model of one having all the advantages of which he speaks, and more, by applying to J. Bramall, 18, Ballantine-street, Wandsworth, S.W. It is similar to one I exhibited to the Secretary of the National Lifeboat Institution. R. Lewis, Esq., said then, eighteen years ago, that it was rather before its time.—Bramall.

[52244.]—**Analytical Theories.**—Most of these theories cannot be proved: as, for example, Ampère's theory of magnetism, in which electric currents are supposed to circulate round magnets. There is no demonstration that this is a fact. Sir W. Thomson calculates by theory the distance of the atoms of copper and zinc, but there is no proof that they exist. Maxwell supposes electrical and magnetic undulations to be produced in ether, which is most likely only an imagination like the theory of Phlogiston. Mascart considers that the ether is the same for all the forces—heat, light, electricity, and magnetism; but these forces are most probably caused by a vibration of matter in itself.—J. Sutcliffe.

[52245.]—**Lever Watch.**—In the first place, put the barrel-hook into the hole in the barrel, then wind the chain carefully on. This is done by catching the square of the barrel arbor with the pliers and turning it slowly round, keeping your thumb upon the chain, so as to prevent it from sliding off the barrel. When you have got all the chain on the barrel, pass the end that requires to be fixed to the fusee inside the pillars, and fix the hook to the pin. After you have done this, put the ratchet on the square of the barrel arbor, and give it about half a turn or so, just as much as will enable the mainspring to pull steadily to the bottom, not more; or, when winding, the mainspring will be full up before the chain is all on the fusee, and so cause it to stop short. Wind up the watch now, and if it catches before it is full up, it must be the stopwork that is not acting properly, which you will easily see, and be able to put right yourself.—Stanley.

[52247.]—**Photographic.**—(1) The main requisites are a small lens giving a perfectly sharp image, a structureless collodion (i.e., if the wet process be used), or an emulsion of the utmost possible fineness. (2) If you mean in regard to its behaviour with gelatin, the action is mainly a coagulatory one, and [illegible] the action of alcohol and silver nitrate [illegible] as a hypo-eliminator, I think [illegible] action is entirely [illegible] the citric, or [illegible] recommended to be used with it.—W. [illegible].

[illegible]—**Bunsen Burner.**—[illegible] The [illegible] should be [illegible] of an inch to [illegible] inch is enough for most purposes. [illegible] tinum should be best for spectrum analysis, but it would be very costly. [illegible] ducing" can be effected with an ordinary Bunsen, but of course at different points of the flame. In fact, it has an [illegible] English [illegible] 66 and 67. In some cases the [illegible] the better tool.—[illegible]

[illegible]—**Spectroscope.**—[illegible] Browning's work [illegible] on page [illegible] work [illegible] Browning [illegible] the source of light [illegible] Unfortunately [illegible] cut, and a [illegible] to guard against [illegible] the spectrum [illegible] I nearly [illegible] did. I [illegible] to one of [illegible] of these pocket [illegible] that I expected too much [illegible] the knack of using it, I was [illegible] satisfied with the result. I would advise [illegible] to pay from [illegible] for an instrument [illegible] to make one for himself.—Ex-Blacksmith, [illegible] Brock.

[illegible]—**Spectroscope.**—There are books on spectrum analysis by Roscoe, Schellen, Sutton, Proctor. The first is a series of lectures to chemists, the second treats of the whole subject very fully. These are expensive works—20s. to 30s. each. Sutton is a smaller book, chiefly on absorption spectra. Proctor is a capital little book, published at 1s., which goes over the whole subject clearly, though briefly. With regard to your other queries, I would recommend you, if you really mean to buy a spectroscope, to write to Mr. Browning, who advertises a rainband spectroscope, as to whether it or one of his direct-vision spectroscopes would suit your purpose. I have always found him very frank in giving the respective merits of his instruments. I should say the rainband spectroscopes would do just as well if they show the full length of spectrum, and are not exclusively adapted to show that part where the rainbands are found. It will altogether depend on the make.—Volvox.

[illegible]—**Lantern.**—The addition to your lantern which you ask about is called an aphengoscope, but it is not much use for ordinary work, as it requires too much light. However, a watch in motion, or small india-rubber dolls with flexible faces, photos on [illegible], and daguerreotypes are some of the opaque objects which may be tried. I fear you will never be able to display your own face in this way. Try what you can do with snow-drops and white [illegible]

[illegible]—**Brush Dynamo.**—Incandescent lamps must be connected up in parallel arc, as the E.M.F. of your machine would not be sufficient to burn them in series. You would not get any better result by connecting up as in Gramme's ring, if commutator is constructed of half rings as I explain. [illegible] run the machine without a sufficient resistance in circuit, or you will burn the insulation. [illegible]

[illegible]—**Brush Dynamo.**—If "Williams" [illegible] him recently, he will [illegible] He cannot connect his machine [illegible] only six coils on it. I [illegible] to put his machine on short [illegible] he will spoil the insulation. [illegible] good results without he con[illegible] lamps in parallel arc, as the [illegible] would not exceed 30 volts. [illegible] higher speed.—W. H.

[illegible]—**Intermittent Pulse.**—How does [illegible] gastric irritation ex[illegible] difficult digestion it pro[illegible] pulse is probably due to [illegible] in which the muscular [illegible] but which, for [illegible] be good enough. [illegible] medical practitioner, [illegible] confidence, and get [illegible] cause of his ailment.

[illegible]—**Intermittent Pulse.**—[illegible]

that the heart and stomach are both supplied by filaments of the pneumo-gastric nerve, and if irritation be applied to the stomach end of the nerve, it affects its cardiac (heart) end, and so may give rise to this intermittent action. He can get his stomach into order by three regular meals a day, allowing five hours between each. He must, if he uses them, give up alcohol and tobacco. At his three meals he must not have meat or fish more than once daily; or he might try the effect of a non-flesh diet for a fortnight.—T. R. Allinson, L.R.C.P.

[illegible]—**Intermittent Pulse.**—Intermittent pulse is by no means uncommon in advanced age, and is usually a symptom of little moment. I believe it is generally caused by reflex action. Irritation of the peripheral centripetal extremities of the pneumo-gastric nerve, which, as its name implies, is distributed to the mucous membrane of the lungs and stomach, stimulates the cardiac inhibitory centre in the medulla oblongata, causing it to send forth impulses by the spinal accessory nerve and the centrifugal cardiac branches of the pneumogastric, which will occasionally arrest the nominal explosive action of the intrinsic cardiac ganglia, and in this manner cause a beat to be missed. In the case [illegible] mentions I should consider that the stomach was at fault, and that it is liable to flatulent distension from muscular atony and abnormal forms of fermentation, and should recommend the use of alkalies and carminatives, or bitter tonics.—St. Bart's.

[illegible]—**Sizes of Tinplates.**—"F. G. S., Artisan," can get tin plates in quantity from Arthur Bird and Co., 18, Leadenhall-street, E.C. This ought to have been in the "Address" column; but it is impossible to answer this part of the query without giving an address.—R. A. R. Bennett.

[52266.]—**Tuning Piano.**—The covered strings are in fault: probably the under covering is of iron instead of copper wire, and, if so, their becoming "tubby" was only a question of time from the beginning. The only remedy is to put on new strings. The cost of an entire set would be about 10s., and that of the plain steel wire for the rest of the notes another 5s. Since "Amateur Tuner" seems already to have succeeded fairly well in tuning the piano, he would have no difficulty in restringing it and roughly tuning the new wires. The sizes of wire will greatly depend upon the length of strings, most likely they will be found marked upon the wrest-plank.—W. H. Davies.

[52271.]—**Lever Watch.**—Presuming that "Vulcan" carefully examined the watch and found no visible foul contact in its parts, I should be inclined to think that the cause of the watch stopping may be that the teeth of the 'scape-wheel come in contact with the "belly" of the pallet: they are not so liable to come in contact with the middle of the "belly" as at a distance from it on either side. I have found by experience that escapement makers often do not give sufficient clearance between these parts, and the result is that the watch is liable to stop, or its action to fall off in certain positions. In remedying the escapement I would always be against the practice of shifting the jewels of the lever, as, besides being a bad plan, it is also a disfigurement to the plates. Another fault I have found in the escapements of modern watches is that the balance pivots are made too small, with the object of reducing the friction to the utmost limit: but that is not at all so necessary, as the balance holes are always jewelled. A very thin balance pivot will wear away much too soon—in fact, far sooner than any other part of the watch—and it is not at all a desirable job to have a new shaft put in, at least, if it be a compensation balance, unless it be intrusted to very careful and skilful hands. As a great deal of jobbers' time is lost in trying to discover the causes of a watch stopping, it might be of service if "Vulcan" would publish the causes on which he seeks information as soon as he has found them out.—J. G.

[52273.]—**Squinting.**—To answer "Rap's" query intelligibly would require the complete discussion and explanation of one of the most complicated problems in ohpthalmology, besides more diagrams than our benevolent Editor inserts in the answers column in six months, so that I must, for brevity, speak dogmatically. The squint was undoubtedly caused by the error in refraction. In a hypermetropic eye, the eye is either unnaturally short, or the lens too flat. By accommodation, the lens is rendered more convex, and hence rays which would otherwise not meet on the retina, are brought to a focus upon it; but the accommodation cannot be exercised without convergence of the eyes—hence the squint. The refraction error is, of course, not corrected by the operation. Therefore, to prevent the return of the squint, which will undoubtedly occur otherwise, "Rup" should continually wear the weakest convex glasses with which he can see distant objects distinctly without effort or squint, be these No. 20 (2D), or No. 5 (8D).—St. Bart's.

[52276.]—**Legal.**—The answer to this query is, over £50 (32 and 33 V. c. 71, s. 87).—B. H.

[52278.]—**Gas.**—Somewhere in the back volumes "W. A. S." will find an article about his idea. It was a paper read before the Society of Arts, in which the author proposed to take all the "smoke" out of coal without reducing it altogether to coke. I believe the reason it was not taken up was because the coal left in that state breaks up too easily for handling.—Nun. Dor.

[52278.]—**Gas.**—"W. A. S." wants to suggest that our gas companies should partly distil our coal before householders are allowed to use it. It is a very good idea, but has been suggested. It would save the country a large amount of valuable products which now accumulate in our chimneys, pollute our atmosphere, cause lung disease, kill our plants and trees, make the sky hideous, and destroy our public buildings.—T. R. Allinson, L.R.C.P.

[52278.]—**Gas.**—"W.A.S." seems to have a very singular notion of the manufacture of gas and the resulting bye-products. To produce an incandescent coke we must remove all blaze and smoke, and this is done by allowing it to remain long enough in the retort to extract all its gas. Certainly there is a richer gas expelled from the coal in the early periods of carbonising, on account of the hydrocarbons being more rich in gases. The practice, however, is generally followed of obtaining the largest amount of gas possible per ton of coal, and this would largely deteriorate if the retorts were drawn (that is, the raw coke withdrawn before being fully carbonised) leaving gases *still* rich enough to mix with those evolved in the earlier period of the work. The only true method of solving the difficulty to which "W. A. S." refers—viz., "obviating the smoke from domestic fires," is to bring into practical use the principle of "flameless combustion," of which Mr. Thomas Fletcher, of Warrington, is, to my mind, the best exponent. With this principle carried out by the use of flameless gas, we see in the near future our towns and cities cleared of the noxious *fumes* and smoky chimneys which now poison *the air*, and at times make it almost insufferable. *I hope to see soon a paper in the* English Mechanic *by Mr. Fletcher on this subject, which I know would be welcomed by all.*—E. Owen.

[52279.]—**N. E. Engines.**—Mr. McDonnell has turned out a new goods engine from Darlington works, numbered 440. It is somewhat similar to L. and N. W. in type; but I am sorry to say I have not yet got dimensions. If, at any time I obtain them, I will send them. Some new bogie-express engines are, I hear, being built at Gateshead.—Meteor.

[52280.]—**L. and N.W. Engines.**—Experiment, Compound, Hydra, Knowsley, and Economist. These are fitted with Webb's vacuum brake. A compound condensing engine is also being built for the Metropolitan Railway out of one of their side tanks. A 6ft. 6in. four-coupled was in the Watford accident, not a compound.—Nomen, Liverpool.

[52280.]—**L. and N.W. Engines.**—The names and numbers of the compounds commencing with 300 are as follows: 300 Compound, 301 Economist, 302 Velocipede, 303 Hydra, 305 Trentham, 306 Knowsley, 307 Victor. The engine in the Watford collision was not one of the above, being No. 482 Pegasus, one of Mr. Webb's "Precedents."—Thunderbolt.

[52280.]—**L. and N. W. Engines.**—To "W. B. P."—The following is a list of 300 class of compounds:—No. 300 Compound, 301 Economist, 302 Velocipede, 303 Hydra, 305 Trentham, 306 Knowsley, and 307 Victor. No. 482, Pegasus, one of Mr. Webb's 6ft. 6in. 4-wheel coupled Standard Express engines, was the engine in the Watford accident, and not a Compound, as you supposed.—H. Bill.

[52280.]—**L. and N.W. Engines.**—The names and numbers of the new compound engines are:—66 Experiment, 300 Compound, 301 Economist, 302 Velocipede, 303 Hydra, 305 Trentham, 306 Knowsley, 307 Victor, 519 Shooting Star, 520 Express. No. 66 has high-pressure cylinders 11½ by 24, low-pressure cylinders 26 by 24. The other nine have low-pressure cylinders 13in. diameter, the other dimensions being the same. The two pairs of driving wheels are 6ft. 6in. diameter.—Meteor.

[52280.]—**L. and N.W. Engines.**—The engines of the 300 class are: Compound 300, Economist 301 (March 1883), Velocipede 302, Hydra 303 (April), Trentham 305, Knowsley 306, Victor 307, Shooting Star 519, and Express 520 (all July). These, with Experiment 66, are all the compounds at present at work; but I hear there are more being built at Crewe. The engine wrecked at Watford was Pegasus 482, a "Precedent," stationed at Rugby, and was a comparatively new engine, having been built in November, 1880.—W. Thompson.

[52280.]—**L. and N.W. Engines.**—300, Compound; 301, Economist; 302, Velocipede; 303, Hydra; 304, Trentham; 305, ——; 306, Knowsley; 307, Victor. The engine in the Watford accid was one of Mr. Webb's "Precedent" engines, 6ft. 6in. wheels, No. 482, Pegasus, January, 1881, stationed at Rugby. It may be interesting to some readers of the "E.M." to state that No. 300, Compound, ran from London to Carlisle, distance 300 miles, in seven hours and twenty minutes, with the 10 a.m. from Euston Station, stopped 5min. at Rugby, 7min. at Crewe, and 20min. at Preston. The speed on an average was about 42 miles per hour.—Rob Roy.

[52283.] — **Surveying Instruments.** — Has "E. M. R." seen Stanley's "Treatise on Mathematical Drawing Instruments"? The fifth edition was published in 1878 (there may be a later edition), and a notice of the book appeared in the English Mechanic on November 22nd of that year.—T. R. Saxton.

[52289.]—**Legal.**—Presuming "Gimel" refers to probate duty, and personalty, the answers will be: (1) Yes. (2) Yes. (3) Only one £3 per cent.—viz., on A.'s death. (4) On the net profit. A proper valuation must be made unless the business is sold, when its price is the sum on which probate duty is payable. (5) If property in the funds is for the benefit of the survivor eventually of two parties, the estate of the first deceased pays no duty on it, as it is no part of his property at death; the survivor, however, must pay "succession" duty on it at a rate varying with relationship to the donor. (6) Either probate, legacy, or succession duty must be paid, unless (7) A. gives away his cheque, &c., three months before his death. The Legislature is "up to the little move" proposed by "Gimel." If he leaves the property by will to his wife, she only pays probate duty; but she must pay that if testator owned the property at his death. As to the business query, the subsequent receipts cannot affect the probate duty, and the wife pays no other. The only way to avoid litigation is to say that, if the business produces so much, the widow shall receive so much, &c.; but it is impossible to provide for everything, and the attempt to cover all eventualities often, by complicating a will, insures litigation.—B. H.

[52289.]—**How to Leave my Property.**—(1) Legacies and residues, or shares of residues devolving to the husband or wife of the deceased are exempt from duty. But if A. leaves his property absolutely to his wife she will only have to pay probate duty, which for £1,000 would be £25. (2) If B. leaves the same property (or any other) to her children, probate duty as above would only be payable as by the Customs and Inland Revenue Act 1881 (44 Vic. c. 12, s. 27). The duty shall be charged on the affidavit to be required and received from the person applying for probate, the stamp duties following which for £1,000 would be £25; and by sect. 41 of the same Act: In respect of any legacy, residue, &c., payable out of or consisting of any estate or effects according to the value whereof duty shall be paid on the affidavit as above, the duty at 1 per cent. (not 3 per cent. as "Gimel" thinks it), that is, the duty payable on a legacy to a child or descendant of a child, or to a parent or lineal ancestor imposed by the Act of 55 George III. c. 184, shall not be payable. And also in respect of any succession to property according to the value whereof duty shall have been paid on the affidavit in conformity with the above Act, the duty at 1 per cent. imposed by the Succession Duty Act, 1853, shall not be payable. (3) A. ought to leave the property to his wife for life, and after her decease to be divided amongst his children in equal shares (5, 6, and 7). By 44 Vic. c. 12, s. 38, duty is now payable on certain properties, which are as follows:—(*a*) *Donationes mortis causa* (that is, property given in anticipation of death, to take effect only on death), made by a person dying on or after 1st June, 1881, or property taken by voluntary disposition, not made *bonâ-fide* three months before the death of such a person. (*b*) Property which such a person has voluntarily vested in himself and another jointly, so that the beneficial interest accrues by survivorship on his death to such other person. (*c*) Any property passing by any voluntary instrument (not being a will) whereby an interest determinable with death is reserved to the settlor, or whereby the settlor has reserved to himself the right, by the exercise of any power to reclaim the absolute interest in such property. Therefore "Gimel" will see, on reading the above, that it will be quite impossible for him to evade the duty, as the object of the 38th sect. given above is clearly to prevent the payment of probate duty being evaded by making gifts by way of *donatio mortis causa*, voluntary settlements, &c. Therefore, the best way for "Gimel," according to his intentions, which are not very plain, would be for him to make a will leaving his property to his wife for life, and after her decease to be divided amongst his children in equal shares. At the same time I most strongly recommend "Gimel" to go to some respectable solicitor to have his will legally drawn for him, as there are several little technicalities with regard to wills, which, if left undone, might altogether frustrate the wishes of "Gimel."—A Liverpool Subscriber.

[52292.]—**Problems from Newth.**—To raise 80 kilos. of snow at 10°C. to water at 0°C. we want 8 × (10 + 79) units of heat. 4 kilos of water at 60° in falling to 0°C., give out 4 × 60 units of heat. If these 240 units of heat be applied to melt snow, there must be as many pounds of snow melted as there are 89's in 240; $\frac{240}{89} = 2{\cdot}7$ nearly. Hence there will be 4 + 2·7 kilos. of water and 8 – 2·7 kilos. of snow. 6·7 and 5·3. These are far from equal. 2nd. One pound of ice requires 79 units of heat to melt it. 1lb. of lead at 327°C. contains 327 × ·0314 units of heat (above 0°C.) = 10·2678, say 10·27.

$$\begin{array}{r} 327 \\ {\cdot}3014 \\ \hline 1308 \\ 327 \\ 981 \\ \hline 10{\cdot}2678 \end{array} \;\therefore\; \frac{79}{10{\cdot}27} = 7{\cdot}69\text{lb.}$$

—J. F. Wilkinson.

[52292.]—**Problems from Newth.**—My edition of "Newth" is dated 1880, and as it seems to take a more comprehensive view than does "N. E.'s" edition, I will deal with his first question in its modified and somewhat more difficult form. In Newth's "Nat. Phil.," page 160, I read thus:—"6. If 4 kilogrammes of snow at – 10 C. be mixed with 8 kilogrammes of water at 60°, what is the resulting temperature?" "7. If in the preceding the proportions of snow and water were reversed, show that the result would be nearly equal portions of snow and water at 0°C." Now, since 4 kilos. of snow at – 10°C. require 4 × 10 = 40 units of heat to bring it to the melting point, and since it would require an additional 79 × 4 units of heat for its liquefaction, therefore the entire heat taken from the 480 units in the water would amount to 356, leaving 124 units to be divided amongst the 12 kilos of mixture; ∴ 124 / 12 = $10\frac{1}{3}$°C., which is answer to No. 6. Again, 8 kilos. of snow at — 10° would require 80 units of heat to bring it to the melting point, and since this would be abstracted from the 240 contained in the water, there would remain 160 units of heat for further diffusion, or, in this case, for the melting of the snow. Now, as every kilo. of snow would require 79 units for its solution, and as we have only 160 units at our disposal, it is clear we will only get about 2 kilos. of snow dissolved; we would then have about 6 kilos. of snow and 6 kilos. of water, or about equal portions of snow and water, at 0°C. This latter is the answer to "N. E.'s" part of the problem.—Ex-Blacksmith, Gorton Brook.

[52292.]—**Problems from Newth.**—There are, unfortunately, several errata in Newth's Chapter on Heat. To solve the questions mentioned, we must know, for the former, that the specific heat of snow is ·5, and for the latter, that the specific heat of molten lead is ·0402, neither of which is given in the book. (A) Specific heat of snow = ·5. ∴ To raise 8 kilos from – 10° to 0°, we require ·5 × 10 × 8 = 40 heat-units. Now, 4 kilos of water at 60° contain 4 × 60 = 240 heat-units, and 40 of these being required to raise the snow from – 10° to 0°, we shall have left 200, which will be expended in turning a portion of the snow into water at 0°, the 4 kilos of water also having the temperature 0°. Since 79 heat-units will melt 1 kilo of snow, we find that 200 will melt $\frac{200}{79}$ or $2\frac{42}{79}$ kilos. We shall therefore have $4 + 2\frac{42}{79} = 6\frac{42}{79}$ kilos of water, and $8 - 2\frac{42}{79} = 5\frac{37}{79}$ kilos of snow, each at 0°. If we take 80 for the latent heat of water, as given by some authorities, the numbers will be 6½ and 5½ kilos, respectively. (B) The answer given in the book is quite wrong, whether we take ·0314 or ·0402 as the specific heat of lead:

$$\begin{aligned} &\text{Let } x = \text{number of pounds required} \\ &\text{Then quantity of heat} = {\cdot}0402 \times 327\,x \text{ heat-units} \\ &\qquad\qquad = 13{\cdot}1454\;x \quad ,, \\ &\text{Quantity required to melt 1lb. of ice at } 0^\circ = 79 \;,, \\ &\therefore\quad 13{\cdot}1454\,x = 79 \\ &\qquad\therefore\quad x = \frac{79}{13{\cdot}1454} = 6{\cdot}009\text{lb.} \end{aligned}$$

Your correspondent may like to know that the answer to the question in Newth immediately preceding the former of the two given above is 12° C., not 2° C., and the answer to the question immediately preceding the latter of the two is 1·406lb., not 1·46lb.—H. C. L.

[52293.]—**Brewing.**—Multiply your produce of 520 gallons by your gravity 25·2, which will give you 13,104; then divide 13,104 by 36 will give 364lb. total extract. Then divide the total extract by $4\frac{3}{8}$ for malt used will give you exactly $83\frac{1}{5}$lb. extract per quarter.—Wm. Cook.

[52293.]—**Brewing.**—Multiply pounds per barrel by number of barrels and divide by the number of quarters. In the case you quote: 25·2 (pounds per barrel) × 14·444 (number of barrels) ÷ 4·375 (number of qrs.) = 83·197lb. extract per quarter. This is per standard quarter; of course the extract is less per bulk quarter.—W. L.

[52293.]—**Brewing.**—520 gallons = $14\frac{4}{9}$ barrels; × $25\frac{1}{5}$lb. = 364lb.; produce divided by $4\frac{3}{8}$ quarters of malt = 83·2 extract. "Ignorant Brewer" should find out what extract his sugar gives per 256lb., and subtract that from total produce, and divide remainder by qrs. malt used. Not knowing extract of sugar, I have taken 256lb. to be equal to 1qr. malt, but it only gives about 75lb. extract.—H. E. Smith.

[52296.]—**Nearest Fixed Star.**—The correspondent in the *Girl's Own Paper*, quoted by "Stellarius," seems to have made a slight mistake in the estimate of the distance of *α* Centauri. The parallax of this star has been ascertained to be nearly one second of arc, which gives its distance as more than 200,000 times that of the sun—or, taking the average distance of that luminary as 92,350,000 miles, it follows that the distance of *α* Centauri cannot be less than 18,470,000,000,000 miles.—John Willis.

[52298.]—**Bunsen Battery.**—A most convenient form of battery is the chromate, by which same position of the elements are retained, as in Bunsens, only they differ in the charging mixtures, which are as follows:—In the outer cells a saturated solution of bichromate of potash and sulphuric acid, two of the former to one of the latter, and inner cell sulphuric acid one part to six parts of water. These cells do not give off deleterious fumes, and are stronger than Bunsens, in which the fumes are very objectionable: but the latter produces a steady current in a low-resistance circuit, superior to the chromate cell. This battery is suitable for incandescent lighting and other numerous experiments where a powerful current is required. By reversing the solutions you have Fuller's battery, which is not so powerful as the ordinary bichromate, and is suitable for electric bells. The action of the former lasts only a few hours, while the latter continues in action for some months.—Electrician.

[52299.]—**Ice and Skating.**—It is safest when broken at the edges, and resting on the water. One long strap passed through the slit at the heel, over the instep, through the slit at the toe, back over the instep, and buckled on the *inside* of the foot.—T. P.

[52301.]—**Locomotive Cylinders.**—The Midland Railway Company are building some new engines with cylinders 20in. diameter, 26in. stroke. These would doubtless be the largest locomotive cylinders yet constructed, and also be about the greatest diameter admissible between the frames without making the axle or crank bearings, &c., too narrow and weak. The valves are to be above the cylinders, and driven by Joy's valve gear; the arrangement being similar to that in use in the 562 class of engine on the G. E. R. The L. and N. W. R. have built some inside cylinder engines with the valve faces arranged in > fashion to gain room. Mr. Stroudley's "Gladstone," having the valves placed underneath the cylinders, is another example of the expedients adopted to provide room for large diameter inside cylinders.—W. H. Y. T.

[52302.]—**The Cheapest Food.**—If "S. B." wants to get cheap, nourishing, and tasty food, he must go to the vegetable kingdom alone for it, and obtain it at first cost. Liebig asserts the identity of animal and vegetable fibrin, animal and vegetable albumen, and animal and vegetable casein. Food reformers and vegetarians get everything that is necessary for health, strength, and long life from the vegetable kingdom at a cost much below that got from a mixture of flesh and grains. Peas, beans, lentils, wheat, oats, barley, maize, rice, &c., contain a large proportion of nutritious matter at a small cost, whilst carrots, turnips, parsnips, potatoes, cabbage, onions, with sweet herbs and seasonings, give variety and piquancy to the food. Fresh and dried fruits make tasty dishes, and are very wholesome. Flesh foods, on the contrary, are dear in price, contain nearly 70 per cent. of water, are liable to contain many dangerous parasites, or the germs of disease. If not very fresh, they may give rise to symptoms of irritant poisoning (sickness, purging, with great depression); and if they are lived on alone, very large quantities have to be consumed. The more flesh is eaten, the more expensive is the diet. These vegetable foods are not only cheap in price, but contain more nourishment than an equal bulk or quantity of animal flesh. These vegetable bodies are so constituted as to supply to the system every element in its proper proportion. Flesh foods present us with too much nitrogen, which throws excessive work on the liver, kidneys, heart, and lungs, and they become diseased in consequence. I can say from sad experience that the beef-eating habits of our Anglo-Saxon race are the cause of the immense number of diseases we suffer from—including epilepsy, liver and kidney diseases, heart diseases, consumption, cancer, and apoplexy, besides that minor, yet terribly common, complaint, dyspepsia. These ailments mean doctors' bills, loss of time, and loss of opportunity; hence flesh foods are not cheap. If "S. B." wishes a list of cheap and wholesome foods, here they are:—Wheat, oat meal, pearl barley, hominy, rice, sago, tapio

1874-5), 6-coupled, double-framed saddle tanks, 4ft. 6in., cylinders 17 by 24; 1801—1812, single-framed saddle tanks (Wolverhampton, 1881), 4ft. 6in., cylinders 17 by 24; 1359, 4-coupled side tank, by Bristol and Exeter Company, 1876, 5ft. wheels, cylinders 17 by 24; 2201, 4-coupled passenger (Swindon, 1881), cylinders 17 by 24.—METEOR.

[52324.]—**Limited Liability.**—In a limited liability company each shareholder's liability is limited to the amount of his shares; so it will follow that if they are £1 each, and A. holds fully paid-up shares, he has no further liability; but if B. has only paid 10s. on his shares, he is still liable for a further amount of 10s. on each share, and there his liability ceases.—T. R. SAXTON.

[52328.]—**Violoncello.**—I should hardly advise "Edinburgh" to make one (without improvements) as he desires, seeing how difficult it is to do so on the old principle. No improvement is possible with the present shape, which has the soundboard moved more by reaction than directly by the vibrations. We can buy "cellos" made by machinery for 30s. that could not be made by hand under 100s. Then, unless there is something new to propose in the way of excellence in sound or power, there is no good in the attempt. One may search in all the timber yards for suitable belly wood and not find a piece. It is deal, to be sure; but it must be without a knot, yet having a straight grain throughout (not necessarily close) and also very light in weight. Three feet long, eleven inches wide, and four inches thick is worth 15s. to the wholesale dealer. The maple back, same size and seasoned, would be from 6s. to 8s. The neck, fingerboard, and furniture would cost 12s. first hand. Now here we have the materials more costly than the finished instrument, with the probability that the first move may be in the wrong direction, for these two planks must be cut lengthwise and as a feather edge, and this can only be done by a machine saw. Each divided plank has to be squared or made level to fit each thick edge, which is then glued and clamped or pressed together. The boards for soft belly and hard back lay flat on the bench, with a rise in the middle of perhaps 2¼in., but 3in. will be better. The length is from 32 to 34in., the larger width 18in., the upper width 14in. But all these sizes vary with the style of wood and thickness of strings employed. The middle thickness of soundboard or belly will be ¼in., tapering off at the *f* holes to ⅛in. Round chisels are required for shaping out the belly, and whether you have it high or low in build, the *f* holes should be made to overlap each other as the lips of a mouth, so that the air may be more vibrated than with a mere open orifice. However, I have said more than I intended, but probably enough to show an amateur that he had better leave the "cello" alone, for a great number of tools, moulds, and appliances are required for measuring, bending, and baking the sides into shape and fitting all together, with the almost certain possibility of a failure after all. When I feel sure of my experiments with the new violin without the soundpost, I will give a résumé. —FIDDLER.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

A SHOULDER of mutton contains one-third more bone than a leg does, whilst there is also considerably more fat and connective tissue. A shoulder of mutton at 10d. is less economical than a leg of mutton at 1s. a lb. To make their values at all equivalent, the shoulder should be sold at 8½d.

QUERIES.

[52329.]—**Electrometer of Small Resistance**—I want to find an electrometer to note very feeble currents. Lippmann's capillary electrometer appears to me the most suitable: but I shall feel much obliged if "Sigma" will tell me if this is so, or if any other kind will be practically better? The electrometer will never have to indicate more than feeble currents.—BATTERY BALANCE.

[52330.]—**Equatorial Circles.**—My telescope moves much more stiffly on the circles than it did, and the hour circle itself is the same when I turn it. How can I oil them, or what should I do to remedy it?—M. A.

[52331.]—**Varnish for Baywood Tops of Carding Engine.**—Will any of your readers kindly inform me of a varnish for varnishing the tops (baywood) of carding engine? I have tried several sorts, but they all go dull in the course of about an hour.—T. T.

[52332.]—**Screwpitch Striker.**—I believe a tool is made by which the correct pitch of any screw may be traced by hand. Will anyone who possess one, kindly describe the mechanism of it?—OUVRIER.

[52333.]—**Legal.**—A man obtains an absolute divorce from his wife. Are the children of their marriage, being of age, liable for the maintenance of their mother; or is there any responsibility on their part towards her? She is an invalid.—SEMAPHORE.

[52334.]—**Draughty Church.**—Will any of your readers please inform me if their exists any means of curing the draught in a church? The church is warmed by a hot-water apparatus with saddle boiler, the pipes being laid in trenches in the centre of the nave and aisles. The congregation complain of a draught apparently coming down on their heads. On holding a candle near the walls, especially in the angles, a very strong down-draught is perceptible. The roof is a timbered one, the slates laid on felt, and there is no visible aperture. Who is the best authority on this subject?—CHURCHWARDEN.

[52335.]—**Lacquering Brasswork.**—Will some kind practical hand assist me? Is it possible to copper bronze brasswork properly without battery power?—also a recipe for good black bronze and the right lacquers to use for red bronze and steel bronze? I have tried numbers of recipes that have been published in the "E. M." for years past, but have failed to obtain good results. I can lacquer very fairly when I can get good materials.—OLD SUBSCRIBER.

[52336.]—**Test for Cane Sugar.**—Would Mr. Allen or any other chemist give a method of distinguishing crystals of cane from beetroot sugar? Chemical or microscopical.—H. C. M.

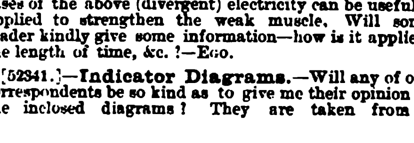
[52337.]—**Telescope O G.**—I have a 4in. telescope with pretty good both defining and light-grasping power, but find after having focussed with low power and then putting in a high power, that it requires to be screwed outwards to focus under this power. Would "F.R.A S." or other astronomical friend kindly explain this?—R. S.

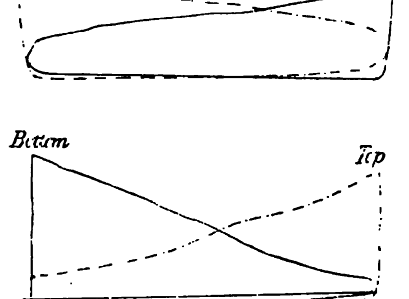
[52338.]—**Holtz Machine.**—Would any kind reader answer the following questions with reference to stationary plate of above? (1) Would it do to be cut across where the holes are to be (thus making it easier to cut the holes) and cementing it together after they are cut out? (2) If the above would not do, how would I cut the holes out? (3) Would it do to have the revolving plate of glass and the stationary one of vulcanite?—AMATEUR.

[52339.]—**Brazing on Ends to Muntz Metal Boiler Tubes.**—I should feel obliged if "Nun. Dor." or some other reader would kindly give some informa- as to how I am to do this. Tried forge fire and failed. Could it be done with a blowpipe? Or if it can be done with a forge fire, How? On a forge fire I find it burns the tube before spelter melts.—Y. Z.

[52340.]—**Strabismus.**—I have heard that in slight cases of the above (divergent) electricity can be usefully applied to strengthen the weak muscle. Will some reader kindly give some information—how is it applied, the length of time, &c.?—EGO.

[52341.]—**Indicator Diagrams.**—Will any of our correspondents be so kind as to give me their opinion of the inclosed diagrams? They are taken from a McNaught's beam-engine, with McNaught's (gridiron) expansion valve regulated by the governors. The engine is not so heavily loaded as it was previously. Consequently, I have to throttle the steam, that is not let the full boiler pressure on, which is on an average of 48lb. per sq. in., as the governors have not the same control over the engine. The diagrams are not so good as they were a few months since, as the point of cut-off is not distinct, as will be seen. P.S.—Diameter h.p. 33in., stroke 3ft.; l.p. 36in., stroke 6ft.; 32½ revolutions per min.—W. F.

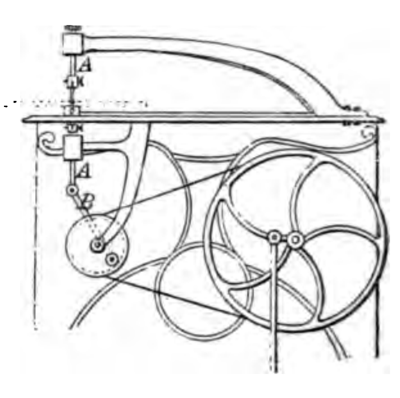




[52342.]—**Siemens Armature.**—Would any of our readers kindly tell me the best size wire, and number of layers, for winding a Siemens armature (H pattern)? It is 10in. long and 3½in. diam. It is proposed to wind the F.M. with No. 16, but am uncertain as to size of wire for armature. Any information will be gladly accepted by—WAG.

[52343.]—**Electric Light.**—To "SIGMA" AND OTHERS.—May I ask a valued reply to the following?—(1) Five granular carbon cells are supposed to light one of Swan's 5c p. incandescent lamps. (*a*) If I use six or even seven cells, will it be detrimental to fittings—as wires, &c.,—and (*b*) if not, could I obtain good reliable light? (2) Lamp to burn 6 hours per night, approximate renewals of acids, &c? (3) Could I regulate power of lamp by using, say, three cells for one hour, when little light was wanted, then join other cells on when required, and get full power of lamp?—INCOGNITA.

[52344.]—**Fretsaw.**—This is a rough sketch of a fretsawing machine I am constructing (or rather trying to construct), which so far explains itself. I find that a spiral spring from the top, of strength enough to stretch the saw very tightly, will not allow the small wheel to go round properly. What could I do to remedy this, or what could I have in its place? Should the working parts A A and B be of steel, or will iron do? I find these make a great noise. What is the remedy for this? How could I affix an efficient dust-blower to be worked by the driving-wheel?—A DECIDED AMATEUR.



[52345.]—**Non-Condensing Horizontal Engine.**—Having bought at a sale a new horizontal non-condensing steam-engine, I should esteem it a favour to receive from some of our practical correspondents a statement of the indicated horse-power which this engine will develop? Also, what is the nominal horse-power of this engine? Following are particulars:—Cylinder: diam. 16in., stroke 42in., 80 revs. per minute; steam pressure as indicated by boiler gauge 65lb.; steam on ⅛ of stroke; piston-rod 3in. diam.; the exhaust will be allowed to fly away and not be confined at all.—YOUNG MANUFACTURER.

[52346.]—**Developing Box.**—I am desirous of making a portable dark tent or box for developing and changing 6½ by 4¾ dry plates, suitable for travelling work. I shall be much obliged if some of your readers will help me by giving dimensions, &c.: one that would not necessitate working under a cover preferred, on account of heat of climate.—PHOTO.

[52347.]—**Vacuum Gauge.**—Our condensing engine (air pump 18in. diam., 4ft. stroke) has had a Bourdon patent vacuum gauge fixed on the condenser, and when the engine is working full speed the gauge shows the vacuum pointer at 25. Is this right, or would 10ft. of ¼in. tubing, which is between the gauge and condenser, make the difference, as we did not expect the pointer going higher than 15 or 18? The engine cylinder is 25in., with 5ft. stroke; boiler pressure 40lb. If "Labor Omnia Vincit" or "Boswell" will give their opinion it would oblige.—BAD VACUUM.

[52348.]—**Boiler Tank.**—We have a boiler for tank which is 22ft. long, 7ft. diam., with a tube 2ft. 6in. dia. through the centre (the tube contains no water, of course). Will some better scholar than I tell me how many gallons of water the tank will hold, and what would be about the weight?—BAD VACUUM.

[52349.]—**Steam Mill Pump.**—Will any of your kind readers instruct me in the following? My mill pump that I use in the brickyard has been blown down. How can I proceed to work it by steam, and what amount of power shall I want to work it? It is a 5in. barrel pump. Please say what size pulley I shall require, and what is the shortest length of rod it should have? The pump is rather high, and I should like to keep the steam gear as low as possible. Some general information on the subject will be thankfully received by—NARVA.

[52350.]—**Legal.**—A. mortgages property to B. for £500. Two years after A. makes second mortgage to C. for £100. A. gives B. notice of his intention to do so. Soon after A. neglects to pay interest to mortgagee. In consequence, B. gets writ of ejectment and turns A. out of the property. Within a week B. offers the property for sale by auction; but not finding a purchaser, sells it shortly after by private treaty for £550. Now B. has never given any notice to C. of his intention to sell, or to A. either; neither has B. rendered any account to C. or A. of the sale. What is C.'s remedy to recover his money, and is B. justified in selling at what price he likes, the property being worth much more?—SECOND MORTGAGEE.

[52351.]—**Waterwheel.**—I should very much like to have the opinion of some of your able contributors on the above. D is the wheel, 20in. diam. and 1in. thick, having buckets formed on its periphery a, a, a, &c., 4in.

deep, 1½in. long, and ¾in. broad, thereby leaving ⅛in. on each side of bucket so as to form said bucket. These buckets are deepest at *d*, and gradually shallow till they become nothing at *e* (Fig. 1). At *b* (Fig. 2) water enters under a pressure of 6 lb. to the sq. inch at an angle of 30°, that is in the direction from *e* to *d* (Fig. 1). Under this force wheel would revolve; but I find that the water escapes between revolving wheel and *c c*, as at *z z* (*g g*, parts of *c c*, are close up to, but not touching, wheel, but are not so in drawing to aid description). Of course, if I jammed wheel up against *c c*, I might be able

Fig. 1.

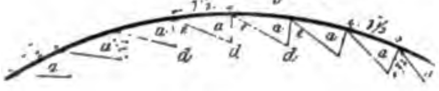


Fig. 2.

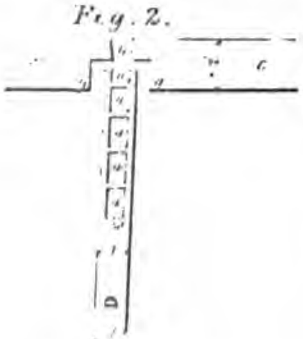


to stop water from spurting out all over the place; but then the wheel could not turn because of the friction produced by such a procedure. What is the best to do under circumstances? let it run on now like it is doing, wasting [illegible] more water than it would do if it were watertight? But the fun of it is, being in town, I have to pay for all the water it consumes by meter. Couldn't any kind reader affect a remedy? Would india-rubber [illegible] periphery of wheel and also round water pipe? What is it they have round piston of a steam-engine? Would that do? Would not water perish it? for I am not using it always, say three or four times a week. Would it get dry in interim and crack? Any hints will be received with thanks by MELBOURNE.

[illegible] **Orchestral Concerts.** The concert season is now beginning. Could any correspondent kindly give a description of the various instruments employed, their special qualities, and any scientific phenomena that one might endeavour to trace during the performance? [illegible]

[illegible] **Legal.** A. died ten years ago, leaving a widow but no children, and by will bequeathed his estate (which consisted of money) as follows: To his brothers and sisters he gave one half, divided equally amongst them, and the other half to his widow, absolutely. If the widow dies intestate, who will have the [illegible] of the house and the funeral, and [illegible] of [illegible] furniture and money)? Will the [illegible] of A. or the nearest relative of widow? She [illegible] nephews and nieces residing [illegible] of A.'s executors is dead, but the other [illegible] is living.—A 14 YEARS' READER.

[illegible] **Gelatine Transparencies.** —I am [illegible] "Wyndell's" more complete description [illegible] Will he oblige me by giving directions for making gelatine transparencies for the lantern [illegible], which he is, I believe, well up?—GLATTON.

[illegible] **Oxidising Silver.** —Would some one inform me how to oxidise sterling silver? I have tried many ways, but it will not stick on. The best way I find is to use sulphate of potash, but a friend told me that a new way has been discovered lately.—E. H., Birmingham.

[illegible] **Watch License.** —Is it needful for the [illegible] with the right of selling watches [illegible] for a firm, to obtain a license, or is the license the firm holds sufficient?—DR. FRANCIS.

[illegible] **Melting Solder on Brooches.** —I have [illegible] been endeavouring to melt the solder [illegible], with the blowpipe, but have not been able to do so. Is it because the flame of a candle which I have been using is not sufficient, or is it that I have not applied the flame properly?—W. J. L.

[illegible] **Portishead Tunnel.** —Can any of your correspondents give me any glimmering of an idea when the Portishead tunnel is likely to be finished and working? I have occasionally to make the long journey between Midford and London, and have for years been looking forward to the hour's saving of time to be effected when the tunnel is completed. But the years come and go, and the only time the tunnel appears in the newspapers is when there is an accident there.—F. B. H.

[illegible] **Medical.** —Will Dr. Allinson or Dr. Edmunds give me their opinion upon the following case? The child of a labouring man, between three and four years of age, whose eyesight was perfectly good until three weeks ago, has suddenly, in a few days, entirely lost his eyesight. There is no apparent reason for this, as the child has not met with any accident, is perfectly well in health, and does not complain of any pain. It does not appear to proceed from the brain, as there are no headaches, and the child is unusually sharp and intelligent. Moreover, his eyes are quite bright, clear, and full of expression, so that no one could imagine anything to be amiss with them. The child has never made the least remark upon his loss of vision. Is it possible that it is not dark to him?—that he can see the light without being able to distinguish anything else? One curious fact is that since the affection of the eyes the child has never shed any tears, though he has cried several times. Does such a case of sudden and entire loss of eyesight often occur?—and is it possible that his vision will return as suddenly as it was lost? An early answer will much oblige.—R. A. B. BENNETT.

[52360.]—**Integrals.**—How are the integrals of—

$$\frac{dx}{x+\sqrt{(x^2-1)}} = \frac{x^2}{2} - \frac{x\sqrt{(x^2-1)}}{2} + \tfrac{1}{2}\log.\,[x+\sqrt{(x^2-1)}],$$

and

$$\int_0^{2a}\sqrt{(2\,a\,x-x^2)}\,dx = \frac{\pi a^2}{2}\ \text{obtained ?}$$

—INT. CAL.

[52361.]—**Equation.**—I should be much obliged if some reader would give the solution of the following equation :—

$$y\,W\sec.\,\theta = S\,C\,\frac{\left(1+\frac{d^2y}{dx^2}\right)^{\frac{3}{2}}}{\frac{d^2y}{dx^2}}$$

and obtain the value of C.—EQUATION.

[52362.]—**Engineering.**—Will "Dubliniensis," or any of "ours," kindly answer the following queries, and give mode of working? (1) What will be the angle of the thread of a screw which is 2·756in. diam., and has a 5in. pitch? (2) Taking an engine and boiler which require 2lb. of coal for every indicated or actual horse-power developed, what percentage of useful effect does this give, taking the mechanical equivalent of heat at 772 ft.-lb., and the coal as yielding 12,000 units of heat per pound?—SILEX.

[52363.]—**Discharge of Water.**—I am desirous to know what quantity of water will be discharged in an hour from a lead pipe 1in. in diam., served at right angles from a 4in. main pipe which has a head of water 50ft. high, and runs a distance of 150 yards. If any kind reader would work this out for me, I shall feel obliged.—S. B. D.

[52364.] **Salamander Crucibles.** — Will Mr. Fletcher, or some other reader, kindly give his experience of salamander crucibles? I find that a 4 by 3in. crucible, after 45 minutes' exposure, to a white heat in a blast furnace (coke and cinders), becomes almost useless; the outside and inside covered with globules of brown enamel, and the substance of crucible so soft as to be easily scraped away with a nail, and resembling granulated blacklead in colour and consistence. When the crucible is white hot it is so soft as to be easily crushed out of shape by the tongs, or disrupted if pinched by one side. The same thing occurs if the crucibles are heated in an ordinary forge. The "Salamander" brand certainly do not crack up on first heating; but I cannot understand their disintegrating so rapidly. My experiments were with copper, and salt was the flux used. Was this wrong? If so, what flux should have been used? It would not appear to me that the flux was the cause of the above condition, as both inside and outside of the crucible were similarly affected. The bottom of the crucible was not injured where it rested on a fireclay shelf in the furnace. This was the only portion which stood well. The furnace was lined with the mixture of fireclay and sawdust, recommended by Mr. Fletcher in his work on Metallurgy.—R. W. F.

[52365.] **Photographs.**—I should be much obliged if some one will tell me whether ordinary mounted prints harm by being varnished, for if not, varnishing would be a cheap substitute for glazing for frames, &c., where prints are exposed to the air and light, and please state best varnish for same.—WYNFELL.

[52366.]—**Skates.**—Can any of your correspondents inform me whether skates made of a plane hoop of steel shaped like a capital C, with plates for the toe and heel of the boot, are good? I have seen some of this shape, which looked to be very easily adjusted.—ARVAS.

[52367.]—**H.P. of Engine.**—Will any reader tell me the horse-power of my engine (high-pressure beam)? Stroke 6ft. 3in.; diam. of cyl. 28in., piston making 24 strokes per min.; pressure of steam 40lb., as indicated on gauge in engine-room; steam ports 15in. by 2in.; exhaust 15in. by 4in.—IGNORAMUS.

[52368.]—**Red and Blue Photographs.**—Many years ago there was a description of how to make these in *Cassell's Monthly*. I cannot now lay hands on the copy. Perhaps some reader of the "E. M." knows how to make them and would describe the operation? I believe the chemicals for sensitising were bichromate of potash and ferrocyanide of potassium; but I cannot remember either the quantities or the process, or how to fix the photographs.—I. O. U.

[52369.] **Squeaking in Musical Box.**—Can any one give me information how to prevent the squeaking of notes in a long-barrelled musical-box? The squeaking is all in the bass. One or two check-springs are off, but there is no jarring. I have tried pitching of notes and other attempts, but to no success. Should check-spring touch the notes or not?—AMATEUR.

[52370.]—**Dynamo.**—Would Mr. Lancaster, or some reader, kindly say how the amount of wire and size is calculated or arranged for the armature and field-magnets of a dynamo? I am about trying a new armature, but do not know how much wire to put on it, or the size. There must be some rule by which dynamo-makers go.—THOMAS PLUNKETT.

[52371.]—**Gem Lenses.**—I have nine of these all screwed into a brass plate, and I want to know how to make a camera suitable for them. Must each lens have a small box or compartment for itself, so that the light from each falling on the sensitised plate may not confuse or weaken each image, or is this refinement necessary? I will be glad of a few hints on this subject, and I would also like to know if these little lenses may be used to take reduced or microscopic transparencies.—A GEM.

[52372.]—**Chemical.**—I shall be glad if Mr. Allen, or other experts, will favour me with an explanation of the following reaction:—If a solution of chloride of [illegible] be mixed with a solution of chloride of lime (hypochlorite of lime), a precipitate is thrown down. What is the precipitate, and is it possible to cause the two compounds to remain in solution, or are they incompatible? As an oxidising agent, which is the most powerful—permanganate of potash or bichromate of potash? and give the equations.—ANALYST.

[52373.]—**Polishing Brass.** — Can any of our mechanical friends oblige with a few hints as to what kind of inexpensive machine I could rig up to polish plates in brass 6ft. long by 6in. broad, generally flat? At present we pumice-stone and polish them by hand, but the labour is so great I would like if mechanical means could be devised to accomplish the same.—JIM.

[52374.]—**Pump.**—Would P. J. Davies, or some other friend, kindly answer the following questions?—It is desired to fix a small hand pump on to sink so as to supply a cottage with water; but the well is 8ft. distant from the cottage, and the water usually rises to within about 6 to 8ft. from top of well. Now will there be any difficulty in raising the water and carrying it so far by an ordinary lift pump? Also what size feed-pipe would it require to supply a 3in. pump efficiently?—PUMP [illegible].

[52375.]—**Gramme Armature.**—Can any of our [illegible] tell me what thickness the ring or armature ought to be? The armature, when coiled with four layers of No. [illegible] c.c. wire will be 5in. in diam. Also the best way to insulate the wire?—RING ARMATURE.

[52376.]—**Removing Varnish from Oak Panelling.**—Could you inform me of the best way to remove a coating of silicate of soda from some oak panelling? It was intended as a varnish, but having effloresced and broken up into flakes, I wish to get it off without injuring the wood.—METEORITE.

[52377.]—**Chemical Problem.**—Would any of ours kindly show me the method of working the following problem :—

The heat of combination of potassium chloride (KCl) having given—

$(K_2O, Ag) = 164560 \qquad HCl, Ag = 39320$

$(H_2O) = 68360 \qquad KCl, Ag = 4440$

$(HCl, Ag, KOH, Ag) = 13700$

—PHONO.

[52378.]—**Chemical Problem.**—Would any one also kindly show me the method of working the following :—

Find the heat of formation of methane (C_2H_4), having given—

$(C\ [\text{amorphous}]\ O_2) = 96960 \qquad (H_2O) = 68360$

$(CH_4, O_4) = 213530$

—PHONO.

[52379.]—**Banjo.**—I have recently bought a banjo, and I am now every evening leathering away with a vehemence which at least expresses my desire to excel in serenade. But I wish to ask my "E. M." friends how I can render the music more brilliant and less tubby. If I strain the vellum more and use thinner strings, will I succeed? *Or is there any gain in oiling* the vellum? Should *the fifth long string be covered* with wire, like a fourth fiddlestring. *A few hints on the* management of the instrument would be thankfully appropriated by—A. LUNATICK.

[52380.]—**Wells' Altimeter.** — Living in close proximity to several mountains, peaks, &c., am desirous of measuring the altitude. How can I make this or "Glatton's" useful for the purpose, as some mountains are probably 1,600ft. high, and I am unable to perceive how I can use either altimeter for so high an object.—PENMAENMAWR.

[52381.]—**Legal—Power of Local Board in Water Supply.**—I am 800 yards from end of water main which is here belonging to the local board. As I am requiring a constant supply for trade and domestic purposes, I wish to know if I can compel them to supply me with water if I am willing to lay all the pipes; or can they refuse me permission to put the pipes down, myself bearing the whole expenses, and I offer them a rental on the water used? Or can I lay the main and then demand supply of water.—WATER.

[52382.]—**Plaster or Cement for Outside Walls.**—The outside covering of my house, which seems to be composed of some sort of clay, is continually dropping off in large flakes. I think of stripping it all off; but before doing so, shall be much obliged if some reader will kindly tell me what to recover it with (not too expensive). The framework of house is wood.—S. B.

[52383.]—**Crumpets.**—I think there was a recipe for these some time ago, but can't find it. Will some reader kindly give me full instructions for making and baking?—S. B.

[52384.]—**Absorbent Cotton Wool.**—I have some white cotton wool which is very absorbent, and has a snowy feeling when pressed by the fingers, and it does not show alkali or acid when tested by the testing paper. Can any one inform me what process it goes through to make it as above?—STUDENT.

[52385.]—**Argelander's Star Chart.**—This question was asked by me on p. 46, but I have had no reply. I shall be very much obliged to any one who can give me the information. Are the Durchmusterung and the Bonn Catalogue the same? What other maps and catalogues of Argelander's are there? I want to get his chart which gives the stars on a scale of four minutes of R.A. by one degree of D; but I do not know which is. Is there a catalogue to go with it, giving places and names of the stars?—BRICKWALL.

[52386.]—**German Mouldings.**—I have some of the above, which appear to have had a coating of tin and then lacquered. Could any one tell me how this is done? Any information would oblige.—B. B.

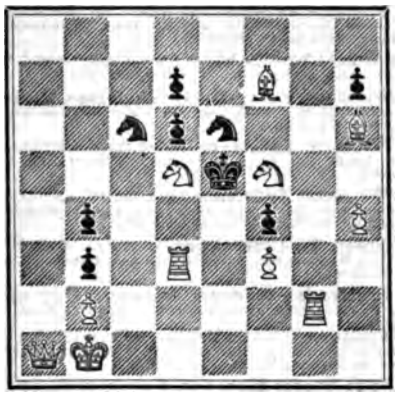
[52387.]—**Bending Brass.**—Can any of the readers of ours suggest a method of bending strips of brass 6ft. long, by No. 12 wire gauge, into an ogee 9in. by [illegible] I have a number of such to make for a shop-front, and find a difficulty in bending them straight and regular in shape.—JIM.

CHESS.

All Communications for this department must be addressed to J. Pierce, Bryn Rhedyn, Llandwrog, Carnarvon.

PROBLEM DCCCLXIII.—By C. R. Baxter (from "Chess Problems.")

Black.



White. [11+9

White to play and mate in three moves.

Solution to 861.

White.	*Black.*
1. R-Q 4	2. Anything
2. Q, B or Kt mates	

(Five variations.)

NOTICES TO CORRESPONDENTS.

Correct Solutions to 859 by G. Seymour Follwell (good problem: sacrifice of R and Q piquant); to 860 by Dicky Sam (splendid, and well merits its title); to 861 by Schmucke and Rev. W. Anderson.

R. A. Bennett.—There is no mate if 1. $\dfrac{\qquad}{\text{Kt-Q B 5.}}$

C. Planck.—Thanks for the very neat prob'em.

H. B. Reynolds, Jr.—Game duly received.

English Mechanic Tourney game between Mr. J. Russell (*White*) and Mr. J. H. Blake (*Black*) :—

(Ruy Lopez.)

1. P-K 4, P-K 4/2. Kt-K B 3, Kt-Q B 3/3. B-Kt 5, P-Q R 3/4. B-R 4, Kt-B 3/5. P-Q 3, B-B 4/6. P-B 3, P-Q Kt 4/7. B-Kt 3, P-Q 3/8. B-Kt 5, Castles/9. Castles, B-K 3/10. B-B 2, B-Kt 3/11. Notes by Mr. Blake.

(*a*) Q-B 3 first is better.
(*b*) If $\dfrac{\qquad}{\text{B takes P}}$ White will be able to extricate himself by 24. $\dfrac{\text{Kt-Q 2}}{\text{Q-K Kt sq}}$ 25. $\dfrac{\text{R takes B}}{\text{R takes R}}$ 26. $\dfrac{\text{R-K Kt sq}}{\qquad}$
(*c*) There is nothing better.
(*d*) Loss of time. K-B sq at once is the correct play.
(*e*) This combination wins. Black has had it on the board for two moves past; but it was advisable to have the Q side P's advanced as far as possible before entering on it, and there was also the possibility of White's attempting to bring his K across, in which case Black would win much more quickly even than now.

White Fire.—A white fire which can be used as an artificial light in photography, is composed of chlorate of potash eight parts, sulphide of antimony four parts, sulphur two parts, magnesia in fine filings, or powder two parts. The ingredients must be powdered separately, and then mixed intimately with a bone spatula.

A Perpetual Clock.—A clock was set going at Brussels some months ago which continued to go for nine months, and had not run down when last heard of. An up-draught is obtained in a shaft by exposing it to the sun; this draught turns a fan, which winds up the weight of the clock until it reaches the top. It then works a brake which stops the fan until the weight has gone done a little, when the fan is free *to recommence.*

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 28, and unacknowledged elsewhere :—

L. Wray, jun.—T. B. Etty.—J. C. Montgomery.—Capt. Lister Kaye.—A. Norfolk.—A. J. Herbert.—Barnett, Foster, and Co.—E. A. Litton.—E. R. Morris.—J. D. Morrison.—H. Gnidrah.—W. Jones.—Orion.—H. J. Sayer.—Chemical.—A J. Walter.—W. H. Richmond. An Apprentice.—A Watchmaker.—G. C. D.—S. R. Bottone.—Orderic Vital.

H. (For hard and soft soldering, see pp. 170, 264, 334, 455, Vol. XXXIII., and the indices of that and many other back volumes.)—Talc. (For gilding, see many references in the indices; but an inexperienced person will scarcely succeed the first time.)—Fred. Wright. (Gas lighting by electricity has been frequently described. See p. 391, No. 927, or p. 472, No. 905.)—Joe. (If of ivory, the aniline dyes will do; but they quickly fade. Many recipes in back numbers. For black, immerse in a strong boiling decoction of logwood for about five minutes, and then place in a solution of sulphate of iron. For red, immerse in a solution of cochineal in ammonia. In both cases the ivory must be thoroughly cleaned with strong solution of washing soda, and in the case of the red dye soaked for a few minutes in water made acid to the taste by aquafortis.)—Simplex. (You should read the laws of magnetism, given in the textbooks. The proportions for electro-magnets which have been found best, and which are generally used by makers, were given in Vol. XXXIV. p. 336. Your dimensions will probably lift 50lb.; but 24 wire is rather fine. A good deal about Altandi magnets in back volumes—see pp. 350, 386, Vol. XXXIII., for instance.)—Bernard. (We do not know; but believe they can be obtained at South Kensington or of Chapman and Hall, Piccadilly. Any science master could tell you.)—Edward S. E. G. (Brailsford's bell and indicator was illustrated and described in No. 947. Similarly, you will find all that can be usefully said about the other query on pp. 456 and 482, Vol. XXXVI.)—Tyro. (A collection of good lead pencils, a piece of rubber, and a sketching block. Such a question would be answered by any dealer in artists' materials.)—W. Coats. (Answered many times. See, for instance, p. 334, Vol. XXXII., or p. 456, Vol. XXXIV.)—Les Dents. (The following extract from index to Vol. XXIV. may help you :—Feathers: cleaning, 466, 489; curing, 294; dyeing ostrich, 22; how to curl, 417, 439.)—Listener. (There is no way of preventing it and keeping the tubes efficient; but a curtain over the end might be sufficient to prevent the words being heard without interfering with the whistle.)—Leather. (There are several recipes in back volumes; and you can make the one which will suit your business best. Crude fish oil, tallow, and rosin is the composition used by curriers; but there are other materials which you might be able to obtain more readily.)—George Broadbent. (Grind up any desired pigment with gum water. Add a little sugar if you like, or use any coloured ink, adding solution of gum arabic or gum tragacanth.)—Mark. (You will have seen that we mention the matter on p. 263, last week. The cost is £7—that is, 35 dollars—but practically you must employ an agent, unless you take a trip to Washington.)—Electrical. (We do not know why it should not. Suppose you try the experiment with millboard, for instance. Probably you will find it as costly as glass.)—Harmonograph. (Can be seen at most makers of scientific instruments. 2. Any ordinary arrangement of mainspring and fan will do to rotate the table. See pp. 18, 93, 188, Vol. XXV., for details of the whole instrument. 3. As to this question, see the answer to "Electrical," preceding.)—Enquirer. (The directions are given in most works on chemistry. It is extremely risky for anyone not skilled in chemical manipulation to prepare it, and any one sufficiently skilled will know where to find the recipe.)—H. D. (Yes, it is quite true; but what has it to do with the resolving power of the microscope?)—Hoinos. (There are several slide-rules in the market, and you will find answers to your questions in the last two volumes. We thought the subject had been pretty well exhausted.)—E. M. E. (Extremely unlikely; but you will have seen what has been said on p. 129, this volume, and in Dr. Edmunds's papers previously.)—A. J. D. (Both queries have been answered many times. We cannot in the case of questions so indefinite do more than refer to the list of Back Numbers, given in this column the first number in each month.)—Jimmy. (Crewe or Derby would be better places. The work is hard, and wages from 12s. to 18s.)—Eyesight. (Better consult a surgeon at one of the eye hospitals, and in future use spectacles of dark glass or look at the arc through a piece of dark green glass.)—R. H. S. (It is a case for examining the instruments and their connections. No one can suggest a remedy on the bare recital of the defects you mention. Most likely the distance of the magnets is not properly adjusted.)—H. O. (The "Grammar of Lithography," Wyman and Sons, Great Queen-street, W.C., and several books on wood engraving. See the catalogue published by Mr. Calvert, Great Jackson-street, Manchester.)—C. R. K. (The time varies. See many articles in back numbers. Most likely the artist you refer to used a different process.)—Typographia. (Try the effect of some lime in the water. 2. The numbers can be obtained only by advertising for them.)—Xmas. (A recipe is given in most cookery books. Brandy is the usual thing added, with noyeau, or other liqueur to taste.)—D. W. (Has been given many times. If of ordinary steel, heat to a cherry red, cool in salt and water, file bright, and put on a hot iron until blue; then quench.)—W. D. L. (See previous answer. 2. Yes, the lid must be luted on. 3. More; the pulley block is the easiest, because speed is converted into power.)—Mechanic. (There is no special recipe; it is simply the usual method of hardening and tempering; but if you refer to p. 320, No. 741, you will find all about hammering them as well. Briefly, the recipe is, heat to a dull red and cool in water. The art of doing it properly can be learned only by practical experience.)—G. D. A. (We gave one on p. 81; but it is doubtful if you will find a permanent polish to remain pliable unless it undergoes the japanning process. 2. They must be relacquered. 3. For bronzing brass, see p. 13, Vol. XXXV., and the indices generally.)—J. (Consult the catalogues of the music sellers. 2. Just as much difference of opinion about the pegs as about the books.)—Student. (See p. 505, Vol. XXXI., and the indices generally.)—A. M. (We scarcely understand you; there is only one way to file them up.)—Electroplate. (If you cannot read up the subject in back volumes you may get some hints as to the first and third questions from the catalogue of the Elmore Co., Blackfriars-road, S.E. 2. For burnishing, see p. 171, Vol. XXX.; p. 169, Vol. XXXV.; and many other places in back volumes. For many hints on nickel-plating, see p. 489, Vol. XXXIV.)—T. J. Milner. (The only difference is that it is done a little easier when the loose leg is rested on a table. Try it, taking hold of the handle, but mind which leg you rest on the table. No magnetism is required. If you had devoted five minutes to trying the experiment, we should think you would have found it out. As many seconds would suffice for most people.)—Jno. H. Milne. (About equal parts, from the size of a pea or less; but the fine dust must be sifted out. You should learn the principles. A number of small cells coupled in series will give the E.M.F. of one multiplied by the number; but the internal resistance will be greater than with one large cell. The E.M.F. of a cell properly made and charged is about 1·5 volt.; but the battery is suited only for intermittent work, such as bell ringing. 2. We cannot possibly determine which articles you refer to; but you will find a list of back numbers often asked for at the top of this column the first number in each month.)—J. D. M. (How could the brake mentioned have as many "failures," when it is used only as an "emergency," and must be tried before it can be found to be out of order? The nature of these "failures" has been explained before, and all railway men are quite conversant with them.)—Anti-putty. (The simplest method is to hold the pieces down by driving in a few brads; but the best plan is to screw fillets on the bars or to use rolled strips of zinc.)—H. J. C. (Something depends on what you mean by "engineering"; but, at any rate, the only way to obtain employment is to seek of those who have the power to give it.)—H. B. (Is not a description given in their catalogue? We do not know the engine by that name.)—Schiox. (You want a gas burner taking its supply from the room and discharging into the air. This burner is made to heat a pipe by which fresh air is led into the room. If you can get a supply of warm air from any other source that would be better still. You will find several ideas in back numbers.)—J. G. B. (If he stood on an insulated surface and you did not, would that explain it?)—E. T. Brydges. (We have already done so in back volumes. The machine named is the best; but you will find some accounts of their economy in recent numbers.)—Darkness. (It is used for the purposes named, and also for steel and iron making. If you advertised that you had quantities for sale, you would, no doubt, soon find customers.)—Retlaw Repooh. (Several queries of the kind have been inserted, the general result being that no one had a good word to say for them. Surely you can obtain gas.)—T. T. (We believe you can obtain just the information you require from the Secretary of the Pharmaceutical Society, Bloomsbury-square, W.C.)—Electron. (The question has been answered frequently. You must use the cells all of one size and of one kind.)—T. J. O'C. (Certainly, and in any textbook; also in our columns over and over again. 2. As to the telephone, several plans have been described; a battery at each end is best.)—J. S. Saddler. (You have nothing to do but to make them of the size you think suitable. A copper jar and a zinc split cylinder, plate, or preferably a rod.)—W. W. W. (Any textbook. Won't the present series of articles suit you.)—Produco. (In many works on mechanics, or briefly in such books as Molesworth's "Engineers' Pocket Book." The data are from actual trials.)—M. B. (*The Miller*," weekly, 69, Mark-lane, E.C.)—J. M. B. (Yes, we believe so; but do not know cost, if any. The workshops would have to be inspected. You should apply direct to the Home Office, Whitehall, S.W. Extra rates are charged; but not very high, and it is compulsory to state real nature of the goods.)—Engine. (Best thing is to fill up with fresh filtered water before starting on each trip. If the boilers lie unused for any length of time, fill them quite full and keep them so. A little salt scale will not do much harm. Common washing soda is the only chemical you need.)—School Boy. (To large firm certainly, with a mixed practice. Premium a matter of arrangement.—W. Seagrave, jun. (The English Mechanic is published here at two o'clock every Thursday, and it is the fault of your local bookseller, or his London agent, if he is not able to sell it to you on the following day.)—Novice. (It is not true.)—T. Lisle. (We do not pay for such contributions. Look earlier than the volume you mention, and we think you will find violin construction has had its share of space and attention.)—Shock. (1. Yes. 2. A matter of choice. 3. Yes; b you ought not to catch cold; in very cold weather t sponge bath instead.)

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade, to write to the Editor if he has any suggestions to make, and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty-four Words, and Sixpence for every Eight Words after.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN

	s.	d.
Sixteen words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid, no reduction is made on repeated insertions, and in cases where the amount sent exceeds One Shilling, the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however, preferably halfpenny stamps, may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements must reach the office by 4 p.m. on Wednesday to insure insertion in the following Friday's number.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 13s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 15s. or 3 dols. 60c. gold; to France or Belgium, 15s. or 16f. 5c.; to India via Brindisi, 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 15s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 6d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 6d. each copy, to cover extra postage.

Vols. XXIV., XXVII., XXVIII., XXX., XXXI., XXXII., XXXIII., XXXIV., XXXV., XXXVI., and XXXVII., bound in cloth, 7s. each. Post-free 7s. 6d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post-free from the office, except index numbers, which are 3d. each, or post-free 3½d.

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each, Post-free 2½d. each. Indexes to Vol. XI. and subsequent vols. 3d. each, or post-free 3½d. Cases for binding, 1s. 6d. each.

Epps's Cocoa.—GRATEFUL AND COMFORTING.—"By a thorough knowledge of the natural laws which govern the operations of digestion and nutrition, and by a careful application of the fine properties of well-selected Cocoa, Mr. Epps has provided our breakfast tables with a delicately flavoured beverage which may save us many heavy doctors' bills. It is by the judicious use of such articles of diet that a constitution may be gradually built up until strong enough to resist every tendency to disease. Hundreds of subtle maladies are floating around us ready to attack wherever there is a weak point. We may escape many a fatal shaft by keeping ourselves well fortified with pure blood and a properly nourished frame."—Civil Service Gazette.—Made simply with boiling water or milk. Sold only in packets labelled—"JAMES EPPS and Co., Homœopathic Chemists, London."—Also makers of Epps's Chocolate Essence.

Holloway's Ointment and Pills are remedies [illegible] the treatment is easily applied, certain in its effects, and perfectly [illegible]. For all [illegible] complaints, this Ointment rubbed [illegible] over the [illegible] night and morning gives ease and [illegible] asthma, &c.

◆

Wanted, **Euphonium**, in good order, exchange [illegible]

"**English Mechanic**," from September 1st, 18[illegible] [illegible]

Wanted, all kinds of useful **Apparatus**, in exchange [illegible]

Net Hammock, watchmaker's tools, materials, watch cases, [illegible] silver watch for camera [illegible] London.

Kent's Patent **Roller Skates**, [illegible] almost new, 10s. [illegible]

What offers in exchange for [illegible] numbers of "**Imperial** Journal [illegible]

Handkerchiefs – Two dozen very fine pure linen cambric [illegible] exchange anything [illegible] Belfast.

Lockstich **Sewing Machine**, quite new, value £5, in exchange for a 3-quarter-horse Boiler or Engine. Advertiser is willing to give a small amount in cash, and 3 years' numbers of ENGLISH MECHANIC.—Address, S., *Chronicle* Office, St. Neots.

Will give Silver Lever **Watch**, for magic lantern and a few slides, out of repair no objection if mendable.—TANNER, North Parade, Horsham.

Exchange pair of **Bell Telephones** and **Electro**-TYPING APPARATUS, complete, for 2½ or 3in. centre lathe or fretsaw machine, with lathe combined.—S. CARTER, 12, Park-street, Stafford.

Bell Fittings, good assortment, sent in by mistake; 50s. worth. Exchange fret machine or treadle grindstone.—11, Minster-street, Reading.

Nearly complete, "**English Mechanic**": what offers? Unbound; want good fret saw.—W. SAWDON, Bridge-street, Whitby.

Wanted, **Slide-Rest**, for 4in. centre lathe, in exchange for five moulds for casting, in plaster or composition, classic busts, 13in., 11in., 7in. high.—J. B., 12, Bessborough-street, Pimlico, S.W.

Engine Castings, one set, partly finished, cylinder 1in. by 2in., with turned flywheel; offers exchange.—S., 20, Blurton-road, Lower Clapton, London, E.

Two turned **Flywheels**, 5 inches, 6½oz. each; four turned Standards, 1¼oz. each; one grooved wheel, 3½in. been Saturday, Wednesday.—As above.

A **Model Force Pump**, in working order, will exchange for electric bell.—Particulars of S. LAMPARD, High-street, Merton.

Have various useful **Exchange** to offer, for a lathe-head, single gear, about 3in. centre; also short heavy lathe bed wanted.—ALFRED CROFTS, Dover.

For exchange, about 50 **Photo. Lantern Slides**, 3¼ size; will exchange for others.—Address, W. FINLAY, 135, Renfrew-street, Glasgow.

American **Orguinette**, with lot of music, cost £3; want emery grinders or vertical drilling machine.—CHILDS, Blandford.

Hancock's Patent **Potato Washer**, equal to new; exchange for small lathe or a good telescope.—CHILDS, Blandford.

Wanted, good **Fret-Cutting Machine**, with [illegible] lathe bed; exchange scientific books.—CHILDS, Blandford.

Pulvermacher **Chain Band** and **Battery**, complete, in case, and in good order; what offers in exchange?—J. FORBES, 6, East London-street, Edinburgh.

Magic Lantern with Slides, and box of conjuring tricks, nearly new. Will exchange anything useful.—A. SUGAR, Lockwood.

Half H.-P. Horizontal **Engine**, in exchange for a good set of Whitworth Taps, from ¼, 5-16, to ⅝ and cash.—C. L. GRAVES, 58, High Cross-street, Leicester.

Stock and Dies, for ¼, ⅜, and ½in. brass tube, scarcely used; for exchange.—GEO. WARD, Amersham, Bucks.

Wanted, 52in. **Bicycle**, at once, roller bearings preferred, in exchange for first-class Silver English Lever, cost 7 guineas, good as new.—T. MALONEY, Tadcaster, York.

Powerful **Medical Coil**, with regulator, two three-pint cells, in handsome case, switch, electro-magnet and lamp. Offers.—A. W. N., 28, Eyre-street, Chesterfield.

Quarter-plate Landscape **Lens**; Solomon's magnesium lamp, opera glass, Sciopticon, 20 dozen gelatine plates. What offers in exchange?—L. DIXON, Hale-street, Colne.

"**Chemistry, as Applied to the Arts**," eight volumes Mackenzie, and "Popular Educator," four volumes Chambers. What offers?—T. M. SMITH, Kirkbean, Dumfries.

Will exchange, **Microphone**, three self-lighting gas burners, photographic disc, Jamieson and Bridge's "Algebra," Ferguson's "Astronomy," Woodhouse's "Astronomy." Wanted, Globes, Field Glass, or offers.—CHAPMAN, Stocksbridge, Sheffield.

"**Tyndall's Electricity Notes**," "Angell's Physiology," "Buckmaster's Advanced Chemistry," "Gardiner's Acoustics," "Hunter's Book-keeping," questions. Exchange "Thorpe's Chemistry," or offers; cost 7s. 6d.—FARNDALE, Loftus, Cleveland.

Wanted, a **Rob-Roy**, or other good make of canoe, for cash and part exchange—lathes, engines, and boilers.—J. DAVIS, London-road, Derby.

Wanted, small **Launch Engine and Boiler**, for cash and part exchange—lathes, &c.—J. DAVIS, London-road, Derby.

¼-Horse **Engine** and **Boiler**, complete; exchange wanted in canoe, launch machinery, small lathe, &c.—J. DAVIS, London-road, Derby.

Splendid **Model Engine and Boiler**, ⅝ bore, brass tubular boiler, all fittings complete, highly finished; exchange.—J. DAVIS, London-road, Derby.

A first-class new **Lathe**, by Mills, Sunderland, 3in. centres, gap-bed, back-gear, slide-rest, 4-speed turned flywheel, iron standards, treadle, tool board; part exchange.—J. DAVIS, London-road, Derby.

Good Treadle **Lathe**, new, 3ft. bed, 4in. centres, flywheel, crank, treadle, pine framework, nicely painted; exchange in small engine or boiler.—J. DAVIS, London-road, Derby.

Six-inch **Slide-Rest**, quite new, too large for owner's lathe; good exchange.—A. TIDMAN, 116, High-street, Southampton.

Electrical Machine, large, powerful, size of cylinder 12in. by 9in., brass conductor, on mahogany stand, cost six guineas; what offers?—HALL, 285, Liverpool-road, London.

Wanted to exchange, **Mortising Machine**, door clamp and floor cramps, for small engine and boiler, to work a [illegible] pump.—V[illegible], Chalk-lane, Hull.

Quantity of **Chemicals** and Chemical Apparatus; will exchange for joiner's tools or anything useful; list sent.—A. M[illegible], Morton, near Bingley, Yorkshire.

What offers for Ramsbottom's Patent **Three**-[illegible] RAM ENGINE, 2¼in. bore, 5in. stroke, in good working order.—WILSON, 15, Gilsland-street, Sunderland.

Wanted, **Lathe** or **Lathe-Heads**, 4in. or 5in. centres, in exchange for valuable series, engravings of Hogarth's works, with letterpress descriptions.—OAKWOOD, Church Stretton.

One-horse power horizontal **Engine**, first class condition; wanted, small dynamo, &c., tools, or offers.—W. C. [illegible], Ramsay-street, Rochdale.

"**Cassell's Family Physician**," 1882, 33 parts, clean and perfect, unbound, cost 16s. What offers?—W. SAUNDERS, [illegible], Dickleborough, Norfolk.

52in. **Bicycle**, new this season, cost £8 10s., cranked handle bar, roller bearings, cones to back; exchange 3in. or 3½in. [illegible] chuck, or pair of 3in. good headstocks back geared, or small back geared lathe with slide-rest, or 3in. inverted [illegible] reverse motion.—T. B[illegible], 20, Lancaster-road, Preston.

Will exchange **Electric Railway**, 5ft. circular line, motor, three carriages to imitate the Egyptian ironclad train, and battery, all complete, quite new. Wanted astronomical rack work slides, no less than 3in. or 3in., or what offers.—HARRIS, 21, Crossburn-street, Glasgow.

Motor Castings, materials for Electric Bells, Batteries, Galvanometers, Intensity Coils, Microphones, Terminals.—KING and Co., Bristol.

Insulated Wire **Table**, showing size, weight, resistance per foot, feet per ohm. Price 3d.—KING and Co.

Wimshurst Parts.—Two 12 inch **Glass Plates**, 1¼ inch hole, 3s. 6d.; fitted complete ready for mounting, 16s.—KING and Co., Bristol.

Wimshurst **Influence Machine**; complete; with two Leyden jars, £3 10s., 4½in. spark.—Makers, KING and Co., Bristol.

Wimshurst **Influence Machine**, sole manufacturers, high-class workmanship; numerous testimonials as to thorough efficiency.—KING and Co., Bristol.

Green, Tool Merchant.—Agent for Booth's Mitre Cutting Machines.—11, Sutherland-terrace, Pimlico. Illustrated Catalogues.

Fretwork.—Illustrated Catalogues of every requisite, and 300 miniature designs, four stamps.—HARGER BROS., Settle, Yorks.

Violins.—Bavarian Violins, half usual price, bright, clear tone, 9s. 6d., and 15s. each. Post free, on approval.—F. PAXTON, Importer, 127, Essex-road, London.

Soda Water Machine, No. 0, by Mondollot, Paris, second hand, £15. Bargain, excellent condition.—Particulars N. G. WILCOCKS, Bath.

Soda Water Machine, American principle, by Davenport, London, complete, £25, 600 dozen daily.—Particulars N. G. WILCOCKS, Bath.

Electric Bell, new Danish pattern, works freely with one cell, 3s. 6d.; free by post, 3d. extra.

The above complete with **Battery, Push, and 25 yards** of Wire, 9s. 6d.—LEWIS and SON, 1A, Lowndes-terrace, Knightsbridge, S.W.

Transit Instrument, for obtaining accurate time, £9 17s. 6d.—A. J. FROST, 6, Westminster Chambers, London.

Boxwood in Log or Waste.—Apply J. and A. WILKINSON, St. Oswald-street, Rochdale-road, Manchester.

Watches and Clocks repaired and cleaned by skilful workmen, work by post punctually attended to. Trade list free.—CHARLES TYLER, 10, Jerusalem-passage, Clerkenwell.

Every man his own **Picture-Frame Maker.**—GREEN, Agent for Booth's Mitre Machines and Instantaneous Grip Vice.—11, Sutherland-terrace, Pimlico.

Music.—20s.-worth of best sheet music, songs, dances, pieces, &c., for 1s., post free, 1s. 2d. Money returned if not satisfactory.—WILLIAM LEA, Church-street, Liverpool.

Birmingham Goods. — Jewellery, Watches, Clocks, Harmoniums, Tobacconists goods. Agents wanted. Wholesale illustrated catalogue, post-free.—Address, HENRY MAY, Birmingham.

Electrical Depot and Manufactory.—Handiest shop in the trade for amateurs.—MILLAR's, 136, Chapel-street, Salford.

Tools.—Best guide to purchasers, send three stamps for our fourth edition Reduced Illustrated Catalogue.—LUNT's.

Supplement Catalogue, twenty-four pages, illustrated speciality of tools, one stamp. Unsolicited testimonials giving all satisfaction.—LUNT's.

Parallel **Bench Vice**, steel jaws, 2¼, to open 3½, weight 5½lb., only 10s. 6d. each.—LUNT's.

Planes.—Malleable iron gunmetal castings, ready for inside fittings. Instantaneous grip vices, only 14s. each.—LUNT's.

Lunt's is the best and cheapest house for Tools.—A. S. LUNT, Tool Maker, 97, Hackney road, E.

Microscopic.—Adhesive Labels for Slides, 26 kinds, samples stamp.—CHAS. J. WATKINS, King's Mill, Painswick, Gloucestershire.

Fretwork Patterns (full size) of every description free for selection, state wants.—MECHANIC, 2, Northbrook-street, Birmingham.

Fret Saws, 2s. 2d. per gross, 1s. 1d. half gross, post free.—J. LE RICHE, Coventry.

Cork-cutting **Machine** on the most improved principle. All kinds of engineering for the cork trade. Old corks re-rounded and made equal to new.—Address, JOHN LOWMAN, 18, Albany-road, Camberwell, S.E.

Gas Engines, small power, used in all trades, simplest made.—Sole Manufacturer, W. HUTCHINSON, Liversedge, Yorkshire.

Cast Steel.—Practical process of welding, tempering tools, springs. Manual, 12 stamps.—J. F. BREMNER, Caparstane-row, Aberdeen.

Carpentry Classes for amateurs now open; prospectus, 1 stamp.—T. SYER, 1, Finsbury-street, London, E.C.

Magnificent collection of Foreign **Stamps**, 2,100, all different, value by "Gibbons" over £32. What offers? No cards.—C. A. P., 23, Duncan-terrace, Islington, N.

Turned wrought-iron **Pulleys**, not polished on a grindstone like those generally sold. Cheap, strong, true.—J. BAGSHAW and SONS, Batley.

Friction Pulleys dispense with fast and loose pulleys—one answers for both. Invaluable for ropes and belts. Illustrated circular free.—BAGSHAW and SONS, Batley.

Wheels, dog cart, van, omnibus, cab, all kind and sizes, new.—10, Pitlake Bridge, Croydon.

Life of Luther.—36 Lantern Photographs and lecture, sale or hire.—Apply, PUMPHREY, Stanhope-street, Birmingham.

Shorthand. Eclecography, best and easiest to learn. "Manual," one shilling, post free.—REDFERN, Newtown-street, Leicester.

Ventriloqual and Marrionette **Figures**, either in parts or complete figures. List one stamp.—E. LE MAIR, 8, Coupland-street, Manchester.

Glazier's **Diamond**, Sharett and Newth's, cash 13s. 6d., bargain, cut 32oz. glass.—A. TOWNSEND, High Town, Hereford.

Sike's **Hydrometer**, complete, with ten weights and ivory thermometer in mahogany box, trial glass, and book of instructions, 25s.—A. TOWNSEND, Hereford.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, DECEMBER 7, 1883.

THE COST OF PRIMARY BATTERIES.

THE statements which have been recently made in the daily papers as to the effects produced by the use of primary batteries in lighting railway carriages have brought us many queries, not a few from persons who appear to imagine that the cost of lighting by that means is measured by the first cost of the battery and the lamps. Most schoolboys have nowadays learned the simple lesson that out of nothing, nothing comes; but judging by some of the paragraphs that we have seen in daily papers, it is perhaps excusable that not a few of our querists should imagine that something remarkably cheap has been discovered, and that they can have the electric light at a merely nominal cost. We have recently pointed out, not once merely, but several times, that an electric light obtained from any known battery is really expensive as compared with the same amount of illumination obtained from gas or other cheap source of light, and that there is no hope of reducing the expense until someone discovers a battery the decomposition of the elements of which will produce a substance or substances which shall be worth at least as much as the raw materials themselves. We have, from time to time, described cells or battery arrangements, patented and otherwise, the inventors of which thought they had made one step towards the desired goal; but at present, notwithstanding all the puffing, we are unacquainted with any battery which, all things considered, is cheaper than the well-known combination of zinc and carbon excited by dilute sulphuric acid and bichromate of potash or nitric acid. For bells, telephones, and telegraphs, electro-metallurgy and medical purposes, other arrangements are more suitable; but in the case of electric lighting and electro-motors, a constant and ample supply of energy to the full capacity of the battery is required, and at present we have not found a cheaper metal to oxidise or consume than zinc. This is an old tale. It must be quite forty years since Staite took out a patent in which the commercial value of the residual products was mentioned, and latterly we have had several inventors taking up the old idea, without, however, demonstrating by actual receipts that they obtained any return worth mentioning for the zinc and sulphuric acid expended. Probably if primary batteries came to be used on a very large scale indeed, a sufficient quantity of residual products might be obtained to find a ready sale; but it is extremely doubtful whether more than a fraction of the prime cost would be recouped, unless the battery can be induced to manufacture some unknown and really valuable substance whilst giving out current. In one of the new batteries, which is, we believe, working very well on several railways, lighting carriages with lamps of 5 to 10 candle-power, zinc and carbon form the two elements, and the battery is excited by a composition named "oxidone," the exact nature of which is kept secret until the patents are completed. The working cost of this battery is stated to be as low as one-eighth of a penny per hour for each 5-candle lamp, and a battery of 16 cells will supply 18 lamps, and can be charged for 40 hours—that is, the battery can be used for 10 hours on each of four days without needing to be recharged. Taking batteries as we know them in practice, such a result as that must be regarded as very good indeed; but if the cost has been arrived at by allowing for the sale of the residual products, it will at once be seen that the battery is not so cheap as a good steam-engine and dynamo, for when current is obtained by the oxidation of zinc the cost is about nine times greater than when a machine is used and the source of the energy is coal at about 20s. a ton. Mr. Sprague worked out this little sum for the benefit of all whom it concerns some years ago, and he found that taking the expense of the battery as only 4d. per pound of zinc the cost of a horse-power for 24 hours was 25s., whereas the same amount of energy could be obtained from a common steam-engine and coal at 20s. for 10·29d. Even if we suppose the residual products of any battery in which zinc is employed return 2d. for every pound consumed—and no one has supposed that possible amongst the most sanguine inventors—it will be seen that the common steam engine has still the advantage as a motive power. Electrical machines have been considerably improved since Joule calculated that 75lb. of zinc would be necessary for one to maintain a horse-power for twenty-four hours; but so have steam-engines, and therefore we are brought back to the simple datum that the oxidation of zinc can produce so much and no more energy, and that unless some one can be found to pay a high price for sulphate of zinc, there is no chance of any of the well-known cells in which it is consumed becoming a cheap source of electric light. It seems abundantly clear, from a number of experiments, that the most that can be expected from the best steam-engines and dynamos is 200 candles of incandescent lighting per horse-power; and as it is also tolerably apparent that two pounds of zinc are necessary to obtain the same quantity of energy, we have sixpence as compared with a farthing as the relative cost of the two sources of energy for electric lighting. It is not impossible that these figures are too favourable to the battery, for Mr. Sprague says that the cost of an equivolt of energy, by a common steam-engine, is only ·00112 of a penny, while by a Daniell's battery it is ·0541. There is this to be said, however, that even if the cost of working a 20-candle lamp is as much as one halfpenny per hour, there are many persons who would prefer it to gas or any other illuminant; and if the new batteries can be made to produce a really useful substance as a residual, the trouble and attention they may entail will not stand in the way of their adoption. So far as we know, a 20-candle light cannot be maintained at a cost of one halfpenny per hour, even when the zinc and the acid can be purchased in quantities at the lowest price; but if a battery is in existence which will yield such results, it is a pity those who own it do not make it known, for it is certain they would have a very wide sale provided they could guarantee its performance. At the price named it would be too costly for lighting on the large scale; but there are very many persons who would go to the expense of fitting up the battery and the lamp, if they could have a light of twenty candles at a cost of a halfpenny an hour. Possibly before long someone may invent an iron or a lead battery, and then those who are so anxious to have the electric light, will probably have an opportunity of gratifying their desires; as, indeed, they may now, if only they are prepared to pay for them. But so long as zinc is used there is small chance of primary batteries supplanting dynamos and steam-engines.

REVIEWS.

Flowers and their Pedigrees. By GRANT ALLEN. London: Longmans.

THIS work is a collection of the author's always readable and invariably interesting essays contributed to several magazines—this time on botanical subjects, and we have no doubt that those who read them in their more ephemeral dress, will be glad to have them in the handsome form in which the publishers have offered them to the reading world. The keynote of Mr. Allen's essays may be seen in the following sentences, in which he says: "We can now answer confidently: Such and such a plant is what it is in virtue of such and such ancestral conditions, and it has been altered thus and thus by these and those variations in habit or environment. Every plant or animal, therefore, becomes for us a puzzle to be explained, a problem to be solved, a hieroglyphic inscription to be carefully deciphered." Each English plant has not only a general history as a species, but it has also a separate history as a member of the flora of these islands; and the author accordingly explains first how it came to exist at all, and then why it exists in this country. The essays are eight in number, and commence with the pedigree of that lowly flower the daisy; then the author treats us to a short historical retrospect, and describes what he sees from Claverton Down, where he has found a wayside weed known as the hairy woodspurge, one of the few genuine links which unite us with a far distant past—a relic of the flora which once bloomed among the lowlands that connected England and Ireland with Europe. The hairy spurge is a Southern European and Western Asiatic plant, which nowhere comes any nearer to Britain than the Valley of the Loire. An easy explanation of its appearance on Claverton Down can be found in the supposition that the seed was brought from the Mediterranean, and, finding a suitable climate, the plants grew and flourished; but that explanation is much too easy for our author, who sees that the hairy spurge is one of the few relics of a flora which is being steadily driven out of Britain because the conditions are ceasing to be suitable for their existence. Thus in the "Romance of a Wayside Weed," Mr. Grant Allen contrives to talk about the Glacial period, and of the time when the British Isles formed the north-western coast of Europe; and that the reader may better grasp the lesson he wishes to teach, he provides him with a sketch-map of Post-Glacial Britain. The hairy woodspurge still lingers on Claverton Downs because that is one of the warmest spots in England, just as the Cheddar Pink grows in a single basking hollow heated by great walls of limestone upon the western flank of Mendip; just as the purple lobelia loiters in the warm valley of the Devonshire Axe, and the white sedum struggles on upon the edge of Malvern. The third essay is a comparison of the wild strawberry and the white potentilla, two sister plants of the hedgerows almost exactly alike except in that, to us, essential particular that the latter does not bear fruit. Cleavers form the subject of the fourth paper, in which the author hopes that his readers will think more tenderly and respectfully than formerly of an ancient and highly-developed English weed. In the fifth paper Mr. Grant Allen takes up the question of the origin of wheat, and startles the reader at the outset by the assertion that it is a degenerate and degraded lily—a text which enables the author to write one of his most interesting botanical essays. "A Mountain Tulip," a "Family History" (the roses), and the "Cuckoo-pint" conclude a volume which can be taken up at any odd moment, and will never fail to interest and instruct.

Energy in Nature. By W. LANT CARPENTER, B.A., B.Sc. London, Paris, and New York: Cassell and Co.

A COURSE of six "Gilchrist Lectures," on the forces of Nature and their mutual relations, was delivered by Mr. Lant Carpenter in the autum of 1881, and with some addi-

[illegible] they are here gathered into a book which has the recommendation of being printed in large clear type illustrated with many useful engravings. The subjects are treated in a popular manner, and as far as possible with an avoidance of technical terms which when necessary are carefully defined. Mr. Carpenter has made an attempt to lay down clearly the distinction between "force" and "energy." The latter he defines as power of doing work, and force may be defined as any cause which alters or tends to alter a body's natural state of rest, or of uniform motion in a straight line. The author proceeds to explain, but whether in a popular work that is altogether advisable may be doubted, for the majority of those for whom this book must be intended would have been contented with the simplest explanation, especially if accompanied by an illustration, and would probably have gained a better notion of the difference than from a whole page of definitions. It is more important in a work of the kind to take care that statements made are as nearly correct as possible, and the author will scarcely contend that the conductivity of copper for electricity is only 73 (silver being 100), or of gold only 59. In a work intended for popular reading it is doubtful whether it is wise to talk of the two electricities rushing together when wires from a copper and zinc couple are joined; but that, perhaps, is a small blemish in a book which forms an excellent present for an intelligent boy, and might be used with great advantage in schools as a reading lesson.

The Smithsonian Report, 1881. Washington: The Government Printing Office.

THE annual report of the board of directors of the Smithsonian Institution for 1881 is a portly volume of over 800 pages, about one-fourth of which are occupied by papers and reports relating to the business of the Institution, and the remainder by a record of recent scientific progress and a number of essays, chiefly relating to anthropological subjects. The system adopted by the board of directors in compiling their annual reports renders them of exceptional value to scientific libraries, and the gratuitous distribution of the volume to all societies in whose charge they are likely to be of value to students, is a feature to be commended as worthy of imitation by other institutions. The record of scientific progress is not so well done as it might be, for, in too many instances the records are simply bald statements that so-and-so has done this or that. The references are given, it is true, but as the periodicals mentioned often give no more information than is supplied by the Smithsonian "records," the student must still hunt up the originals if he wishes for fuller information. It would be better to select the really important items of progress and give more details, as Prof. Holden does in his report on astronomy. The miscellaneous papers on anthropology describe many interesting "finds" in the more settled parts of the United States, and serve to indicate what a rich field awaits the labours of the archæologist and the anthropologist of the future.

The Constellations and How to Find Them. By Wm. Peck. Edinburgh: Archibald and Peck.

This is a neatly printed and very clear guide to a knowledge of the starry heavens, [illegible] twelve maps showing the positions of the constellations in the sky during each month of the year, and in addition two [illegible] the stars near the North Pole which are always visible, and the [illegible] near the South Pole which [illegible] visible in Britain. An introduction [illegible] explanation render everything [illegible] to the novice, while separate editions of the maps will be found useful by the observer as he studies the stars from month to month. A list of the Arabic names corresponding to the Greek indicating letters, and tables of dates and hours at which the maps represent the appearance of the heavens, make the work as complete as can be desired by the amateur.

We have also received *Lantern Readings of Travels in the Eastern Island World, China, Loochoo, and Japan*, by F. W. SUTTON, R.N. (W. F. Stanley), consisting of short but pithy descriptions of a number of lantern photographs of scenes in the East. There are altogether eight readings descriptive of 421 lantern photographs taken by the author, including many subjects of interest to be observed during a voyage from Plymouth to China and amidst the Eastern Archipelago. Judging from the descriptive matter, these Lantern Exhibitions will be found a very attractive and interesting entertainment.——*Workshop Appliances*, by C. P. B. SHELLEY (Longmans), is the sixth edition of a well-known textbook, which has been revised and enlarged, and at the same time condensed to make room for new matter, chief of which is a supplementary chapter on steel. The book is freely illustrated with engravings, several of which represent very important modern workshop appliances.——*The Practical Boiler-maker, Iron Shipbuilder, and Mast-maker*, by R. KNIGHT (Wyman and Sons) is the third edition of a handbook which will be found useful by those to whom it is addressed. It is illustrated by 112 lithographed figures.——*The Artists' Table of Pigments*, by H. C. STANDAGE (Wells, Gardner, Darton, and Co.) is a useful work giving the composition, conditions of permanency, non-permanency, and adulterations, effects in combination, and reliable tests for purity of the known pigments. The size adopted may have been necessary for the tabular arrangement, but is very awkward.——*Designing Wrought and Cast Iron Structures*, by HENRY ADAMS, Professor of Engineering at the City of London College, (60, Queen Victoria-street, E.C.), is an endeavour to present the subject to the student in such a manner that he can grasp its principles, and at the same time the details which are usually known only to experienced practical draughtsmen. Part 1 contains notes, calculations, and working drawings for wrought and cast-iron girders of 20ft. span.——*The Patents, Designs, and Trades Marks Act*, 1883, by JAMES JOHNSON and J. HENRY JOHNSON (Longmans), is a reprint of the new Act, with notes on points of interest, by the authors.——*One Hundred Chess Problems*, by Rev. A. CYRIL PEARSON, M.A. (Civil Service Printing and Publishing Co.), is the third edition of a book of problems which has been already favourably received by all lovers of chess.

OBJECT-GLASS WORKING.—IX.

By "PRISMATIQUE."

OUR lenses are now ready for smoothing, and as this process is the same for all classes of work, and has been so frequently described in the pages of the ENGLISH MECHANIC, I will not here repeat the instructions, or the process of emery "elutriation," but refer the reader to letter 22,022, page 219, Vol. XXXVIII., and preceding volumes there referred to. The plan adopted by Mr. Wassell will commend itself at once. The purpose of smoothing is to produce a surface as fine in grain as possible, also as nearly spherical as possible; if any removal from the spheric shape is made, it must be done in the final polishing or figuring. It must not be supposed, however, that absolute spheric curves are got in the smoothing process: there is invariably a depressed zone, certainly of extreme minuteness as to depth, but still effective in spoiling the work of the o.g. if followed up. Fig. 11 is an exaggerated illustration of this condition. It will be seen that to bring about an approach to spheric curvature, either the centre and edge must be polished down, or the centre polished down and gradually worked out to the edge, or the edge polished off and gradually worked up to the centre. It will thus be seen that there is no arbitrary rule; still I am sure that the method of working off the centre is the least likely to produce rounding off or marginal error, and is the safest for the amateur of limited experience. We will suppose, then, that our lenses are smoothed as well as we can do them. We must look that the pitch is in perfect adhesion at the back: this will easily be seen, as the polished surfaces of the pitch will reflect more light where the air has got in. If there is any appearance of this "starting" as it is called, the lens must be warmed on by being placed in the tool it fits, if possible, and all warmed together, or on a thick iron plate. It is well to give it one or two wets of the finest emery before beginning to polish, if this proceeding has been found necessary. There are few methods of polishing that give so good results in a simple manner as dry polishing on paper: this method may be used in the present case, either with the polisher stationary, or on the vertical "mill" described in these papers. In the first method a strip of paper, the thinnest used for negative photo. printing, is laid across the centre of the tool, and the starch used pushed out at the edges, as described in my papers on "*Glass Specula Working.*" As the thickness of paper makes a great difference in the "take," it is not possible to give exact dimensions, two-thirds the diameter for the convex, and four-fifths for the concave surfaces, is generally about the mark. This can generally be decided by giving the lens four or five minutes' polishing with straight rubs, and at least two complete turns round its axis. The paper strips may extend to the edges of the tool to begin with, and, if the take comes on at the edge instead of the middle, the polisher may be shortened by cutting off ½in. at either end until a decided take in the centre is shown, or the stroke may be changed to a narrow ellipse, which will frequently answer the same purpose. By taking note of this, the operator will see the possibility of making use of these effects in the final figuring of the surfaces, for by altering the width, length, stroke, or size of the cork back sufficient variation may be obtained to produce elliptic curves, if such are seen to be needed. The material best fitted for polishing with is "Tripoli de Venise;" rouge may be used, but is troublesome unless the paper is first treated with "Tripoli." For polishing on the "mill" the method is slightly different; the paper used for this purpose should be Swedish filtering paper. This is a very thin paper much like blotting paper. The whole surface of the tool that has smoothed the glass is covered with this paper, which must be cut into three, four, or more pieces, so that it will fall into the curve without folds or ridges. There cannot be any pushing out of the starch with this; but the bruiser may be used with gentle pressure to remove air. If the tool is a little warmed, and the paper starched with a brush, it will be drawn down to the tool and will not need any pressure at all.

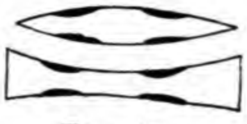

Fig. 11.

(*To be continued.*)

THE DYNAMO: HOW MADE AND HOW USED.—IX.*

By SELIMO R. BOTTONE.

§ 20. THE pattern for the *legs* of the electro-magnet (*field magnets, exciting magnets*) will next require our care. Since the two legs are exact counterparts, the one of the other, so we need only make one pattern, from which, however, *two* castings must be obtained. Fig. 15 illustrates the form and dimensions of this pattern on a scale of about one-quarter the real size. The dimensions are marked in inches.

---

* All rights reserved.

A represents the outside view, *i.e.*, as seen from the side which is farthest from the armature; B gives the view from the inside (close to which the armature rotates).

To make this pattern, procure a piece of pine 6in. in length, 4in. in width, and ½in. thick, planed smooth, and free from knots and roughness. Glue and dowel along the bottom edge a strip 1⅛in. wide, 4in. long, and ¼in. thick, as shown at Fig. 16*a*. Now, with a sharp plane,

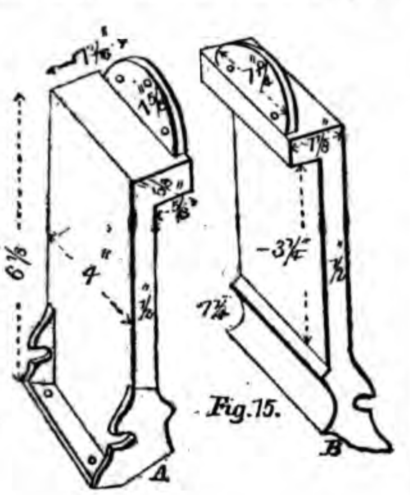

Fig. 15.

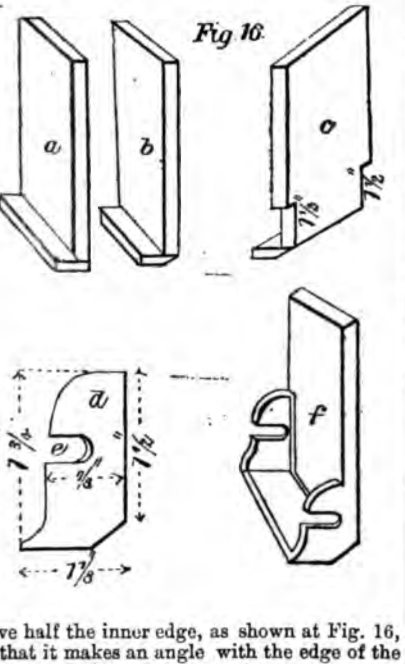

Fig. 16.

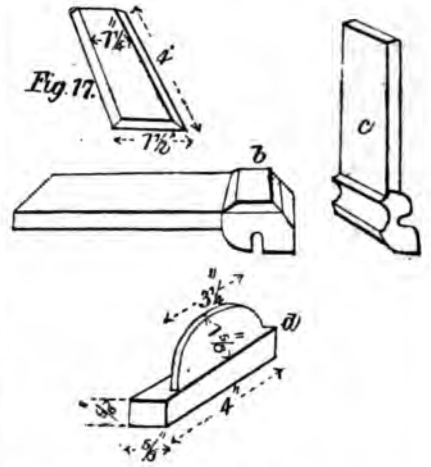
remove half the inner edge, as shown at Fig. 16, *b*, so that it makes an angle with the edge of the 6in. piece. With a fine saw cut a recess on each side of the jointed piece 1½in. long by 4in. deep, as shown at *c*, and glue and dowel in each recess the two flanges, made of ¼in stuff, of the shape and dimensions given at *d*. To insure the slot *e* being exactly at the same point in each flange, the two flanges, after being roughly shaped with a fretsaw, or otherwise, should be clamped together, and the finishing touches given with a rat-tail file, for the slot *e*, and with sandpaper along the rounded edges. Care must be taken that these flanges should be a trifle thinner near the edge marked 1¾ than on the opposite edge, to insure the pattern coming out clean from the mould. For this reason the slot *e* must not be narrower at the outside than at the inside, but rather the contrary. The slot *e* must be ¼in. wide, and must reach in depth to the 6in. piece, to which the flanges are attached. At this point our pattern will present somewhat the appearance shown at *f*. A piece of wood 4in. long by 1½in. wide, and ¼in. thick, perfectly smooth, square, and free from knots, must now be chosen, and the two sides planed away, on the upper side to such an extent as to make an angle of 60° with the base (see Fig. 17, *a*). With some good thin, hot glue (not Prout's), this piece is to be glued along the bottom edge of the 6in. piece, on the side opposite the flanges, and in such a manner that the slope of the base is continued by the *slope of the piece, as shown at* Fig. 17, *b*. When the glue is quite dry, by means of an inch gouge, cautiously hollow out along the entire length of this piece, in a semicircular form, nearly to the depth of the original 6in. piece, so as to fit accurately the pattern of the armature, which has already been made. (§ 19.) When this is as true and smooth as it can be made with the gouge, fold a piece of fine glasspaper over the pattern of the armature, rough side outwards, lay the armature in the channel, and work it backward and forward until perfect smoothness and a perfect fit are insured. The pattern should now present the appearance given at Fig. 17 *c*. When this end has been attained, four small dowels should be inserted



into the thicker portions of this semicircular piece, to hold it firmly down to the 6in. piece. We now need only make the top flange, by which the bracket or standard that bears the wheel is clamped to the legs of the dynamo. This is made most easily in two pieces, one being squared up to 4in. long, ⅝in. thick by ⅝in. wide. The other piece is to be ⅝in. thick, and must be cut into a perfect semicircle, with a radius of 1½in. By means of Prout's glue and a couple of dowels, this is neatly attached to one side of the other square piece, as illustrated at Fig. 17, *d*, and then the whole is carefully and squarely glued and dowelled, in like manner, to the top of the 6in. piece, so that it now presents the appearance shown at A and B., Fig. 15. The holes shown in the bottom and top flanges may be bored, and core prints inserted, *if the founder will take the trouble to put them in his mould;* but, as a rule, founders do not care to cast small castings with holes in them, as they seldom come true, so that it will be, perhaps, as well to have them bored afterwards, which can be done at a cost not exceeding 2d. a hole. This pattern must now be carefully smoothed, the sharp edges rounded, to insure parting from the mould, and finally paraffined and polished, as recommended for the armature, § 19, when it will be ready for the moulder.

PRACTICAL NOTES ON PLUMBING.—LXXXVI.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from page* 260.)

Roof Work.

We will first commence our work by laying a few gutters, which will be a familiar kind of work to most of you, and I hope that you will all endeavour to work strictly to the rules and diagrams which I am about to lay before you, so that one and all may be able to answer any questions which I may have occasion to put to you from time to time. I particularly ask you to follow the instructions here laid down, because I have worked in almost every conceivable manner, and, after taking everything into consideration, I am now of opinion that the following rules properly carried into practice will be found the best and most suitable.

Measuring for Lead Gutters.

This is a point in your work which will require your particular attention, for although it is a simple matter to measure a single gutter, it must not be lost sight of that it must be done correctly, for what is worse than a short gutter? And yet it is a very common thing to find men in large London shops! holding the position of foremen of plumbers who are *continually* in the habit of cutting the gutters too short or too long, very seldom the latter. These men do this kind of thing continually, and will often get the men to stretch the lead from 2in. to 5in. or 6in. in ten feet; that is, in order to make the lead come in instead of sweating, burning, or soldering a piece on. I speak of this, knowing full well that it is practised, not only in the small shops, but in the large ones, which is a disgrace not only to the men, but to the foreman and his employers. Therefore, I ask you to be at all times very particular in all your measurements, and if you practise to do your work regularly it will save you a great deal of trouble, and be the means of your work coming out at a fair and reasonable cost, which should be of great importance to the foreman plumber. Suppose the gutter which you are about to lay to be one similar to that

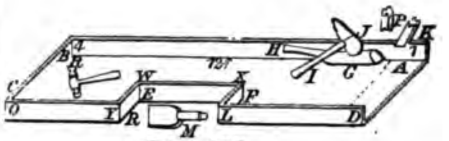


Fig 407.

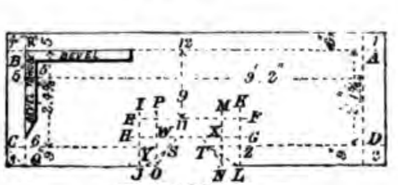

Fig. 408.

illustrated at diagram No. 407, which is an elevation, and let diagram No. 408 be a plan of the lead, and diagram No. 409 be the drip. Here

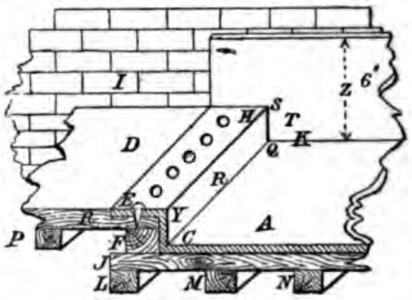

Fig. 409.

you have three views of what you will have to do. I shall now explain the method of taking the size and entering it in your pocket book.

First take the height of the turn-up against the wall. We will say that the specification states it to be "6in. all round brickwork (as at Z, Fig. 409) and 9in. under the slates," as at H E G, Fig. 409 A, and at springing, Fig. 411.

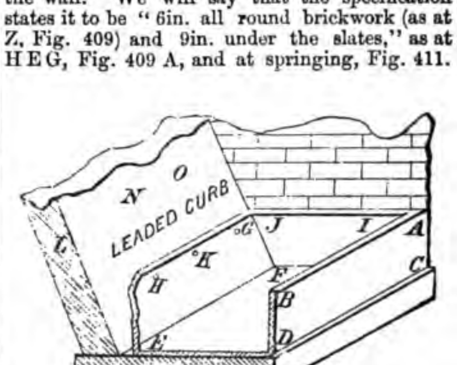

Fig. 409 A

But sometimes your lead may be only 5in. at the head, as at R, diagram No. 410; and if you have, say, 1½in. fall, then your lead may be 5in. at the head and 6in. at the drip. This will allow you to put in a straight length of flashing, and the gutter will be all the better. Therefore, we will say that the turn-up shall be 5in. at the head and 6in. at the drip. This being the case,

---

* From the *Building News*. All rights reserved.

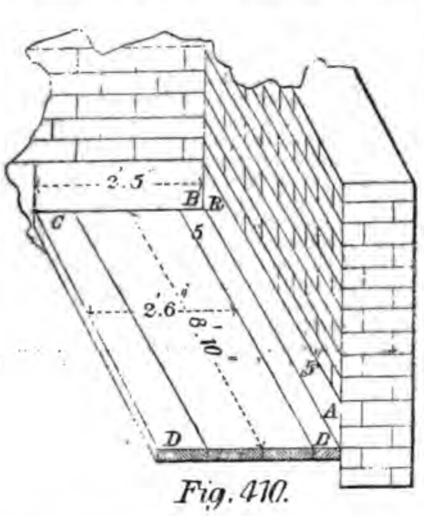

Fig. 410.

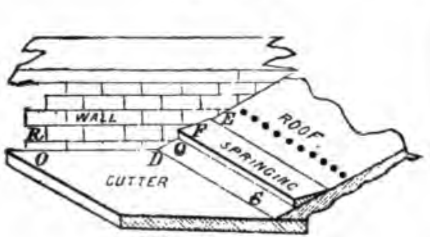

Fig. 411.

next measure the width of the gutter at the head; here say it is 2ft. 5in. Next measure it at the drip; here you will most likely find it to be considerably less, according to the pitch of the roof and the fall of the gutter; say that it is found to be only 2ft. 1½in.; next measure for the other turn-up, which may be to go up a slated roof with springing. If so, and the springing is nailed on, say, 4in. up the roof as at F (diagram 411), then the lead should be cut to come up the springing, and if the pitch of the roof be easy, as there shown, it should go well up the roof at least 5 or 6in. past the sharp arris F; but if the pitch of the roof be very sharp, as at F (diagram 412), then from 3in. to 4in. will answer. Now, having seen how far the lead should stand up against the walls and up the roof, proceed to examine the drip. Let us say that it is a 2in. drip, as at Y, Fig. 409, and that the splash lap G C (Fig. 113) is 2in. This will make up 4in. Now proceed to measure your gutter, and enter it in your book as follows. Say the measurements are in this case 5in. up the wall, 2ft. 5in. at the wide end, and 9in. up the slates, in all 3ft. 7in. The narrow end is 6in. up the wall 2ft. 2in. wide, and 9in. up the roof, which amounts to 3ft. 5in. This will suit your sheet, which is, say, 7ft. wide. Next take the dead length, which is, say, 9ft. 2in., say 5in. up the wall, or at the head, and with 4in. for the work*ing of the drip. Allow, say, 1in. more for trimming, &c., in all, 10ft.* *This will also suit your sheet, which is 30ft. by 7ft.* Now proceed to cut out your lead and mark each gutter, and as you measure them, beginning at the outlet gutter, number them 1, 2, 3, 4, &c., also the side of the building as east, south, north, &c. Having the lead cut out, next let it be hoisted and carried to its proper place, then proceed to lay it as follows. Again refer to diagram No. 408. Unroll the lead upon a clean place, let the lead be dressed out flattened, or smoothed over with a dresser. Now measure the side turn up, as at B4 and A1. Say that at B4 it is 5in., and at A1 6in. Now with a chalk line snap the line BA. Next measure the end or head BC, which should also be 5in. and with a level as shown at bevel (diagram 414), take the exact angle of the wall, as there shown, and place it upon the chalked line as shown at BEVEL diagram 408, and with your chalk line strike the line R Q parallel to the tongue of the level. Next take the width at the head of the gutter, which, as you remember, is 2ft. 5in. Do not measure 2ft. 5in. on your lead, for if so your lead would not go into its place, simply because the two turn up edges have a thickness, and which must be allowed for; say that it is 7lb. lead, then it would be nearly ⅛in. thick, and twice this equals ¼in., say ⅜in. more to allow the gutter freedom, this is ⅜in. less than 2ft. 5in.; therefore, measure the head 2ft. 4⅝in. Next measure the foot or bottom end—this was 2ft. 2in., therefore measure on your lead 2ft. 1⅝in. and strike the chalk line C D. Now measure the length to see if your lead is cut the proper size; say that it is, and let us assume that the gutter is a plain one, therefore, take no notice of the break lines at I P, F G, J L, &c. Now, according to the elevation in diagram 407, let the corners be worked or bossed up square. If so, cut the corners off as shown by the dotted lines at 3 and 4, diagram 408. Now that the gutter is lined out, the next thing is to "pull it up." This is simply done as follows: get a "pulling up stick," which is simply a piece of quartering, anything about 3in. by 4in., 4in. by 4in., or even, if nothing handier is at hand or cannot be procured, a scaffold board will answer; lay it on the line A B; now kneel upon this, say about 3ft. from the end, and your mate do likewise; you take the head and he the foot of the gutter (be particular that the "pulling-up stuff, or stick," is fair upon the line), and now with your hands, say 3ft. apart, take hold of the side, and *both together* pull up the turn-up as sharp as possible, and as shown at 1 and 4, diagram 407. This, if very stout lead, or if the lead is of a hard nature, or the weather very cold, may not turn quite so easily as you may wish, but if it does not come square up, push it back again and vigorously pull it up again, do it two or three times until it is middling sharp. Now serve the other side the same. This done, with a shorter piece of pulling-up stuff, pull up the end B C. Now the sides and end are turned up, get a dull-edged *hornbeam* dresser (some plumbers use a box dresser, but I prefer a good hornbeam for this purpose, as it does not strain the lead), and place it as shown at G H (diagram 407). Then let your mate, with a "holding down stick," K, hold the end of the gutter firmly down to keep it from springing up, and with a hammer, or better, with a mallet, as at J I, knock the dresser into the arris of the gutter, as shown at G (diagram 407), which will make the arrises squarer. Do not begin too near the end, but always keep away from the parts which are required to be *worked for the drip*, for if you should set this part in square, the chances will be that you will have to take the trouble of working the lead *very carefully* to prevent the making of holes, called "bird's eyes" or "cock's eyes," &c., for which you may be fined half a gallon for each offence, and for the second offence most likely told to go off the job.

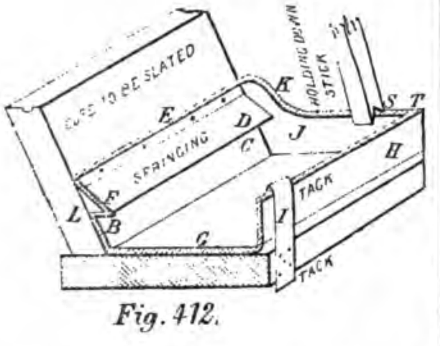

Fig. 412.

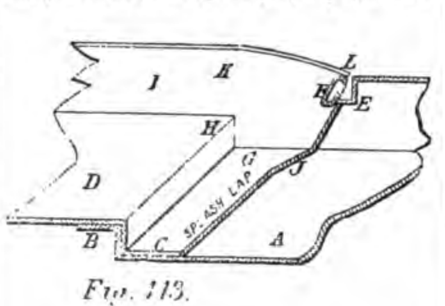

Fig. 413.

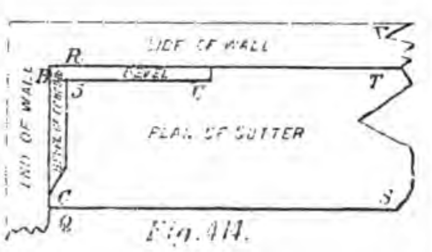

Fig. 414.

This setting in, as it is termed, must be done all round the sides and ends of the gutter, after which "square the sides." "Go round it" with the dresser. This is nothing more than beating (hereafter called dressing) the edges inwards, which thickens the lead in the arris and makes the lead come up quite true and square.

Having done this, next "break it up." This is done by putting your hands on the two stand-up edges, and about 3ft. from the end, and let your mate pull up the end at the same time you push the sides outward as shown at D T G (diagram 415). Some lazy plumbers do this with their feet.

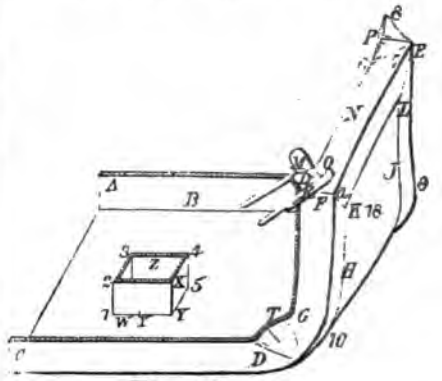

Fig. 415.

Now take the hornbeam dresser, and with its edge, and also with the mallet, make the stiffeners H K L J S, which is nothing more than the lead knocked back in a line, as illustrated.

(*To be continued.*)

SETTING AND CENTRING CORES.*

If there is any one thing that a machinist dislikes it is boring out holes that are not cored centrally. And why a moulder cannot always set cores centrally is something of a conundrum to him. Moulders can sometimes make excuses, and are generally ready to take a cast-iron oath that the core was set right, which the machinist, of course, cannot dispute. Still it will, I believe, be acknowledged by nearly all moulders that excuses for cores out of centre are about the worst kind of excuses we have to make. When you get a moulder so that he cannot say anything, it is a sin to torment him further; but it isn't often that you will get him there.

Why it is that *all* cores cannot be set centrally, is something that cannot be fully explained. To set a core centrally or straight does not call for any great mechanical skill. What is demanded is *care* and *thought*.

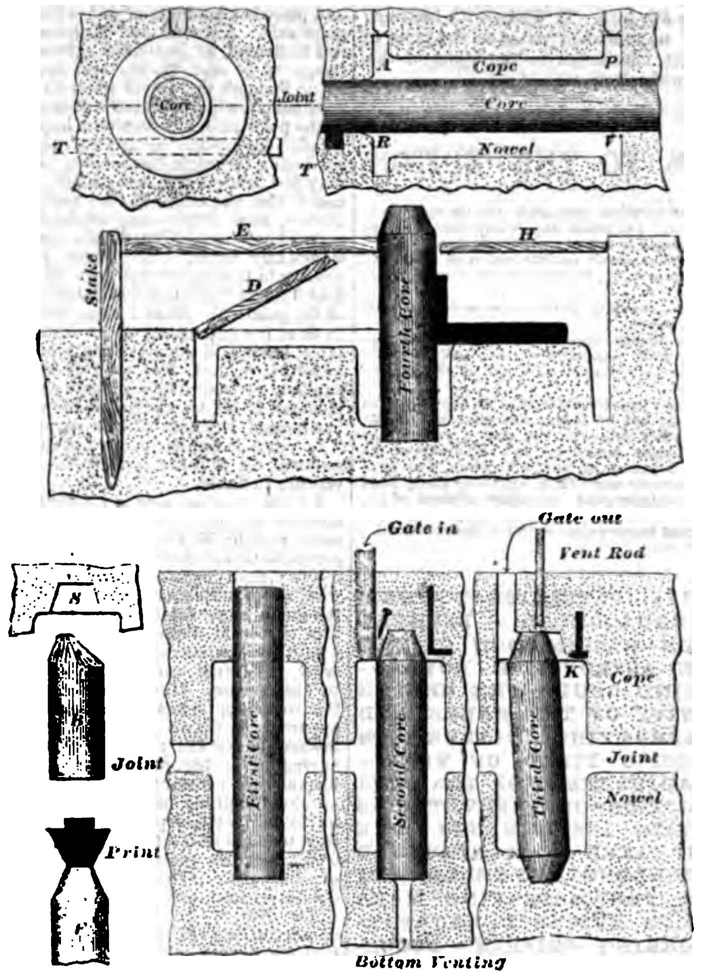
The accompanying engraving may assist in showing why some holes do *not* come central, and perhaps afford some help in setting cores.

The cause of holes being out of the centre is not always on account of the cores not having been set centrally. There are many things, such as uneven closing of flasks, bad fitting flasks, ill fitting cores, &c., any of which may result in crooked holes. Some readers of the *American Machinist* will remember about three years back some discussion upon core prints. To my mind the elaborate systems that some writers advocated had but little to do with what prints are practically used for. Prints are for no other purpose than giving bearings, and holding cores.

And whether bottom core prints are tapering, as seen in *Third core*, or straight as shown in all the others, has but little to do with the holes being out of the centre, which I think is a vital part of the question. The top prints are the essential ones, and even they often have but very little to do with poor holes. As a general thing long top taper prints afford a better chance for the cores to accommodate themselves to their centre. For long cores where there is uncertainty about measuring, such prints as are shown with *First core* are reasonably certain of

---

* By Thos. D. West, in the American Machinist.



providing for a true hold. This form of a print is the most reliable one that can be used, as with it the moulder can see whether the core is in its right place or not. In fact, by the use of such a print, it would be a hard matter to get the core out of its centre. Some may think such prints should always be used; but they are objectionable, from the extra labour and time which their use involves. It may be said that there is no gain, if through the quicker plan the casting is lost; but all castings are not lost. It is only the ones that are wanted in a hurry that we lose.

The cause of many crooked holes where the popular common top-tapering print is used, is as illustrated at *Third core*. As a general thing nearly all pulleys, gear wheels, &c., have either feeders or pouring gates on the hub. These holes break away or weaken a portion of what should be a firm, true, sound, tapering point, and the core leans to the weak side, with the result shown.

There are a few moulders who always close such moulds as the above, with the gates in place, as shown at *Second core*. By this plan it is evident that much of the risk is lessened.

The gaggering and nailing around the *Second core* is another safegard against the core crowding the print to one side. Another point that will bear looking at is that of the taper ends of cores.

A large number of foundries make all their common sizes of round cores, without having the taper end formed. Then, again, a large number of shops make their cores, having the taper end on them.

Filing a taper on cores is often very objectionable, especially when done by a careless moulder. A fair illustration of careless work of this kind is shown on core B. If a central hole is got with such a core it can't be charged to good management.

A careful moulder will compare his print and core together, as seen at F, thereby making a core that is likely to fit and fill the female print S.

Cores with taper prints are often one-sided, from being laid down upon plates to dry, although some, by nailing the heads, or packing sand under to hold them up, will get a very fair tapered head.

In some shops, in order to get good round straight cores, they are dried in half-round iron boxes of the same diameter as the cores. This is the only reliable way of making true taper end round straight cores. The plan is an old one, and the cause of its uppopularity is the expense of making the cast-iron boxes.

At E, D, H, and at the square, are shown the methods generally employed in setting and centring cores. With the exception of E, the plans are popular, and call for no comment. E is a plan whereby cores in such *moulds as green-sand* propeller wheels, and others having no points to measure from satisfactorily, can be centred. The plan is simply the driving of three or four stakes outside or away from the mould, before the pattern is drawn, the stick E being placed against the pattern print, and all the stakes driven the length of the stick away from the print. The core, when set by the same stick, will of course occupy the same position in the mould as the print, and therefore as far as centring is concerned must be right. The plan is applicable in other ways than shown; and while the idea may be old to some, it will be new to many.

The carrying off of such core vents through the cope is often the cause of weakening top prints, and also the cause of blow ups, from metal getting into the vent. To avoid this danger, it is the better plan to carry off the vent through the bottom board, or by running a long vent down into the moulding floor, as in the case of bedded-in moulds.

Some will say, that is all right, providing you have a cinder bed under the mould. I have carried off the vent of cores as large as 1ft. in diameter, and more in length, by simply driving a ⅝in. vent rod down 2ft. or 3ft. in the sand below the mould. Green sand, where you have a large body, is capable of carrying off and holding more gas than is generally thought; and to such as never tried this plan I would say, Do so; for I know they will find it a safe and reliable way of carrying off vertically set core vents.

In the upper part of the cut are represented ideas that to the novice may be of some value. It represents the finning or chamfering of core prints, in order to prevent the crushing of flanges, &c.

There is much that might be said upon the question of horizontal core setting. But I will at present confine myself to saying a few words upon flange crushing, a thing very likely to occur. The greatest cause of flange crushing is probably due to the irregularity and over-size of cores. Should any of my moulders lose a casting through the above cause, I would hold them responsible, although I might reprimand the core-maker for making the core too large. In our shop it is the custom for all pipes or moulds having flanges upon them to be tried off and on. This gives the moulder a chance to see if there is any liability of his mould or flanges being crushed; and if there is, he has time to go for the core-maker, in which he will have my assistance. The practice of thus trying off and on all such moulds, has been the means of saving many a casting from going to the scrap pile. I think it is a safe assertion to make, that in not one of fifty shops (and I feel like doubling the number) is this the rule. I know that it takes more time; but will say that in our shop I have yet to see a casting lost through having a crushed flange—a thing that but few foundrymen can say.

Having all castings good, far more than balances, in dollars and cents, the little extra time taken up in trying off and on all such copes.

NEW METHOD OF BRONZING IRON.

ACCORDING to L. Meyer, in the *Polytechnisches Journal*, the following method is successful in producing a bronze-like surface which practically prevents rust. All the methods as yet known for producing a bronze-like surface, by rubbing over the surface of the iron an acid solution of copper or an iron solution, letting it dry in the air, brushing off the rust produced in this way, and an abundant repetition of this method, give a more or less light or dark reddish-brown crust of rust on the iron body. Objects formed of iron can easily be covered with copper or brass by dipping them in the requisite solution, or by submitting them to the galvanic method. The surface, so prepared, however, peels off in a short time, especially if the surface of the iron be not polished at the time: by exposure to moist air in particular. By the method given below, it is possible to cover iron objects, especially such as have an artistic aim, with a fine bronze-like surface; it resists pretty satisfactorily the influence of moisture, and one is, moreover, enabled to apply it to any object with great ease. The clean, polished objects, are to be exposed to the action of the vapours of a heated mixture of hydrochloric acid and nitric acid, in equal portions, for from two to five minutes; they are not to be shifted, and the temperature may range from 300° to 350° C. The heating is continued so long that the bronze-like surface is well developed on the surface of the objects. After the objects have cooled, they should be well rubbed down with vaseline and again heated till the vaseline begins to decompose. When again cold they should be a second time treated with vaseline in the same way. If the vapour of a mixture of the two concentrated acids is allowed to act on an iron object in this manner, a light reddish-brown tone is developed. If some acetic acid be mixed with the two acids, and the vapour of all the acids together be allowed to act on the metallic surface, a surface of a fine bronze yellow colour can be obtained. By using different mixtures of these acids, every tint, from a dull red-brown to a light brown, and from a dull brownish-yellow to light brown-yellow can be produced on the surface of the iron. In this way some T-rods for iron boxes were covered with a bronze-like surface, and at the end of ten months, although exposed during the whole time to the action of the acid fumes of a laboratory, they had undergone no trace of any change.

Digestibility of Raw and Cooked Meats and Milk.—E. Jessen has recently completed some interesting investigations regarding the time required to digest meat and milk prepared in different ways. His first experiments were made with artificial gastric juice. Twenty-five grammes of beef were placed in it for 24 hours, and the undissolved portion weighed at the end of that time. Of the raw beef about 5¼ grammes only remained, of the half cooked 9¼ to 9¾ grammes, while that which was well done left from 17 to 18 grammes. The next experiments were made on a dog with an opening in the stomach. Here too the raw meat digested more quickly than boiled or roasted meat. The time for raw beef was 5·3 to 5·5 hours. Experiments were also made upon men by introducing 100 grammes of meat and 300 cc. of water into an empty stomach. After a certain time the contents of the stomach were pumped out, and if the microscope detected no muscle fibres, the digestion was considered finished. The time required was as follows:—Raw beef, shaved fine, 2 hours; half done boiled beef, shaved fine, 2½ hours; well done boiled beef, shaved fine, 3 hours; half done roasted, shaved fine, 3 hours; well done roasted, shaved fine, 4 hours; raw mutton, 2 hours; raw veal, 2½ hours; raw pork, 3 hours. In the experiments with milk such a quantity was given as to correspond in the quantity of nitrogen it contained to 100 grammes of beef. The time was as follows: 602cc. raw cow's milk, 3½ hours; 602cc. boiled cow's milk, 4 hours; 602cc. sour cow's milk, 3 hours; 675cc. skimmed cow's milk, 3½ hours; 655 cc. raw goat's milk, 3½ hours.—*Zeitschrift für Biologie*.

New Catalogue.—Messrs. H. and E. J. Dale, of 25, Ludgate-hill, have issued a new catalogue of Electrical and Physical Apparatus, which will be useful to many of our readers. Messrs. Dale supply all the modern forms of static electrical machines, including the Wimshurst and the Molison: all sorts of bells and batteries, and the various parts for making them. Their catalogue is something more than a mere price list, as it supplies a great deal of useful information, and answers many of the questions which we receive regularly every week.

SCIENTIFIC NEWS.

THE death is announced of Prof. Sven Nilson, the well-known Swedish naturalist, at the ripe age of 97. He was born at Landskrona, in March, 1787, and so long ago as 1811 obtained the degree of Ph.D. from the University of Lund. His magnum opus is the work on the Scandinavian fauna, which occupied him for more than 35 years.

Mr. J. E. Howard, F.R.S., chemist and quinologist, died the other day at the age of 76.

The death is also announced of Prof. Ercolani, of Bologna.

At Leeds, the other day, Mr. Arthur Nicols delivered a lecture on "Snakes and Snake Charming," in which he referred to the highly-poisonous character of the true sea-serpent, and gave an instance of the appearance of the mythical monster which occurred in his own experience. That turned out to be the body of a dead whale around which were collected thousands of gulls and albatrosses, and which simulated the shape and form of a monster with a mane and long tail. It is a pity that every master of a vessel from which the sea serpent is seen has not courage enough to steer close to it, so that its real nature may be made evident.

At a recent meeting of the Manchester Association of Foremen Engineers and Draughtsmen, Mr. J. Nasmith read a paper on the recovery of by-products in the manufacture of coke. After describing the Simon-Carvé and the Jameson processes, he mentioned some applications of the principle in the utilisation of the waste heaps which often become a nuisance in the colliery districts. In two experiments the heap was covered with sand and the gas was withdrawn by means of a blower through pipes sunk to a depth of six feet in the heap, resulting in the recovery of a considerable quantity of ammoniacal liquor with some tar oil. A Mr. H. L. Annom has taken out a patent for dealing with similar waste in future. Culverts are laid in the ground and the heap piled over them: when sufficiently large, it is fired and the gas withdrawn through the pipes.

Dr. Forster, of the Laboratory for Hygiene, Amsterdam, is of opinion that boracic acid is not to be recommended for preserving articles of food, and more especially should not be added to milk intended for young children.

M. [illegible] of Stockholm, has sent to the Academy of Sciences a note relating to copper and cholera, in which he says that in 1853 small bars of copper were worn over the pit of the stomach with wonderful advantage. Cholera has raged several times at Stockholm, but has never extended so far as Falun, where the copper mines are situated. He, however, evidently thinks that it is not the [illegible] vapours, which sometimes are discharged in considerable quantities, that give to Falun its immunity from cholera.

Dr. Friedlander has added to the history of the germ theory by exhibiting before the medical societies of Berlin specimens of the micrococcus of pneumonia. Injections or inhalation of the pulverised masses invariably produced true croupous pneumonia in mice.

Leech farming is successfully carried on in [illegible], and the industry has been recently started in Florida.

The water having been recently drawn off from the carp pond near the White House, Washington, which is one of those under the control of the Fish Commission, the increase in one year was found to be [illegible]. The fish varied in size from the young of half an inch long to respectable carp of two and three pounds weight. The pond has an area of about five acres, and is of very small depth.

The collection illustrating the fauna of the Bay of Naples, which was shown at the Fisheries Exhibition, has been secured from Dr. Dohrn for the Cambridge Museum of Comparative Anatomy.

Mr. W. O. Crosby has been studying the coral reefs of Cuba, and has arrived at the conclusion that they indicate a slow subsidence of that island during their formation, and that Darwin's hypothesis is consequently the true one.

What is called a "posthumous" essay of the late Mr. Darwin's was read at the Linnean Society on the 6th inst. It deals with instinct, and is full of unpublished notes on the facts of animal instinct, considered in the light of the theory of natural selection.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *31, Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original."

JUPITER'S IVth SATELLITE—THE NEW PARIS EQUATOREAL — DIURNAL NUTATION—RESIGNATION OF THE BELGIAN ASTRONOMER-ROYAL — AN UNKIND "CUT"—THE CENTRE OF GRAVITY OF THE EARTH AND MOON—SURVEYING INSTRUMENTS —TELESCOPIC FIELD OF VIEW — FOCAL ADJUSTMENT OF TRANSITS —DESCRIPTIONS OF OBSERVATORIES AND THEIR INSTRUMENTS — THE NEAREST FIXED STAR—APERTURE AND FOCAL LENGTH OF TELESCOPES —POWER FOR OBSERVING MARS —MENISCUS EYEPIECE—EQUATOREAL WORKING STIFFLY — FOCUSSING EYEPIECES — WELLS' ALTIMETER, AND MEASURING MOUNTAIN HEIGHTS — ARGELANDER'S STAR CHARTS.

[22097.]—LOOKING through the last Volume (XXXVII.) of the ENGLISH MECHANIC, I have just come across a report of the April meeting of the Royal Astronomical Society, on p. 147, whence it would appear that Captain Noble read a paper on an extraordinary discrepancy between the time at which Jupiter's IVth satellite really disappeared on April 4th, and that at which its eclipse was predicted in the *Nautical Almanac*. According to your report, the author of this paper seems to have held the satellite in view for 24 minutes and 6 seconds after it ought (theoretically) to have disappeared. Reading on, I find that Mr. Marth attempted in some way to justify this discrepancy; albeit, it is not easy to make out whether his contention was that it ought to have occurred, even were the tables perfect or not. Turning now, though, to p. 237 of your current volume, I find Dr. Wentworth Erck inviting attention to identically the same error of 24 minutes in the *Nautical Almanac* in connection with the egress of this same satellite, after transiting Jupiter's face. This coincidence is at least worth noting; pointing, as it would seem to do, to a constant and well-defined error in the tables of Satellite IV. It is idle to blame Dr. Hind for this. Even a man of his ability cannot make bricks without straw. The money absolutely thrown away and wasted in one single year on the trumpery little "Committee on Solar Physics" at Brompton would very much more than suffice to furnish the material for removing a standing opprobrium to our National Ephemeris. Should, as I earnestly hope, Lord Crawford ever become a member of a future administration, astronomers will look to him to urge upon his colleagues the transfer of Imperial funds from a mere scientific imposture to the practical object of supplying a means of easily, and very approximately, finding the longitude.

The number of the Paris weekly scientific periodical, *La Nature*, for September 22, contains an engraving and article descriptive of an altogether remarkable equatoreal which, thanks to the munificence of M. Bischoffsheim, has just been installed in the Observatory in Paris. It would seem to be the invention of M. Loewy, the subdirector of that establishment, and consists, in effect, of an enormous instrument, bent at right angles towards the bottom of the Polar axis, such axis itself forming the eye end of the telescope; as the part bent at right angles to it and moving in the plane of the Celestial equator may be regarded as the object end. This second tube issues from a cube containing a small mirror bedded in flannel, and placed at an angle of 45° with both it and the polar axis. A second and larger mirror, also bedded in flannel, at its distal extremity reflects the image of a star to the one in the cube, and so up through the object glass to the eyepiece or micrometer, which is placed at the northern extremity of the polar axis. It would be impossible to give a detailed description of this instrument without reproducing the original engraving; hence, to all who may feel interested in the matter, I would recommend the purchase of the number (538) of *La Nature*, now before me, containing it. It only costs 50 centimes. The details are, some of them, sufficiently novel. The main principle of the novelty in this equatoreal is as old as the "Englefield Transit" of our fathers' days. The upper end of the polar axis enters a room, and the observer is to sit at the micrometer as he would at his writing table, having all the movements of the instrument under his control, by means of rods, screws, and handles, conveniently arranged at hand. Mr. F. Hément, in his description of the equatoreal which has formed the text of this paragraph, says that "La perte de lumière par le fait des réflexions successives est à peine sensible"—which I humbly venture to doubt.

I have, so far, seen no notice in any English scientific journal of what seems to me a noteworthy essay, read by M. Folie at the meeting of the Astronomische Gesellschaft, held in Vienna from the 14th to the 17th of September last. It was on the somewhat novel subject of *diurnal* nutation, and also on the much more familiar one of annual nutation. The idea of M. Folie is that if the earth consists of a fluid nucleus, surrounded by a relatively thin solid crust, a diurnal nutation must exist appreciable by observation. Having worked out the theory of this nutation, he has found that it should be most apparent in Right Ascension for stars situated towards 0h. or 12h.; and in Declination for those having 6h. or 18h. of R.A. Calculating from his formulæ the constant of diurnal nutation, as well as the longitude of what he calls "the first meridian" (or that passing through the axis of the least moment of inertia), he gives the constant as 0·05", and his prime meridian he fixes 20° west of Pulkowa. The stars he has used for this determination are those employed by the Elder Struve in determining the constant of aberration. M. Folie seems to have no doubt that his figures establish the existence of an observable amount of diurnal nutation. He expresses the opinion that the fluidity of the earth under a relatively thin solid envelope would thus register itself in the sky in a manner much more certain than has ever been believed to be possible by geologists and mathematicians. The geologists (M. Folie asserts) believe in the solidity of the entire globe; the mathematicians in that only of its crust. He does not conceive that such crust can exceed 186 miles in thickness.

Apropos of the author of the essay of which I have been speaking, I hear him spoken of as a possible successor to M. Houzeau, whose resignation of the post of Director of the Royal Observatory at Brussels has recently been such a deplorable loss to Belgian official astronomy. The reasons for this resignation seem to be very imperfectly understood even in Brussels itself. Of the regrettable result of it there can be no difference of opinion. M. Houzeau is best known in England by his most valuable "Répertoire des Constantes Astronomiques"; and by his really astonishing work (brought out in conjunction with M. Lancaster) the "Bibliographie générale de l'Astronomie," which you reviewed on p. 252 of your XXXVth Volume.

I do wish that your engraver had listened to my appeal to "reproduce accurately what I drew most carefully at the telescope," in cutting the wood block of Saturn for my letter (22053) on p. 261. Imprimis, I am at a loss to know why he has eliminated the black surrounding sky of my original drawing; and, in the next place, I drew the inner edge of the crape-ring in the ansæ perfectly sharp, while the engraving in my copy of the ENGLISH MECHANIC makes it *fade off* into the black sky. Mine seems a very indifferent impression, by the bye. I hope that the majority of my brother readers have got better ones.

I may tell "P." (query 52267, p. 272) that I deduced the centre of gravity of the earth and moon from the best and latest determination of their respective masses. As I told my querist in letter 22012 (p. 217), the centre of gravity of the earth and moon is 2898·54 miles from the earth's centre; and, of course, she must revolve round this point once a month. Hence, every fourteen days she is alternately 2898·54 miles before and behind her mean place, with the effect of causing a corresponding seeming oscillation in the sun's apparent motion; and this is called in astronomical books the lunar equation. Within the limits of accurate observation of such a body as the sun, this agrees with the result determined by theory.

"E. M. R." (query 52283, p. 273) should get a book which I have before recommended in these columns, Heather on "Mathematical Instruments" (Nos. 168, 169, and 170 in "Weale's Series"), published by Crosby Lockwood and Co. He will cognise parts of "Simms"—both engravings and letterpress—in parts of it; but accompanied by a mass of the most recent information with reference to mathematical, optical, surveying, and astronomical instruments.

With regard to the succeeding query by "E. M. R." (52284, p. 273), What does primarily determine the angular subtense of an eyepiece is the diameter of the diaphragm between its eye-lens and field-lens and the focal length of the object-glass. Hence, your correspondent will see that his concluding question is, in its existing form, unanswerable. He may find the angular diameter of any given eyepiece from Delambre's formula. Calling A such angle in seconds of arc, F the focal length of the object-glass, and *d* the diameter of the diaphragm, then $A = \frac{d}{F . \sin. 1''}$.

Let us take his own telescope, and suppose (as is most likely) that the diaphragm in the eye-pipe is ½in. in diameter. Then the formula becomes

$$\frac{0·5}{14 \times ·000004848} = \frac{0·5}{·000067872} = 7766·8'' = 2°2'46·8''$$

Hence, he would have a field of view of rather more than 2° in diameter. Were he to employ the same eyepiece with a telescope of 60in. in focal length, he would find that the diameter of the field would be reduced to something like 28′ 39″. But the only real way of accurately determining the angular diameter of the field of view of a telescope with any given eyepiece, is that which I have myself given in these columns, I think, at least, four or five times. It is to observe, by the aid of a sidereal clock, the exact number of seconds and fractions of a second occupied by a star as near the equator as may be, in transiting the field diametrically, and then multiplying this time in seconds by 15, and again by the cosine of the star's declination. Thus, suppose that *α* Aquarii was found to take exactly 1m. 33s. in crossing the field of an eyepiece centrally. Then we say

93sec.	log.	1·968483
15	log.	1·176091
0° 53′ cos.	log.	9·999948
1394·84		3·144522

So that the angular diameter of the field of our eyepiece would be 1394·84″ or 23′ 14·84.″

I may answer query 52285 (p. 273) by saying that astronomical transit instruments have the system of wires rigidly fixed in the focus of the object glass; capstan-headed screws, as a rule, clamping the inner and outer tubes firmly together. Then any focussing is done by pushing in or pulling out the eyepiece in its tube; inasmuch, as ex necessitate, when the wires are in focus, a star must be too.

I know of no work exactly answering the description given in query 52286 (p. 273)). An early volume of "Weale's Series," reprinted from Bohn's "Pictorial Handbook of London," contains an excellent popular illustrated description of Greenwich and other observatories; but it does not now appear in Crosby Lockwood's catalogue. It only cost a shilling. Engravings and descriptions of the Greenwich instruments, too, appear in some of your own early volumes; and there are splendid engravings, accompanied by elaborate descriptions, of the Washington instruments, in Vol. II. of Chauvenet's "Spherical and Practical Astronomy." This, however, is scarcely a "cheap" book, save in the sense that it gives abundant value for its price.

Possibly "E. M. R." will find what he wants in "L'Astronomie pratique en les Observatoires en Europe et en Amérique," of which Part I. is devoted to England, and Part II. to Scotland, Ireland, and the British Colonies. It costs 4s. 6d. a part, and (I think) Nutt, the foreign publisher in London, sells it.

If "Stellarius" (query 52296, p. 273) will promise not to tell anyone, I will, in confidence, inform him that the answer which he quotes from the *Girls' Own Paper* is hopeless rubbish. *α* Centauri is the nearest of all the fixed stars, but as its parallax is only 0·93″ it must be 221,000 radii of the earth's orbit from us, or, in round numbers, 20,411,400,000,000 miles!—a distance which light (travelling 186,000 miles a second) takes *nearly three years and a half* to cross. I should strongly advise the editor of the *Girls' Own Paper* to give a week's notice to the gentleman who "does" the astronomy in his valuable journal.

Mr. Nelson supplies a by no means unnecessary caution in the concluding sentence of letter 22070 (p. 279). Perhaps I may supplement it by advising all purchasers of telescopes to procure them of as long focus in proportion to their effective aperture as they can. It is a golden rule for obtaining the very finest definition, to get all the magnifying possible performed by the object glass; leaving as little as may be to be effected by the eyepiece. A long-focussed telescope is not, of course, quite so portable or handy as a "dumpy" of similar aperture: but this is an inconvenience to which anyone who intends to do real work will cheerfully submit.

I cannot say that my experience in connection with the observation of Mars is coincident with that of Mr. Holmes (letter 22075, p. 280). *Cæteris paribus*, Mars bears, with me, more magnifying than Jupiter; but, of course, at present he is very unfavourably placed for observation with the telescope, being much too near the eastern horizon during the available hours of the night. During the oppositions of 1877, 1879, and 1881, I had glorious views of the planet (of which I made numerous drawings) with a power of 250 on a 4½in. achromatic. It is but rarely indeed that Jupiter will bear such an amount of amplification as this.

I am entirely ignorant of the "Meniscus Eyepiece" (spoken of by "Makeshift" in reply 52319, p. 290) under that name; in fact, if it be true that it consists of "three meniscus lenses," I now hear of it for the first time in my life. Of course, the meniscus has been introduced into the astronomical eyepiece, with good results, as in the case of Sir George Airy's modification of the Huyghenian form (R.A.S. *Monthly Notices*, Vol. XXIII. p. 70); the Steinheil solid eyepiece (English Mechanic, Vol. XXXV. p. 570), &c.; but I must repeat that I have never in my life heard of such a construction as that which "Makeshift" describes, either for use with the telescope or the microscope.

"M. A." (query 52330, p. 291) says nothing of the construction of his equatoreal. Assuming it to be of the ordinary German form, there is nothing for him to do but to dismount the instrument, clean carefully all pivots and bearing parts with a soft duster and some sweet oil (which must be afterwards wiped off with a clean rag) and, on putting the mounting together again, touch all moving parts with a little of the finest watch oil.

The query of "R. S." (52337, p. 291) is a very puzzling one indeed, if, as I assume, his eyepieces are all mounted alike; because, *a priori*, the higher the power the further the eyetube has to be moved *inwards* to obtain the true focus. Unless I could actually see the telescope, or in the absence of more definite description, it would be impossible to answer your correspondent's question.

Assuming that "Penmaenmawr" (query 52380, p. 292) is familiar with the 4th Proposition of the VIth Book of Euclid, does he not see that he has only to call the 2, 4, 6, 8, &c., on the perpendicular of the triangle in the diagram on p. 218, 200, 400, 600, 800, and so on, to convert the corresponding figures on the base to similar quantities. Thus, to modify "Glatton's" example: If your correspondent were 1600ft. from the base of a mountain, and the plumb-line intersected the face of the altimeter as shown in the engraving, the height of the mountain would be 900ft. In connection with this subject, though, I may perhaps be allowed to refer "Penmaenmawr" to a letter of my own, 20518, on p. 60 of your XXXVIth Volume.

In reply to query 52385 (p. 292) Argelander's Durchmusterung is the Bonn Catalogue, and is contained in Vols. III., IV., and V. of the "Astronomische Beobachtungen auf der Sternwarte zu Bonn." It includes every star down to the 9·5th magnitude down to 92° N.P.D. It is accompanied by maps of all the stars contained in it. Besides this, Argelander's "Uranometria Nova" shows, in a series of 17 maps, all the stars visible to the naked eye down to 116° N.P.D., with the magnitudes carefully distinguished. This was published in Berlin, but, I should think, might be picked up through one of the London foreign scientific booksellers.

A Fellow of the Royal Astronomical Society.

SPECIALISM IN ASTRONOMY.

[22098.]—I quite agree with Mr. Gemmill in his remarks (letter 22036., p. 239 Vol. XXXVIII.) on the growing tendency to specialise astronomical work. Astronomy is, as I have found, distasteful to many, from the fact that a great number judge it to be, for them, hopelessly involved in abstruse forms and technicalities; whereas, in fact, it is, in some of its simpler aspects, one of the most interesting and attractive of the sciences. This mistaken idea no doubt arises in a great degree from what Mr. Gemmill points out, and, as he says, much valuable aid is thus lost—a circumstance which is to be lamented. Now, it seems to me that if at times a little more emphasis were laid on the "common" work, which may be done with the naked eye, or with optical means at the command of almost anyone, much valuable assistance would be given towards advancing the study of astronomy. If a student becomes impressed with the idea that he can do little or nothing towards gaining freedom in his subject unless he may at once consult high authorities and command a first-class telescope, it is not likely that his progress will be very encouraging; yet this danger threatens him in no small degree, for at every point he is confronted with the work which may be done with a telescope, while what may be done without one or with one he would be apt to despise, is left very much for him to guess at. Now, if without pining to split or elongate double stars, or to do any other of the minutiæ of telescope work (all of which is valuable in its own place), the young observer were to use the good means he possesses, and turn his mind to what lies immediately before him, he would have every chance of gaining a most encouraging range and scope in his subject, and the time spent and the work done would be anything but profitless and worthless. I am aware that such work is, by some, looked down upon as rather trivial; but, to my mind, it does not appear so. The subjects of stellar light and stellar variation, both of which can be pursued to a large extent with the naked eye, or with very small optical means, are important and valuable, and in the latter especially, as Mr. Gemmill well points out, much is to be discovered, and consequently much may be expected; while in the matter of star colours, I think there is room for anyone proceeding on a thorough and well-grounded method to establish at least something. In any case—and this is the main point of my remarks—such work, from its nature and breadth, and related as it must necessarily be, mainly to young observers, would go far towards reducing that tendency to specialise which Mr. Gemmill laments, and which I cannot but think unfavourable to the advancement of astronomy.

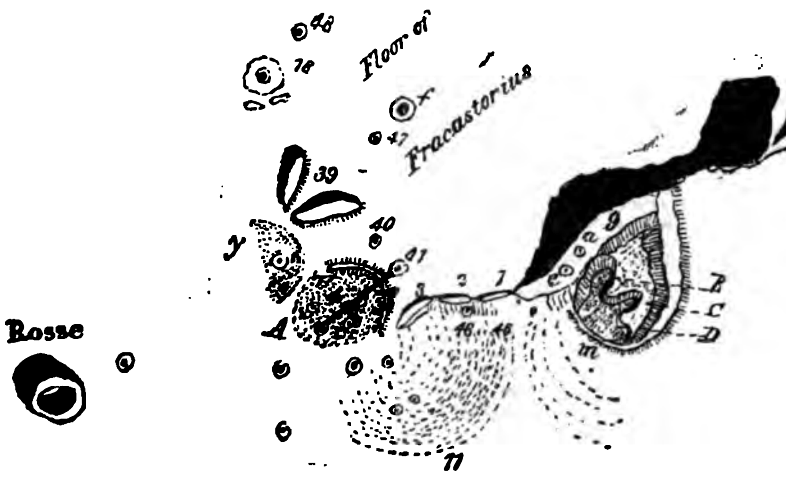
I cannot just agree with Mr. Gemmill in his estimates of *α* and *ε* Ur. Maj. All my estimates, which, I may mention, are quite recent, show these stars nearly equal, but make *α*, if anything, the brighter. However, they differ in colour, and may therefore differently affect different eyes, though I think that would hardly account for an excess on one side of three-tenths of a magnitude. In "Celestial Objects" Alcor is given of the 5th mag. Can any of your correspondents say if this star is *known* to be brightening? I generally pick it up in twilight from 6 to 8 mins. after *ζ* becomes visible. As other stars of the same magnitude, or even brighter, cannot be seen so early, I think that either the estimate in "Celestial Objects" is too low, or else the exact position of the star being known, it is more readily detected—probably the latter. In pausing, I may mention that some excellent lessons may be laid to heart during twilight observation of stars. I have frequently noticed that in an apparently clear blue sky, the fainter stars blink in and out, and the brighter ones constantly vary in lustre, illustrating, I suppose, the presence of haze quite insensible to the eye—a circumstance worthy of note in reckoning star magnitudes. Deeper haze, again, often changes the colour of the stars altogether—and this too is worthy of note. For example, on Nov. 11th, Vega at 4.45 p.m. seen through the faint rosy mist of a clear but windy sunset, was a beautiful pale emerald. It would seem that red or dull stars assert themselves in twilight quite as early as blue or white ones, though at present I would hardly venture to make a generalisation to that effect.

On Nov. 3rd, about 8 p.m., I looked at Saturn with a field-glass (2in. o.g.), magnifying about 25 diameters. I saw the ring easily with the dark sky distinctly visible through the *handles*. The body of the planet seemed to be of a whiter yellow than the ring. I thought I glimpsed one of the moons a little below [non-inverting glass] and to the south of the planet. This observation is of no importance, and I mention it simply because I think that when Galileo said he saw a large globe between two smaller ones, he hit the appearance of Saturn in a small telescope to a nicety. Webb says he has seen the ring with 20 on 1½in. aperture, and then adds, "though Galileo's glass magnifying it 30 times, could not define it thus"—of course it should be remembered that Galileo was groping in the dark.

On Nov. 13th the main group of spots on the sun was quite visible to the naked eye; and on Nov. 19th no less than three spots could be seen with the naked eye on different parts of the disc—one the group of Nov. 13th. **Orion.**

FRACASTORIUS — HORROX — CRATER BETWEEN THEOPHILUS AND MAEDLER.

[22099.]—I have read with very great interest letter 22035, No. 973 of the English Mechanic, on Fracastorius, from your clever correspondent, Mr. Thos. Gwyn Elger. His drawing of this formation as a whole supersedes, in my estimation, any yet published in your pages. As Mr. Elger kindly alludes to a cleft of mine, shown on page 405, Vol. XXIII., allow me to say a few words about its discovery. I first saw it, with another, on the E. on April 21, 1874, 8h. to 11h. p.m. I then wrote in my observing book: "Fine night, though at times the air is somewhat tremulous. Telescope driven by sandclock. The cleft *a* (the one on the E.) seen first, is easy when the air is quite still. It runs from between craterlet 30, and the E. large crater on the wall to a point between mounds 31 and 32 on the N. This is cleft *a*. While observing it, another cleft, *b*, came into view, and was not quite so easy. It was, however, well seen from crater c to its junction with cleft *a* and about its middle. The portion of cleft b from crater c to mound 5 [illegible] was [illegible] and requires other observations. It would appear from this that Mr. Elger's [illegible] corresponds to the eastern portion [illegible] that the remaining portion, [illegible] escaped him, for his cleft φ does not [illegible] with that portion of cleft [illegible] the place occupied by Mr. Elger's [illegible] I have on several occasions seen a *white* [illegible] in which were several minute craterlets. For aught I know, this may be a real cleft, and deserves attention. The number of small details which a good 8½in. mirror can reach is so great in studying such large formations as Fracastorius, that I have resolved to limit myself to only a portion when occasion to observe it offers. The sketch I here send represents the first, and, as yet, unique, of these portions. It represents the N.E. border of Fracastorius, and agrees very fairly with the same portion in Mr. Elger's drawing. Its only value consists in the fact that it contains details of objects not yet [illegible], so far as I know. I have marked the formations A, B, D and Y of Mr. Elger's; but it would have been well if your correspondent had used the symbols already published to designate objects identified by him. At the telescope, I know [illegible], but when preparing for publication [illegible] I wish to draw attention to [illegible] depression A, which [illegible] craters it contains with [illegible] Fracastorius shown by Mr. Elger [illegible] same direction as my [illegible] Fracastorius, [illegible] whether there is [illegible] elongations [illegible] may be [illegible] yet been seen [illegible] when observing [illegible] whether any [illegible] always [illegible] I have seen myself [illegible] as far as [illegible] very little [illegible] system of [illegible] known that [illegible] known to [illegible] relation [illegible] hand and [illegible] on the [illegible] and the second [illegible] the attention [illegible] where I [illegible] for they [illegible] observers [illegible] the [illegible] I always see [illegible] in a good [illegible] they [illegible] crown [illegible] but rough, [illegible] craterlets [illegible] however. [illegible] precludes the [illegible] their north [illegible] coming from [illegible] a ridge would have [illegible] A, B, C as closed all [illegible] are two [illegible] Schmidt, but which I [illegible] of his map, N. of [illegible] and Schmidt gives [illegible] from *f*. The two [illegible] much closer to it. 18 [illegible] of which there is a [illegible] seen the same, but [illegible] Schmidt's map, seems to [illegible] formation *y* is not shown either by Schmidt or Elger. Besides the craterlets being given, I saw 39 others in the Mare Nectaris, on Sept. 5, 1882.



Horrox.—I hope the eye of observers is kept on this formation, Dr. Julius Schmidt writes to me, that on March 15, 1875, with the great Berlin refractor, he saw three abnormal craters in the plane of the western interior ridge. Since I sent him my observation of Oct. 9 last, he has made five sketches, which he has kindly sent me, and which remarkably agree with what I see. On Oct. 21, 15h., when the eastern shadow had reached the middle of Horrox, Dr. Schmidt drew a dark spot at the foot of the western interior ridge, exactly at the place shown by me, so that this object is seen as a dark spot like a hole *both at rising and setting sun*. It is well to note this because, observing Horrox on Nov. 9, 1883, at 6h. p.m., I saw the same dark spot distinct from the shadow of the western wall and in front of an opening in the interior ridge; but at nine o' clock on the same evening a point of shadow coming from the western wall of Horrox had penetrated between the opening of the interior ridge, and had doubtless reached the dark hole, as no distinction could any longer be made between it and the shadow of the western wall. Closely surveying, then, the western wall, to know the cause of this pointed shadow, I saw a peak projecting eastward from the wall. The dark hole, or dark spot, might then, at times, be ascribed to the shadow projected by this peak, when the sun rises on the moon, and the shadow goes from W. to E. (though even then the dark hole can be seen when the western shadow has not yet reached it), but it is impossible that this can take place when the sun sets, and the shadow goes from E. to W. It seems, therefore, that there is here, at the east side of the interior ridge of Horrox, a dark spot, or dark hole—a crater without border—which had not been seen before Aug. 11, 1883, when my attention was first drawn to it.

Crater beween Theophilus and Mädler.—On Nov. 14, 1883, at 5.30 a.m. I saw between Theophilus and Mädler a very distinct and white crater, not given by Schmidt, who gives in this neighbourhood other craters much more diffiuclt to see. If the "wire" of the minometer is placed a little N. of crater B on the N. slope of Theophilus, and directed to the N. border of Madler, this crater will be seen along the line at equal distance from Theophilus and Mädler. The terminator was passing through Goclenius at that time. Next morning, however, when the terminator had encroached on the western border of Mare Nectaris, the whiteness of the crater had disappeared, and was itself rather difficult to see among the various ridges situated in this region. Would some one say if this crater is given by Schroter, Lohrmann, or Neison, or has any observer seen it already? It was an easy object, and attracted the eye at once when first seen.

I can assure Mr. S. Maitland Baird Gemmill that if my communications on selenographical matters have become unfrequent of late, it is only on account of unfortunate circumstances entirely independent of my own will. May I be permitted, at the same time, to thank him for the favourable view he takes of my labour in selenography?

β Delphini, δ Equulei, and γ^2 Andromedæ.—On every available occasion I have looked on these doubles. With β Delphini, I obtain the same results as before stated. As to δ Equulei, I have not had weather sufficiently good to satisfy my eye when using a power above 300. However, through frosty, unsteady air, I think I may say with certainty that the *comes* lies between 300° and 310°. Perhaps "H. S." will say if I am far wrong. γ Andromedæ now comes into very good position, and will certainly draw the attention of all those who possess instruments sufficiently powerful and good to compete with it. As for myself, all I can say is that I elongate it readily with any power from 180 upwards, position 100°+. I thank Mr. Perry for his measures of β Delphini, and I look for those of δ Equulei which he has kindly promised to give. Perhaps he will also tell us something about γ^2 Andromedæ. It would have been interesting to hear from him how β Delphini looked in his fine large mirror—i.e., if the *comes* was neatly separated; if the space between the two stars was comparatively large, and the power he used. My impression is that δ Equulei is more difficult; but of course my opinion has no weight at all—my mirror being only an 8½in. one.

Nov. 22. **C. Gaudibert.**

SELENOGRAPHICAL—FRACASTORIUS.

[22100.]—In reference to "M.A.'s" flattering notice of my drawing of Fracastorius (letter 22072) of the five crateriform objects shown on the N.E. side of the formation, I have only seen the ring complete in one instance—viz., in the case of that marked E, which is found at the termination of the long ridge that extends in a N.E. direction from Fracastorius *d*. Schmidt shows B, C, D, and E as perfect rings. B. and M. represent E as truly circular with a central mountain. Lohrmann also shows it complete. In the Rosse drawing, under date 3rd October, 1860, 4h. 30m., A, B, C, and D are depicted as in my sketch, open towards the N., while E is drawn of an elliptical shape. There are several small craterlets between Rosse and the N. border of Fracastorius; but I find that they are usually more easily visible under morning illumination. None of them, however, can be compared in point of magnitude to that shown in my drawing on the ridge connecting Rosse with the western wall of Fracastorius.

November 30. **Thos. Gwyn Elger.**

EQUATORIAL STANDS.—II.

[22101.]—Since my last, I have been endeavouring (before further entering into the details of those already described), to work out a stand of a different form to the usual patterns, which should, while fairly easy to construct, combine some of the conveniences of more elaborate contrivances. It is not intended to aim at the niceties of construction found in expensive stands; but I trust the illustration and the following description will show that essentials have not been neglected.

The circular base B, and the ring C C (of "I" section) are in one piece, as well as the web-plates or gussets at K, L, and M, and this foundation frame is proposed to be of cast iron. The ring C C is thickened out into cylindrical sockets at D, E, F, and H, to serve respectively for the holding-down bolt, for the bearings of the polar axis, and for a clamping screw. All these sockets, except that for the holding-down bolt, are intended to be bushed with brass.

The gusset-pieces L, M, carry a disc (part of the casting), which serves to support the hour circle O O. This circle is, in fact, a stout brass cap or ring fitting over, and turning pretty stiffly round on the cast-iron disc, just as the cover might be turned round on a wooden box. To facilitate this rotation the lower rim projects somewhat, and is milled on its edge.

Above the hour circle is the disc R, either cast in one piece with it if the polar axis is of brass, or solidly attached to it if it is of iron or steel, and having on its edge an index and vernier to read the hour circle by. This latter disc carries the two supports in which the declination axis turns as usual, the clamping-screw inserted in one of the supports serving to fix this when desired. Though not so shown, this clamping is best done with a split bearing.

The declination axis carries at one end the bar P, to hold the telescope, and at the other end the declination circles and balance weight. Of the two declination circles the inner one is fixed to the support; the outer one is free to turn on the declination axis, but can be clamped by the milled-headed nut against a shoulder formed on the axis, with which it will then turn.

The large V-grooved disc fixed on the middle of the polar axis is merely shown as intended to be clamped by the conical-ended screw, thus preventing the axis from rotating; but, if preferred, this disc may be made to serve as the hour circle by having an index and vernier fixed to the stand. It would then be advisable to have it loose on, but arranged to be clamped to the polar axis. I think, however, the hour circle is more convenient where shown. The base-plate B has three stout bluntly-pointed studs projecting from its lower surface; these rest in three conical holes in the underplate A A, which latter plate is fixed on the top of the oak or iron pillar.

It is thus easy, by unscrewing the centre holding-down bolt, to lift off the entire stand, *and to replace it exactly in the same position*. These studs are tapped (a very tight fit) into the baseplate B, so that by screwing them up or down, a certain amount of adjustment is obtained when first getting and this axis is often continued *through* its frame and made to project *both* ways, so that the handle can be applied to whichever end is most convenient.

Next we come to clamping arrangements (verniers had better be left for a future letter), of which there are several kinds. At first sight it seems easy to clamp two discs together, or to clamp an axis to prevent its turning, but it is less easy to do this *effectively* than it appears. Fig. 3 shows the simplest contrivance, merely a screw (a "set-screw," in fact) inserted through the side of the socket and jamming the axis inside it. This, though often used, is very defective, as the clamping action is too feeble to resist even a slight force tending to turn the axis round in the socket, and the usual result is a polished groove worn into the axis by the point of the screw. Next we have in Fig. 1 a collar embracing the axis, or spindle, which collar can be closed tightly round it by the clamping screw. This screw is made with a flat handle to enable it to be more firmly grasped. This clamp, though far superior to the set screw, is still liable to slip when, in course of time, the inside of the collar and the outside of the spindle get mutually polished and lose their frictional "bite." By the way, the tangent screw in the figure should have been shown more nearly parallel with the clamping screw, for though it changes its position and thereby partly rotates the balls through which it passes, it would be almost parallel with the clamp screw when half through the ball nut as sketched.

If is self-evident, speaking of clamps in general, that the farther the clamp is removed from the central axis of the wheel or disc, the less is the force required to restrain the wheel from turning, and for this reason *rim*-clamping is, when practicable, far preferable to *axis*-clamping.

Even rim clamping may, however, be (sometimes as) badly contrived, of which Fig. 4 is an illustration. In this instance there is a liability to bend one or both the discs when the screw is tightened up, and if these are too rigid to yield, a strain is put on the axis which carries them.

In Fig. 5 this is avoided, as the screw merely tends to pinch the edge of the rotating disc between itself and the upper jaw of the clamp. In practice it is usual to introduce a loose piece between the end of the screw and the underside of the disc, which prevents the screw indenting it, and also increases the surfaces in contact and gives more grip. Various modifications of this are in use. Sometimes there is a square or V groove to receive the loose gripping piece, but these need not be separately considered.

In the "Popular" stand a V-grooved disc is clamped by the pointed screw, and as the clamping is at the rim, the force required is small; while to prevent any bending of the polar axis under even this slight strain, the axis is made pretty substantial. *As a rule*, no axis liable to bend should be subjected to cross strain by the action of clamping. I have seen double-jawed clamps like a vice, but with both jaws movable: these avoid all strain on wheel or axis, but are troublesome to fit up so as to be free from shake. **A. S. L.**

P.S.—Since sending my former letters to press I have formed the division of the polar circle into 24, and the consequent long vernier (or quasi-vernier) has been suggested by another correspondent—See page [illegible], Vol. XXXVI.

NOTES AND QUERIES ABOUT THE TELESCOPE.

[illegible]—As so many readers of the "E. M." take an interest in the telescope, I have thought that a few notes and queries in reference to matters of real interest might not be unacceptable.

I shall begin with a query. Observing in this periodical that Mr. [illegible] in resilvering his great mirror had used glucose as a reducing agent, I have to ask whether any of the many readers of the "E. M." have tried that reducer, and, if so, if they have found it equal in the deposit it produces to the reducing agent recommended by our valued Transatlantic correspondent, Mr. Brashear, of which the main ingredients are sugar and nitric acid. I have tried Mr. Brashear's process and find [illegible] would wish to have the opinion of [illegible] in Mr. Common's process.

[illegible] In a German journal [illegible] für [illegible] there is a very interesting and seemingly impartial account by Dr. Klein of the performance of a refractor of [illegible] aperture. I give a translation of the most interesting parts of Dr. Klein's statement. He mentions that [illegible] worked with a dialyte of [illegible] aperture [illegible] the fine definition of which [illegible] instruments of much larger [illegible] the exhibition of the most minute [illegible] However, in order [illegible] to get more [illegible] he was induced to order a refractor [illegible] from Reinfelder and Hertel [illegible] that firm [illegible] an instrument of six inches aperture [illegible] which would be entirely satisfactory in respect both of achromatism and definition. The telescope was accordingly made and delivered to Dr. Klein, who observes that the testing of such an instrument is a very delicate affair, requiring above all a great deal of time, and he states that he had used it for two years before giving a definite opinion in regard to it.

He says, in speaking of its performance, that it has a secondary spectrum of violet blue. The light of the instrument was the first thing to strike him, and quite surprised him. He had repeatedly seen with it the companion to Sirius, as also the second moon of Saturn, Enceladus. It showed the feeble satellite of the Comes to Beta Equulei clearly at its position angle of [illegible], though he was not previously to the observation aware of its position. With this instrument he was enabled to recognise in the Nebula of Orion those delicate gradations of light and shade which are represented in Temple's masterly drawing. He sees the 5th star of the Trapezium, but has not hitherto been able to detect the 6th star. *In the course of last December* (i.e., the December of 1881) *there repeatedly appeared to him to be a minute feeble star twinkling in the middle of the Trapezium* (uebrigens kam es mir im vergangenen December wiederholt vor, als flimmere in der Mitte des Trapezes ein schwaches Sternchen). He adds that he does not doubt but that under favourable conditions the 6th star of the Trapezium would be also visible in his instrument; but he cannot credit those who allege that they have seen both the 5th and 6th stars with apertures of 4in. or even less.

In the case of η (Eta) Orion, the principal star with a power of 550 is widely separated from its companion, and the interval between them is equal to about half the diameter of the star discs.

The equatorial belts of Saturn are, under favourable conditions, shown covered, as it were, with light clouds. The ring shows Cassini's division (that is, the principal division) very sharp, but of Encke's division he has till now only seen traces at the ansæ (habe ich bis jetzt auf den Ansen nur Spuren gesehen). When the air is good the limit of the dark or crape ring is very distinctly defined *on the side next the planet*; on its side next the bright ring he cannot observe any separation between the dark and bright rings, and he does not believe that any definite separation exists.

Jupiter shows a multitude of details, but in the case of this bright planet the violet halo of the secondary spectrum is extremely noticeable (äusserst augenfällig). The same holds true for stars of the first magnitude.

He has, however, chiefly used the instrument for observation of the Moon. With a power of 550 the multitude of details observable on the lunar surface is so great that it would be an endless task to enumerate them.

So far Dr. Klein. I would remark, by way of note, that it seems strange that Dr. Klein should have repeatedly seen what appeared to be a feeble star in the middle of the Trapezium whilst he admits that he could not see the 6th star. In reference to this star in the middle of the Trapezium, the following curious corroborative observation appears in the *Observatory* of March, 1882, in the shape of a letter from Mr. Byles:—"Professor Hall states that he was not able to detect a star within the Trapezium. Some years since, my friend, the late W. Bateman Byng, formerly member of the R.A.S., was observing the Trapezium with power of 400 on a Ross 4¼ object-glass. He exclaimed to me, 'Look, look! You see an *indistinct* star in the centre of the cavernous sky beyond our system, and in the depths of eternity.' And so I did.—Jeremiah Byles, Ipswich, December, 1881."

Can it be that this central star, which has not been seen with large apertures, is surrounded with a nebulous halo, and so, like the nebula in the Pleiades, is best or only seen in instruments of moderate apertures? Or is it a variable star? Or finally, is it an illusion, occasioned by coruscations from other stars in the Trapezium?

In regard to the colour shown by the Munich refractor when directed on Jupiter and stars of the first magnitude, it seems to me strange that an instrument otherwise so good should be defective in achromatism. I have two refractors about 4in. aperture, and they both show Jupiter and the largest stars free from colour, though in regard to double stars they have no great separating power.

It will be seen from the far too short notice given by Dr. Klein of the performance of a dialyte by Plössl that continental makers have made excellent telescopes of that construction, while, singular to say, English opticians by their own confession have failed in making good dialytes. By the way, should this meet Mr. Bradbury's eye, I would wish to ask him if there is any particular virtue in the curves of long focus given by Professor Smith in his account of his dialyte—viz., for object-glass one radius [illegible], the other radius [illegible] focus [illegible]. Would not a plano-convex of the same focus—viz., [illegible]—theoretically answer as well? Again, for flint corrector, one radius is 161·1in., the other 9·973in. Would not a plano-concave of, say, 10in. radius for concave surface do as well? Otherwise, it will be difficult to get opticians who have tools to give the particular curvatures specified by Professor Smith.

In this connection, I would mention that while Dr. Klein could not see the 6th star of the Trapezium with an ordinary 6in. achromatic, Professor Smith states that with his dialyte reduced to 6in. he saw both the 5th and 6th stars of the Trapezium. We may infer from this that the dialyte is at least equal in light to an ordinary achromatic of the same aperture. Meanwhile, I desire to cordially thank Mr. Bradbury for the valuable information he has given us respecting that instrument.

Having propounded the above queries, and made the above notes, I take my leave. Before doing so, however, I must record my grateful acknowledgments to Mr. Wassel, whose elaborate papers on the figuring and testing of specula appear to me the most valuable contributions to the practical construction of the reflecting telescope that have ever appeared in this or any other journal. They well deserve to be republished in a separate form.

James Dunlop.

Bonnington-bridge, Edinburgh.

TRICYCLES.

[22103.]—Your correspondent "E. B. S.," in last week's issue, refers to various chain and direct-action machines, but does not even mention cog-wheel action, which is surely as important as the former methods. I now ride the "Folding Excelsior," and find it splendid for all-round work. This part of the country is very hilly, but I find no difficulty in keeping up with double-drivers, and down hills can keep even with all the front-steerers I have seen. On level ground it is not so fast as some other machines, for, being geared level, the very quick pedalling required is tiring after a while; but its great breadth, and length of backbone, make it remarkably safe down hill, enabling higher speeds than eight miles an hour to be indulged in with safety.

"E. B. S." is right about the brake wearing away, as it frequently requires to be renewed; but the tires ought not to be replaced in less than four years. I cannot agree with him about back-pedalling, for having several times met restive horses that would not pass my machine, I have had to go back when there was not time to turn. Besides, back-pedalling up hills is a great help in certain cases.

"E. B. S." says the narrowness of the Coventry "Rotary" is a disadvantage when turning corners, although convenient for entering narrow doors. The "Excelsior," having the folding arrangement, has this advantage over the "Rotary," that it will go in a narrow door, and yet is so wide, when open, as to be quite steady round corners. Of course the folding framework adds weight, but that is turned to account by the greater stability obtained.

A letter from "D. H. G." would be welcome now, and I should be glad to see the opinions of other riders of "Excelsior" machines.

Ventnor. **C. J. Ryan.**

[22104.]—To "Y. B." (22056, page 264).—With reference to this matter, although I am not a tricycle rider, I should think a level geared 48in. Premier front-steerer, about 80lb., or other of the same type, would suit. A band brake is preferable. "Y. B." has evidently not had enough practice on the Otto. It is not to be learnt in a few days. By this I mean that a beginner cannot expect to become an accomplished rider in such a short time. In learning he finds that he can first ride on the level fairly, but not up hill. This is because he is not very confident about his balance, and consequently does not ride so vertically as he would later. This only comes by practice, and if "Y. B." will persevere, in a little while he will discover and appreciate the good hill-climbing qualities of the Otto. He will by this time, by using the straps, and, riding almost vertically and with their assistance, be able to ascend any hills that tricycles of like gearing can, and probably some that they can't. I should like to take this opportunity of stating very strongly that when riders publish hill-climbing feats, they should mention the gearing of the machine, as I am sure many are geared down. I have not yet heard of a tricycle geared 56 level ascending Muswell-hill, though I read the cycling papers. The spinning round that "Y. B." complains of may come from two causes. He either turns the steering handle a little without thinking, or in back pedalling one of the bands might slip if they were at all slack. It may be laid down as a rule that the handles should be turned inward when back pedalling; but if the machine is properly adjusted the brake alone will be powerful enough. The bands, if not lined, are liable to slip in wet weather. Screwing down the springs a little will tighten them. I have never heard of one breaking, and should think it quite impossible with ordinary usage. If one did, I might be the result. To guard against this, I fix a thin piece of wood as a shield, which would not only protect the hand from the point of the tool, but which also, being inclined downwards, catches the water occasionally thrown off by the tool and returns it into the trough of the grindstone.

M. A.

WIMSHURST V. VOSS INDUCTION ELECTRICAL MACHINES.

[22111.]—In an earlier number of your excellent paper I noticed certain comparisons drawn between the above machines, and I saw a suggestion thrown out that a trial of their respective merits should be made. I have, since that time, seen no further notice of that trial, and as I was anxious to obtain information on the subject I had two sample machines made.

After a series of trials with these in all states of the weather, I have arrived at certain conclusions which I thought might prove interesting to the readers of the English Mechanic.

The glass plates of the influence machine are 14in. in diameter; those of the Voss are 16in. and 18in. respectively—the 16in. plate being, of course, the one which revolves. Both machines are made according to orthodox patterns, the directions for the influence machine as taken from *Engineering* being the inventor's own as far as I know.

I made a comparison of the machines on the following points:—

(1) The ease with which the current is generated.
(2) The liability to redistribution of the electricity on the plates.
(3) The intensity of the spark.
(4) The quantity of current evolved, as tested by the time taken to fully charge a Leyden jar.
(5) Length of spark.
(6) Ease of manufacture.
(7) Stability of the machines for the purpose of carriage.
(8) Cost.

I obtained the following results:—

(1) In perfectly dry conditions of the atmosphere, or as nearly dry as we can obtain, both machines start as soon as the plates begin to revolve. But when the air is more charged with moisture, the influence machine starts much more readily—that is, it requires fewer turns of the plates before the current is induced.

(2) The distribution of the electricity on the plates of a Voss machine is one of the most annoying points in the machine, for it is constantly varying, and the slightest circumstance, such as slackening or increasing the speed, will cause the electrodes to change their polarity—a change which, when one is working with different sized terminals to the electrodes, and exhibiting the electric discharge either in the form of a spark or a brush, causes great inconveniences in an experiment.

With the Wimshurst machine, I find that the polarity of the electrodes remains unchanged as long as one works the machine.

(3) Despite the smallness of the plates of the Wimshurst machine, the intensity and thickness of the spark is far greater than that produced from the Voss machine, and the report of the spark is far louder.

(4) I fill the same Leyden jar from the influence machine in half the time that I require when using the Voss machine, with the plates running at the same rate of speed.

(5) The length of the spark obtainable from the Voss rather exceeds that obtainable from the influence; but differences in insulation and in the size of the plates must be taken into account.

(6) In the ease of manufacture—"a great point with amateurs"—the influence machine, from the smaller number of parts and the greater simplicity of design, appears to me to be the most valuable, though merit must be given to the Voss machine for greater style in appearance, which is a point, however, that is not by any means an essential in an instrument intended for work.

(7) The stability of the Wimshurst machine, as shown in the ease with which it can be transported without fear of breakage, and in its compactness, without, at the same time, a sacrifice of insulation, far exceeds the stability of the Voss; for unless the fixed plate of the Voss is very firmly held, and with such insulating materials as vulcanite, which much increases the cost, the machine is very liable to breakage.

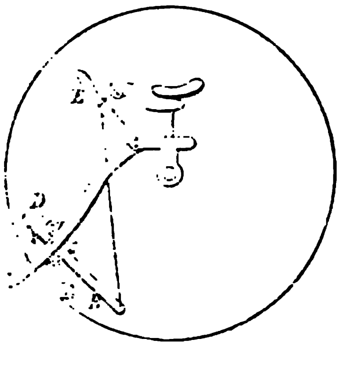
(8) As there are far less working parts and greater simplicity in construction, the cost of manufacture of the influence machine is necessarily less than the Voss.

I have made these experiments in an entirely disinterested spirit with a view to gaining information for myself, and I have tried to act fairly in judging the merits of the two machines; but every test has gone to prove to me the superiority of the influence machine in nearly every point, and as a machine for classroom, laboratory, or lecture table *I consider it* invaluable.

November 27th. **A. J. Walter**, Dulwich.

SIMPLE AUXILIARY POWER FOR TRICYCLES.

[22112.]—This is not intended for application to tricycles in the course of manufacture, but as a simple addition to tricycles already in existence, but without hill gearing. As will be seen from sketch,



it can be applied to either front or rear steering machines, though this is supposed to be a front steerer—a "Salvo," for instance. I should very much like to have the opinion of such as "D. H. G." and others competent to judge. I don't think it needs much explanation.

A, ratchet wheel 6in. diameter; B, lever 18in. long, working freely on same shaft by pulling handle C, which is attached to lever by catgut cord; the pawl engages with the ratchet and helps the feet; when not required it may be thrown out of gear by placing the toes on pawl at D and drawing it smartly back, which will cause it to revolve till the pin at the end of pawl rests on lever; the ordinary purchase handle may now be used, and the machine will run without any extra friction. The position of pawl when out of gear is shown by dotted lines; a smart tap with the toes from beneath throws it in gear again. Of course, the same arrangement can be fitted to both sides of machine if desirable.

E. P. R.

KEY CHARACTERISTICS OF MUSIC.

[22113.]—I must certainly object to the statement of your correspondent (letter 22068) that "it is entirely through defective tuning that the key characteristics arise," as I have frequently noticed they are very clear to me when the instrument is very carefully tuned to equal temperament.

As a practical tuner I must also take exception to what he says about "an experienced tuner's ear," the great point being to get the circle of fifths equally flat, independent of any scale whatever. But supposing they are perfect, as he seems to imply (evidently he does not mean them tempered), then, before he gets very far, he will find his thirds getting very sharp and his "six keys" anything but well tuned. The E will be too sharp for the key of C, and the B still worse for G, &c.

Again, supposing he is right, all tuners must take the same plan, or what becomes of the peculiarity of each key?

Sutton in his "Elements of the Theory of Music," page 41, says:

C is bold and massive.
D strongest of all keys.
E flat warm and beautiful.
E bold rich and clear.

In regard to the inequality of semitones, I hope the "experienced tuner" would not leave them so unless ordered to do so, as it is not equal temperament at all, and the instrument is not in tune in all the keys.

I seem to feel something of the characteristics when playing myself, but not when other people play, and I also find that if I test those who appear to hear them strongest, by modulating in a roundabout way to destroy the tonality, so to speak, they very soon mistake E-flat for E-sharp, and make soft flat keys bright sharp ones, and vice versa.

That there are some peculiarities in them I should say there can be no doubt, but I do not think it lies in the direction pointed out by Mr. Hardie.

H. Gnidrah.

[22114.]—I think if Mr. Westwood Oliver (p. 283) refers to Helmholtz again, he will find that the distinguished German meant musical keys on a justly-intoned instrument. To sensitive ears the keys on equal-tempered instruments are, no doubt, readily distinguishable; but if any one can detect the difference on say, Colin Brown's voice harmonium, or on a violin played by a master, it can only be by a nice appreciation of pitch, for the keys on justly-intoned instruments are all alike, except in pitch. It is not much use to speak of orchestral music, for even with the most expert players, the instruments are never absolutely in tune during a whole evening's performance. Surely Mr. Hardie and Mr. Westwood Oliver know that this question of key characteristics was thrashed out in Vols. XX. to XXVI. (I think) by, amongst others, the late Capt. J. Steel, Rev. H. C. Key, and others.

N. E. Child.

THREE-MANUAL REED ORGAN.

[22115.]—In No. 969 of "ours," you illustrate a design for "three-man. reed organ," by "Joiner." Now most exhaust instruments are heavy of touch. In looking over "Joiner's" sketch the same result would seem to happen. There is the great organ with two or more pallets to each key. Then great to swell makes a 3rd and to swell oct. a 4th pallet. What will "Joiner" do to keep the touch from being heavy? I should like to know, as I contemplate a two-manual of about nine rows.

It would seem that the two tubeboards to great, which he places vertically, and each under its own pallet, might be placed under one pallet if channels of suitable proportions connected both tubeboards, with the pallet apertures half-way between. The reeds might not speak so quickly—I don't know. Has anyone had experience on this arrangement which they can give? "Joiner's" notice of this will oblige.

Leinad.

EXTRAORDINARY MESMERIC SLEEP.

[22116.]—In view of my former letter (p. 174), I have the pleasure to inform "Sigma" and all other friends of the "E. M." that on Tuesday, the 20th ult., at the Glasgow Western Infirmary, the great Dr. Nature waked up Mrs. McInnes from her long sleep of *nearly half a year*.

Slowly but surely must come the waking up of the world itself to see in sleep a much higher conservation of energy than we at present dream of in our philosophy.

May I ask "Sigma" and other thinkers to give the "E. M." their best thoughts on "What is Sleep"? Also, to give their *philosophical* rendering of the following two lines on Sleep from the inspired and inspiring Shakespeare:—

"Balm of hurt minds, great nature's second course,
Chief nourisher in life's feast."

Edinburgh. **J. D. Morrison.**

"HIDDEN LIGHT."

[22117.]—

"When yawning with my eyelids closed"
(Pray do not laugh),
I saw a light which I supposed
Was P, of which the brain's composed
[Per cent. "Saul Rymea's" disclosed
One and a half].

Newton and Huxley when they pressed
With finger nail
Their eyelids had their vision blessed,
As you no doubt 'ere now have guessed,
With gorgeous spots in colours dressed
Of Peacock's tail.

But when I try the self-same game,
With like intent,
Instead of tails of feathered game
I'm dazzled by a sunbright flame,
Although I try the very same
Experiment.

John Scott.

COILS—CHUCKS—DISSECTING NEEDLES—FISH VERSUS FLESH, AND THE ILLS THAT FLESH IS HEIR TO—RUBBER NOSES—FRET SAWS—OXYDISING SILVER—REMOVING SOLDER—POLISHING AND BENDING BRASS—"NOT TOO EXPENSIVE" BUILDING.

[22118.]—I have not sufficient impudence to call myself an expert in coil building, but I will say a little about Mr. Harcourt's coil (22088). Now, the first thing to be considered in the construction of such a coil (or indeed any other) is to get all the wire as near as possible to the coil as near as can be made compatible with *sufficient* insulation. Between each layer of secondary, Mr. H. places $\frac{1}{16}$in. of paraffin, and I should say from his description about $\frac{1}{8}$in. of something else—nearly all of which is quite unnecessary; and more than that, it has spoilt his work. The insulation should be as thin and as perfect as possible. A certain thickness of insulation is very desirable between the primary and secondary coils; but the respective coils of each should be as close as possible, and the best insulator is paraffined tissue paper. This does not want soaking in the paraffin. The best way to make it is to spread the sheet of paper on a flat board or table, and with a (laundry) flat iron made hot melt a few spots of paraffin over the paper, and then iron it in. This can then be cut in strips of from $\frac{1}{2}$in. to 1in. wide ing to the size of the coil, ar like tape, using a hot knife to wards. The joints certainly ought to be soldered; but the soldered joint should be from 1in. to 1½in. long; if they are twisted and cemented the cement is very apt to run between the wires and spoil the insulation. The joint need not be covered, as it spoils the smoothness of the winding, and will not to any appreciable extent affect the coil. These remarks are not made from hearsay, but are the result of my experience, as I have built coils which compare favourably with any others made: but in any more which I make I shall use silver solder for all joints in the secondary. It is just as easy to use as the other and makes a neater joint, and is even a better conductor than the wire itself; soft solder is a bad conductor, therefore beware of using too small a quantity, which is probably the case with the neat joints spoken of by Mr. Harcourt. I fully coincide with both conclusions arrived at in the ultimate paragraph of his letter—14 or 16 would have been better for primary.

For chucking wood in the lathe (22072), I have for some years used the boxwood spring chuck lately figured by "O. J. L." For light work, the spring of the wood is sufficient to keep it in place. I sometimes secure the work with a bolt and nut, as figured by "O. J. L.," or by a wooden ring to screw on outside; rings or hollow work will hold very securely on the outside of these chucks. I have a habit of making a chuck to suit any special piece of work, and thus a large number accumulates, and the time soon arrives when a new one will be seldom required. I back them with pieces of sheet brass, ¼in. thick, tapped to fit the lathe.

A week or two since a correspondent sent a method of fastening needles in handles by splitting the wood and tying the needle in. Now, my way is to place the needle in the vice between two pieces of brass, or hold it in a pair of pliers (the eye need not be broken off) and then force it into the end of the holder; it will be very secure and answer every purpose. The end containing the needle is now planed down with a knife, which gives it the appearance of a pencil with a very long point. This is much neater than the previous method, and in my hands has given great satisfaction.

I have reason to believe that an ailment for which I recently underwent an operation was caused by a change in diet—namely, eating an increased quantity of meat. I am led to this by reading the remarks of Mr. Allinson. Excessive meat eating is really a vice of the worst description, and I feel inclined to place it next to drunkenness. It is all very well for people to say they feel hungry after eating anything else, as some workhouse people lately said after a fish dinner; but that is owing to an abnormal and depraved condition of the stomach. That feeling, after a time, goes off, and fish can be eaten with as great a relish as flesh. I would allow a greater latitude to a man whose occupation is hard manual labour, though these, by the bye, are generally those who can the least afford to buy meat. I would certainly recommend any man of sedentary occupation to try fish for a change, and meat not more than twice weekly, and that, rabbit or poultry. There is no doubt an immense amount of disease engendered by meat eating, and I can date my discomfort from the time that I commenced to eat meat twice a day. I now eat my supper of oatmeal and milk with greater relish than I before did the meat. I think Mr. Allinson will agree with me that fish is a lesser evil than flesh meat, and that a change to even a rational diet should not be too sudden.

Will "W. G.," page 271, kindly refer to my reply (52175) and then to the original query. He will find that I did *not* recommend indiarubber noses. I ventured an opinion that they were somewhat troublesome to wear. The query referred to caoutchouc, and to that I confined myself. Though well acquainted with the method mentioned by "W. G.," I did not happen to think of it.

My advice (if it is worth having) about fret saw' (52344) is, don't use any spring; it will not act quickly. It is better to have the saw extended on a frame similar to the "Holly" and some other machines. Querist signs himself a "'Decided' Amateur"; he seems, however, to be rather undecided; hence his query. Get a look at one or two machines. Many ironmongers sell them, and he will find lots of figures in back numbers.

"E. H." (52352) would do well to try a solution of platinum bichloride.

It is very difficult to give "W. J. L." (52357) much advice, as he does not say what sort of solder it is, whether hard or soft. If the latter, heat the article in any way till the solder softens, and then brush it off with a small brush or hare's foot. The only kind of work for which a candle is at all suitable is to solder gas-pipes, and I can do that much better and cleaner with a spirit-lamp.

"Jim" (52373) must rig up some kind of a lathe, and get a circular brush made as long as his brass is wide. He can either use a brush or a piece of wood covered with leather. Brushes wear out very quickly, but they also do the work quickly. He won't want a very elaborate lathe, as the pulley and brush can be mounted on the one spindle, and placed between anything in the shape of centres. Should think, however, that the roughness had better be taken off first by hand-stoning.

"Not Too Expensive" (52382) is the secret of very much decayed building work. Don't put on the cheapest thing you can get; you will find it the dearest in the end. I am not in the building line, but I should say Portland cement and sand; but whatever is used, nails should be previously driven into the wood to hold it. Should recommend "Jim" (52387) to get a piece of wood planed up on which to hammer his moulding. The proper way would be to have it rolled between two correctly-shaped rolls. It would, I think, cost him much less to have it done where the brass is made and rolled.

Os.

CABINET-MAKING.

[22119.]—An amateur who wishes to make a drawer, or a nest of drawers, need not be deterred from making an attempt because he thinks the dovetailing requires a practised hand. This is true no doubt when a thorough good job is required; but still, the amateur can turn out a neat and strong drawer with a little care. In choosing the wood, well-seasoned stuff ought to be got: the sides of the drawer and front will vary in thickness according to the size. For instance, if I were making a drawer for a sideboard the stuff I should use would be as follows:—Drawer front, 1in.; sides, ½in.; bottom, ¼in.; back, ⅝in. or ½in. But for a drawer for a small cabinet or nest as follows:—Front, ¾in.; sides, slight, ⅜in.; bottom, ⅛in.; back, stout, ¼in. Now to work. I shall describe a large drawer, say about 2ft. long; the following remarks will apply just the same for one 6in. square. Having selected the stuff, the first thing is to plane it up. Always have a sharp plane-iron, as this is the secret of a clean cut; plane up the way of the grain that shows the cleanest cut without tears; then mark, so that you will know which end you started to plane from, make this the front end, or that part which is dovetailed into the front. Having done this, then run them into the partition to fit. I make a practice myself of fitting in the sides just as easy as the finished drawer, seldom having to put the plane on top or bottom edges after the drawer is together; having done this, square up the front and back edges from the bottom edge, put another mark for the bottom edge; next thing fit the drawer front, the bottom edge, and the ends. Fit this in tight, so as to allow for a shaving or two to be taken off when finished; the best way to secure a good fit is to fit the front a little larger on front edge than the inside edge—that is, in shooting the edges get them a trifle out of square on the edges, but only a very little, just about a shaving. The idea for this is, allowing the smallest edge inside, a greater dependency can be placed in getting a good fit when finished. Having fitted these, plough out the drawer front to the depth of ¼in. or ⅜in. to allow for the drawer bottom; that is, make a groove about ½in. from the bottom edge. Then get the back, lay it down on the bench best side up; lay the drawer front on to this, getting the top edge of groove level with the bottom edge of back—that is, to leave the back narrower than the front, the ½in. and the width of groove, then marking the length of draw front. I would not advise the marking awl, but the point of a thin knife: this makes a cleaner and better cut; shoot the ends of back, leaving the mark just on; put a mark on the back of this, showing the bottom edge. Then get a thin-toothed cutting gauge, set the tool to the thickness of the sides, but a trifle less to allow for planing, mark the inside edge of front, set the tool again to the back edge of the side, mark the drawer back; having done this, set the tool to the front, working from inside to about ¼in. or ⅜in. from the outside edge. Mark ends of front, also with the same mark the front edge of drawer side, set the gauge to the thickness of the back, then mark back end of sides. Next thing is to make dovetail; first get the sides together, then, having put them in bench screw, make the first cut about ¼in. from the bottom edge; use as thin a saw as you can get—a great deal depends on this; the next cut about the same from top edge, next cuts about 1in. apart. In making these cuts care must be taken not to make the pins too large. In filling in for dovetails, make the next cut, bearing the saw a little to the left hand, start again in the same cut, this time bearing to the right hand; when finished it ought to be about $\frac{3}{16}$ at bottom of cut, or between the two cuts tapering upwards till the both meet in the one cut. Having turned the back edges upwards, do the same, but start the cuts from the top edge, the reverse way, and set the gauge to the width of groove in drawer front, namely, the ½in. and thickness for groove. Mark from bottom edge of sides; this gives the distance for the back to come, too, leaving the ½in. and the groove open to slide the bottom into. Get a sharp chisel and chop out the small parts of the dovetails. Mix up a little red ochre and water to a thin paste, put the draw front in bench-screw, end upwards, just put a little red colour on with a brush, then the side, matching with that end of front; get level with gauge mark on the draw front and the bottom edge. Having made a small pad of whiting (that is, break up some whiting into powder, and tying it loosely in a small bit of rag), pounce through the parts chopped out, remove the side, and a first-class impression is made of the pins. In sawing these pins, just leave the white marks on, chopping out the red parts. Glue with thin, hot glue, and set aside to dry. Next measure the depth of drawer from inside to the back. Get some drawer side stuff, cut off slips, about 1¼ wide, plane up with truth to insure a good joint; plough a groove in these the same as the front, round off the outside edge; when finished, glue with hot glue on to the inside of drawer sides, getting the grooves of the slips level with the groove in drawer front. Having put in the bottom, it now remains to be finished. In fitting in, plane with a trying-plane, starting from the front edge, shooting straight to back; set the plane fine, and take a firm stroke.

A. Best.

Erratum.—**Key Characteristics.**—In my letter on p. 267, second line following the table, the word "experienced" should have been "inexperienced."—W. Hardie.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[51073.]—**Ammonia.**—The calculated sp. gr. of ammonia gas is 0·5803. Humphrey Davy found 0·5901 and Biot and Arago 0·5967. According to Miller the calculated sp. gr. is 0·5882, observed 0·69. One litre, however, at a pressure of 760 millimetres of mercury weighs, according to Biot and Arago, 0·7752gr. Its specific heat, water being taken as one, is 0·508 (Regnault). Liquefied ammonia is a colourless and mobile liquid. Its sp. gr., according to Watts, is 0·75. According to Andreef 0·6364, or according to Joly 0·6324. Its tension at – 17·78° C. = 2·48 atms.; at 0° C. = 4·44 atms.; at 10° C. = 6 atms.; at 19·44° C. = 7·60 atms.; at 28·31° C. = 10 atms. According to Miller its tension at 15·5° C. = 9 atms. It freezes into a white solid at – 75° C., and boils at from – 38·5° C. to – 37·5° C.—Lux.

[51912.]—**To Violinists who are Mathematicians.**—I beg to inform "M. W.," p. 268, that "gently plucking each string in succession" is not the proper method of tuning the violin. De Berist would have told him to draw the bow slowly and evenly across two strings at once, at the same time carefully turning the pegs until the fifths were in tune; but De Berist was an old notationist, so was Paganini, so are all the greatest violinists of the present day, and as "M. W." has discovered that defective intonation "exists in its most exaggerated form" amongst followers of this school, he will doubtless prefer his own method of tuning and playing to theirs.—T. E. D. Craven.

[51912.]—**To Violinists who are Mathematicians.**—We are approaching satisfactorily the solution of the problem we are considering. The reply of "M. W.," giving the result of his experience in the tonic-sol-fa system of music, as enabling those who have acquired a certain degree of proficiency in it, to tune with facility the violin, on their proceeding to the study of that instrument, and also testifying to the existence of difficulty in tuning it experienced ordinarily by pupils who are instructed only according to the established musical notation, justifies the insertion of the query propounded, and the consideration it has received. It is probable that the existence of this difficulty has hitherto prevented the violin from being studied, except by professional gentlemen, so much in England as otherwise it might be expected to be. Playford, in his "Introduction to the Skill of Musick," including his "Brief Introduction to the Playing on the Treble Violin" and his "Art of Descant, or Composing Musick in Parts," published in 1687, referring to the violin, recommends the beginner to tune by eighths, as easier than by fifths, and, in his quaint way, says: "To begin which, he must wind up his first or treble string as high as it will bear, and stop it in F (*i.e.*, fretted for A), then tune his second an eighth below it; then stop the second in F (fretted for D), and tune the third an eighth under it; then stop the third in F (fretted for G), and tune the fourth an eighth below that: and so," says he, "your strings will be in perfect tune." But we have yet to consider how many times per second each string vibrates when it is struck by the bow, and is in perfect tune up to a certain pitch, as the Philharmonic or Concert A. In this query will also be necessarily included what are the exact lengths of the strings, and their relative dimensions and proportions. Thus it will be seen at once that it comes as well within mathematical range as that of musical ear training.—I. F. Ballard.

[51[illegible].]—**Crystal v. Paraffin Oil.**—There is a vast deal of difference in both the colour and smell of crystal and paraffin oils. Again, in the flashing test, crystal oil is known as petroleum imported from America and other foreign parts, whilst paraffin or coal oil, as it is known by, comes mostly from Scotland and parts of England. If "Querist" will address me, I will forward him samples that he may test for himself.—W. Jones, 1, Viaduct-street, E.

[[illegible].]—**Dynamo.**—"Spark" will do well to wait until the present series of articles on the subject is finished. His armature seems rather a peculiar shape, and it is impossible to say how many lamps it will light until it is made, and its E.M.F. gauged.—[illegible]

[[illegible].]—**Defective Coil in Battery.**—To "Nun. Dor."—The instrument in question is a small medical battery; the core is ⅜in. in circumference and [illegible]in. in length. What I would like to know is the sort of wire required and the quantity, and what insulation is necessary? I have the numbers of the English Mechanic for the last [illegible] months, and if you could refer me to any particular number during that time, I shall feel much obliged.—J. D.

[[illegible].]—**Improving Draught of Chimney.**—The exhaust led into the chimney would improve the draught; but the advisability of turning it in that direction depends very much on the general conditions, which are not stated.—Essar.

[[illegible].]—**Watch Mainspringing.**—The subject was, I think, explained with tolerable completeness in Vol. XXXV. pp. [illegible], 174, and certainly in many places in back numbers "Scotia" can find the directions for putting the main spring in.—[illegible]

[[illegible].]—**Medical.**—The case is far too important for anything but expert advice to be worth anything, and no expert would say what should be done without an examination of the ear.—Bolus.

[[illegible].]—**Drilling Nickel.**—As a rule nickel dulls quite fast enough if exposed to the damp; but what the querist means I suppose is some positive means. That would no doubt be a lacquer. Acids will corrode the surface.—Nun. Dor.

[[illegible].]—**Wood Pulp.**—By heating under pressure in a boiler with the aid of caustic soda.—[illegible]

[[illegible].]—**Engine Query.**—You can easily ascertain which way the engine will run by taking note of the valve movements. Take the cover off the valve box, note when bottom and top ports open, and make marks on the rod or some other part accordingly. By noting those marks afterwards you will always be able to tell which way the engine will run.—Essar.

[[illegible].]—**Lake Strangford.**—As this query has been inserted, I suppose it is of sufficient importance; but the querist would have found the information sooner in most cyclopædias—that is, by doing a simple little sum. Lake Strangford is about 17 miles long by 4 broad. The Zuyder Zee might be measured with sufficient accuracy on any good map; but if your correspondent can turn to some of the papers presented on the drainage scheme, he would no doubt find an approximately accurate estimate of its area.—Nun. Dor.

[[illegible].]—**Electrical.**—Question is most easily answered by experiment; but as the cell described cannot have an E.M.F. greater than, say, 2 volts, it seems that it will not do the work unless the lamp has a less resistance than a potential of 2 volts can overcome. It is doubtful whether any lamp has yet been made that can be worked by one cell, no matter how large it may be.—Nun. Dor.

[[illegible].]—**Cutting Circular Glasses.**—Mount your diamond in a lever arm, and put the glass on a turntable underneath. By shifting fulcrum of arm, any size circle can be cut.—Nun. Dor.

[[illegible].]—**Lathe.**—"Miner" must excuse me if I refer him to the papers on a Cheap Lathe. I do not understand everything, only just enough to arrive at the conclusion that I know precious little.—Nun. Dor.

[[illegible].]—**Cotton Spinning.**—It is not usual to put anything on the mule bands if the latter are of good quality; but if they are inferior in this respect they are in some mills rubbed with the following mixture in order to prevent rapid wear and tear. Equal parts of blacklead and soot, mixed with a certain amount of tallow and treacle to make a suitable paste.—Silex.

[[illegible].]—**Battery.**—"Salopian" should try the Powell Battery. It is the most constant and at the same time the cheapest that I have yet met with. I have used it for lighting small incandescent lamps of one or two candle power with great success, as well as for many other purposes where a constant current is required.—Current.

[52175.]—***Perspective of an Interior.***—Very many thanks to "E. H." The diagram will, no doubt, be as useful to others as it will be to me. I am sorry to find, however, that it does not elucidate the difficulty in my picture. I wrote my query in a hurry, and without re-reading it, and, consequently, did not say what I meant to say. I did not know the right place, and put my "point of disappearance" on the north wall 5ft. from the ground, and 5ft. from the west wall (always inside). I hardly know how to describe the north ceiling, but it does not *meet* the south ceiling, but consists of a quarter of a circle, therefore it extends only 7ft. 6in. in a southerly direction from its own wall. If "E. H." would kindly help further, I should be greatly obliged. The "interior" is purely ideal, though I have painted it (incorrectly) on paper. It may be the crossbar pattern on the end of sill that is wrong alone; but I think not. "I want to know."—Murano.

[52182.]—**Inks for Bonework.**—Try the following recipes:—1. Mix well with 2oz. of diluted acetic acid, 1oz. of powdered sulphate of copper, and ½oz. of powdered sal-ammoniac. To colour it red, use vermilion; and for black, add lampblack. 2. In 10 parts of nitric acid dissolve 1 of copper, and add 10 parts of water.—W. Henley Richmond.

[52208.]—**Ink for Type Writer.**—This mixture makes a good printer's ink:—To 13oz. of rosin add 1lb. of rosin oil, and 1½oz. of soft soap. Leave the solution till cold, and then add the desired colouring matter.—W. Henley Richmond.

[52221.]—**Legal.**—The directions of the testator seem to me to be perfectly plain—viz., that when the eldest son is twenty-six the estate shall be realised; then he makes provision as to the annuities, "then to my children," &c. The whole of the directions of the will, as regard the farm, seem to hang on the presumption of the landlord's carrying it on till the eldest son is twenty-six (which, I presume, will not be for six years). As he refuses to do so, you can't compel him. You do not say whether there is any other property; I expect there is, from the proceeds by sale of which the proposed annuities are to be paid. Anyhow, you must not make the division among the children till the eldest is twenty-six.—G. Russell Pridham.

[52226.]—**Equatorial Motion.**—I fear I have not made my description of the equatorial motion to alt-azimuth stand very plain, and as "Lon" uses a Calver 10in. on this sort of stand, I will endeavour to describe plainly what I should do if my telescope were mounted in a similar manner. Referring to Mr. Calver's pamphlet on the silvered glass reflector, I see the representation of the stand, and from Mr. Calver's remarks I believe it has an iron cylindrical tube. I should, therefore, proceed in the following manner:—Presuming that the telescope is fixed in an observatory, I should draw a line on the floor due south from under the centre of the spindle on which the telescope turns. I I should then put the telescope directly over that line, and attach a string to one of the trunnions on which it rises and falls, and noting the distance this trunnion is from the centre of the telescope, should mark a line just as far from the meridian line, and on the same side of it as the string is. I should then take a common carpenter's 2ft. rule, and open it to an angle of 51°, or the latitude of the place. I should then place the rule on the last-made line and bring the string down to it, moving it backward and forward until the string was parallel to the upper side of the rule. Then I should mark the line as being opposite the place on the meridian line for the rod to support the telescope to turn on. As the telescope does not turn on the centre of the spindle, but around it, this mark would not be in the proper place; but it may be corrected hereafter, as described in my former letter. I should have previously stated that the stand must be truly upright, and the way to try that is to place the telescope horizontal by a level, and try it when over each leg of the stand, packing each up as required, until the telescope is truly level in all directions. If a spirit level is not to be had, a convenient one may be made by nailing three laths together like the capital letter A, the cross lath being placed low, and a plumb line fixed to the point at the top and hanging just below the cross lath; then placing the legs on a table or bench, mark the place where the line cuts the cross lath; turn the level round, placing each leg where the other stood. Mark again, and half-way between the two marks is the place for the line when the legs are level. The telescope being truly upright, and the mark made on the meridian line for the place of the hook, the next thing is the rod for the telescope to lean on. Place the telescope on the meridian line, so elevated as just to clear the wall of the room; then measure the distance from the bottom front of the tube to the mark for the hook on the meridian line. This will be the shortest length for the rod. Get two pieces of oak, 6in. shorter than this length, about 1½in. by 2in., planed up smooth and true. On one end of each fix a square tin ferrule, large enough for the other piece to slide through freely. Place each in the slide of the other, and there will be a compound rod capable of sliding out to nearly double its length, [illegible]in. thick when double, and 2in. by 1½in. when single. These sizes must be regulated by the weight to be carried; but this, I believe, will do for a 10in. mirror. On the end of each where the ferrule is not, screw into it a screw eye, the bottom one to turn on the hook on the meridian line on the floor; the top one for the telescope to rest on. The hook on the floor must be made of a piece of stout iron wire or rod six inches long, and one end bent to a right angle one inch from the end, which is to be driven into the floor, and the long end to lie on the meridian line just above the floor, so as for the screw eye on the bottom of the rod to slide over it and turn on it. It is made long, because we are not certain of the place for the rod to be fixed; but as the rod will stand aslant outwards, a few pieces of wood with holes in them may be put on the wire to keep the screw eye in its place, until the proper place for it is found by trials. The attachment of the upper eye to the telescope tube must be made thus—On the bottom of the front of the tube a piece of beech wood must be fixed about a foot long and four inches wide, having a deep groove cut in it for the upper screw eye to slide in, and a string being fixed to this eye, and passing through a pulley on the spindle of the stand, and thence to a gimlet in the front piece of wood, passed round the shank and made fast in a niche in the handle. The telescope may be raised or lowered by pulling the eye nearer to or letting it slip farther from the spindle of the stand. On the piece of the rod that stands on the floor must be a thumbscrew to fix the sliding piece at the proper height for the telescope to point at or near to the star to be viewed, and the correct adjustment must be made by the string and sliding eye in the groove on the end of the telescope. The weight of the telescope being on the rod, will cause it to fall from the meridian, and a string must be fixed on the mirror end of the telescope, and thence through pulleys to a lever fixed and weighted as described in the former article, because levers cannot be fixed on the spindle of the stand as in my telescope. The bladder clock must also drive the end of the telescope. Things being thus arranged, it will require a little contrivance to place the telescope on a star. It may be done thus—I will here remark that the readiest method of fixing the piece of wood on the front of the iron tubes, is to punch or drill four holes through the iron, and put through these holes common wood screws into the piece of wood on the outside of the telescope; by this means the wood is firmly fixed on the iron. Now to place the telescope at the proper elevation for a star east or west of the meridian, we require to know not only the declination of the star, but also to have some means to point out the height above the horizon to which the telescope is raised. The readiest way appears to be by the plumb line, thus: Fix a square piece of board on the side of the telescope opposite the eyepiece, and from the front corner, hang a plumb line to indicate the degree of elevation on a quadrant described on the board, and the degrees marked thereon. If, when the telescope is level, the line hangs parallel to the side of the board, and the scale begins there, the equator will be pointed at by the telescope when the line cuts the 39°, if the latitude of the place is 51°, and if to this you add the declination of the star, if north of the equator, or subtract it if south, the telescope will point to that star if on the meridian, and if the rod is truly placed, and the telescope bearing on it, the star should be found either east or west of that; at all events it will most likely be in the finder, and a turn of the gimlet to raise or lower the telescope by the sliding-screw eye on the top of the rod, will place the telescope on the star.—Philip Vallance.

[52230.]—**Legal.**—You can make over the money payable at your decease to your wife. Better consult some respectable solicitor to see the deed properly drawn and executed.—G. Russell Pridham.

[52242.]—**Deferred Agreement for a Lease.**—When A. took the farm for twelve months with an agreement with B. for a lease of seven years—I take it that the granting of the lease by B. to A. was conditional—that is, that A. should do certain things which he does not appear to have done. A. cannot now take any proceedings against B. for a lease, as (if you state the facts correctly) the agreement with B. was that at the expiration of twelve months B. should grant a lease to A. (as I suggest, not knowing the facts) on condition of A. doing certain acts. If A. did not do those acts, he cannot compel B. to grant him the lease.—G. Russell Pridham.

[52249.]—**Chromograph.**—"J. S. M." will find the following a good 'graph composition—viz., Water, 2 parts (by weight), glue 2 parts, glycerine, 4 parts, a few drops of carbolic acid, and sufficient powdered whiting to give the whole a milky appearance. Leave the glue to swell in the water for five or six hours, melt, and add the glycerine, carbolic acid, and whiting, stirring whilst doing so. When the ingredients are thoroughly mixed, pour into the tray or other receptacle prepared for it, and leave it to set. Wash the surface well before using. For melting purposes a large earthenware jam jar slung in a pot of boiling water will be found to answer well, but the jar must not touch the bottom of the pot. This composition is easily made, cheap, and will give a great number of copies, and the ink can be quickly washed off with a sponge and warm water. As to the method of preparing ink and "sheets" I cannot speak, never having tried to make them myself.—W. C.

[52256.]—**Brush Dynamo.**—To "Light" and W.H.E., Coventry.—If the E.M.F. of my machine is too low, what result should I get by rewinding it with fine wire on "A"? At present 26 yards of wire on each coil. Suppose I try No. 18, giving 47 yards to a lb., instead of a present No. 16, 26 yards to a lb. I have increased the speed from 1,500 to 2,000 revols., and get slightly better results in my arc light, but very far short of what it should be. Here is where I want to succeed, not being particular about incandescent lamps. At what speed would it be advisable to run A. at, to be safe when at work? So far as the construction is concerned, I have no fear up to 4,000, having run it this speed. The E.M.F. is so low that it will not draw the A. of lamp into coil, the weight being supported on springs. A reply will be esteemed.—Williams.

[52257.]—**Medical—Intermittent Pulse.**—If "D" would take 5 globules of titim in drink at breakfast, 5 globules of betonica in drink at dinner, 5 globules of thymus in drink at supper, he would find himself better very soon. Titimalus lathyris.—The properties of the milk thistle. The use of these globules bring back the normal state of the intestinal functions. Thymus vulgaris.—Common thyme is an aromatic stimulant; it is used in atony of the digestive organs. Flatulency.—From Dr. Count Manzetti, Manual, page 40.—Etheropathy.

[52259.]—**Sizes of Tinplates.**—The usual sizes of tinplates are 14in. by 10in., 15in. by 11in., and 16¾in. by 12½in. The term "common" is applied to thin plates, a box of which containing 225 plates weighs 1cwt. Every "cross" signifies an addition to the thickness of the plate. Tin plates are made of various qualities, "ternes" being the commonest and "charcoal" the best, "coke" being an intermediate quality. The cooking utensils sold by the best makers are made of charcoal tin of two or three cross thickness. Tin plates are made in the neighbourhood of Wolverhampton. There are also some makers in South Wales.—Thos. Lisle.

[52259.]—**Sizes of Tinplates.**—The usual sizes are 14 by 20 and 14 by 10, and are put up in boxes of 112 of the former and 225 of the latter size, which weigh 1cwt. The terms "commons," "crosses," "cokes," and "charcoal" signify the description; the plates being sold on the basis of 1 C, which represents one common and weighs 1cwt. of 14 by 20 112 plates, and of 14 by 10 225 plates. A cross signifies additional weight, and each cross represents a price of 6s. per box extra. Thus, if a box of 1 C costs 16s., 1 × will cost 22s., × × will cost 28s., and so on. The terms "coke" and "charcoal" represent the kind of iron of which the plates are composed. The best tinplates are procured in the neighbourhood of Kidderminster; but the largest number of works are around Swansea. I will gladly furnish "F. C. F." with any particulars if he sends his address. I may add that I am not a dealer in them, or in any way an interested party, but a regular shipper thereof to Australia, where a large quantity are sent annually.—J. G.

[52259.]—**Sizes of Tinplates.**—Tinplates are properly thin sheets of iron coated with tin, and are called after the quality of iron from which they are made—as coke tinplates, the commonest charcoal, best charcoal, and soft steel, the latter having the past few years superseded charcoal. A coke tinplate is not so well tinned as a charcoal tinplate, and, being of a harder nature, will not stand working like a charcoal: it is used for case lining, making canisters, common teapots, kettles, &c.; but for deep stamping and where much strain is required, a charcoal or steel tinplate is used. They are made principally in South Wales, and a few comparatively in Staffordshire, the principal sizes, &c., are as follows, applying alike to charcoal and coke quality:—

		Sheets. to box.	cwt.	q.	lb.	B.W.G.
1 C.	14 × 20	112	1	0	0	30
1 x.	,,	,,	1	1	0	28
1 x x.	,,	,,	1	1	21	26 easy
1 x x x.	,,	,,	1	2	14	25
1 x x x x.	,,	,,	1	3	7	25 full
D C.	17 × 12½	100	0	3	14	28 full
D x.	,,	,,	1	0	14	25 easy
D x x.	,,	,,	1	1	7	24

Further information if desired.—Henry J. Sayer.

[52260.]—**Tinware Manufacturing.**—The fact of "F. C. F., Artisan," requiring information on this subject shows that it would be imprudent for him to commence business in this line. The plant for manufacturing the articles he enumerates would cost several thousands of pounds. A list of the tools required would *occupy too* much of your valuable space; but it would include a steam engine, a large lathe, several stamps, presses, and many tons of dies. The competition in this class of goods is so keen that a thorough knowledge of the business, and a large capital, is absolutely necessary to make a profit. As a proof of this, I may say that patty pans are sold wholesale at three halfpence per dozen, this being as near as possible the value of the raw material. Your correspondent may guess how a profit is made.—Thos. Lisle.

[52268.]—**Will.**—I see no reason why Mary Jones should not take the £400 in full satisfaction, if it is mutually agreed upon; but it would be scarcely legal, because the testator (or testatrix, you don't mention which), seems to stipulate that she is to be paid "20s. weekly," &c. Of course, if she took the £400 there would be an end of the matter: she would have no further claim. I am not certain about the latter part of your query, but will look it up and try and answer you next week.—G. Russell Pridham.

[52271.]—**Lever Watch.**—1st. Perhaps in certain positions the 'scape-wheel touches the lever, or else the belly of the pallets. 2nd. Though the balance jewels are not broken or worn, they may be loose, as they sometimes are, and therefore should be fixed by making the end-stones press tightly against them. 3rd. If neither of these reasons be the real cause, I can only suppose the defect is in the motion work. Perhaps the motion wheel gets partly off its stud, and so gets wedged in its action. When the hairspring is tightly pinned in, the action of the watch is not so liable to fall off as otherwise.—A Watchmaker.

[52271.]—**Lever Watch.**—In the hundreds of watches that I have had to examine, I never found one escapement left in the conditions stated by "J. G."—i.e., escape wheel teeth foul of the "belly" of pallet; neither did I hear of the idea of shifting jewel holes to free such. I should say most likely the following are at fault—i.e., when in a hanging position the balance falls nearer to the lever, and the roller comes foul of the guard pin; and probably the ruby pin strikes the horns of lever in entering the notch, if the staff has a lot of side shake, would cause this fault. Examine the fit of staff, and see that the pivots are long enough to come through jewel holes, and very little side shake. If the pivot holes have this fault, you must either have new jewel holes fitted to the staff or turn in a new staff, which is not a difficult job for a practical man to do—about two hours' work—and no man ought to be trusted to repair watches that cannot turn in a staff. Also see that you have not bent the guard pin in cleaning. Try shake of lever at each banking, and see that there is equal run to each—just enough to see daylight through roller edge and guard pin, and that balance is free of everything; also hairspring.—G. Sumner.

[52272.]—**Superheater.**—By far the best plan would be to pass steam through separate fire. If "A. G. H." will send me his address, I will advise him as to best course.—F. M. Rogers, 21, Finsbury-pavement.

[52275.]—**Notary Public.**—A n.p. need not now be necessarily a lawyer, therefore need not serve articles with a lawyer. I believe the examination is the same as that through which an accountant has to pass to enable him to become chartered—that is a member of the Society of Accountants.—G. Russell Pridham.

[52275.]—**Notary Public.**—There are two methods by which a person may obtain a notarial faculty. First by what may be termed the orthodox way—that is, by service for five years as articled clerk to a notary, who, at the expiration of that period, must file an affidavit of proper and due service. The applicant must then produce to the Faculty Office the original articles, together with a certificate from two notaries testifying "to his skill and probity." These notaries are expected to examine the candidate; but the work is somewhat formal. Certain oaths are then administered to the candidate—namely, the oath of allegiance, the oath of supremacy, and the oath of due service. If the candidate intends to practise in London, he must then become a member of the Company of Scriveners. These formalities having been duly complied with, a notarial faculty is issued from the Court of Canterbury by the Archbishop. The total cost, exclusive of any premium, is about £50; and a practising certificate, costing £6, is needed every year. The second, or unorthodox method of becoming a notary, is to be admitted under the provisions of 3 and 4 William, c. 70, under which Act solicitors or proctors are admitted to practise as notaries, in certain districts only, on a petition being sent to the Faculty Office showing that there does not exist in the district a sufficient number of notaries. If this point be established to the satisfaction of the Court, which will also hear any opposition from notaries already in the district, the applicant receives a limited faculty, granting him notarial powers in the district mentioned only. I do not know the cost of this proceeding. This Act only admits persons who are already on the Law List, so I suppose it will not be of much service to the querist. The office of notary is of very great antiquity, having existed in the reign of Edward the Confessor. Notaries are under the jurisdiction of the Master of the Faculties. If "Banker" desires any further information, he may communicate with me privately.—Wm. John Grey, Notary Public, Newcastle-on-Tyne.

[52279.]—**N.E.R. Engines.**—If Mr. M'Donnell has not turned out any new engines, he has altered the general appearance of some of the old ones to a considerable extent by fitting them with turned-out funnels, new doors on the smokebox, &c., besides painting them a brown colour, which makes them hardly as "showy" as the old Gateshead engines used to be.—W. Thompson.

[52280.]—**L. and N.W. Engines.**—66 Experiment (Jan. 1882), 300 Compound (March, '83), 301 Economist (March, '83), 302 Velocipede (April, '83), 303 Hydra (April, '83), 305 Trentham (July, '83), 307 Victor (July, '83), 519 Shooting Star (July, '83), and 520 Express (July, '83) are the L. and N.W. compounds. They are stationed at Crewe, and (with the exception of Experiment) are fitted with the vacuum brake. Full dimensions have been given in back numbers. The engine in the Watford accident was not a compound, but "482 Pegasus," one of Mr. Webb's "Precedent's" stationed at Rugby).—J. E. Spencer.

[52281.]—**Boiling Frosted and Chased Silver Articles to Whiten Them.**—Boil in a strong solution of cyanide of potassium. Be careful with it—being a deadly poison; afterwards wash with soap and warm water, and dry in fine boxwood sawdust.—Henry J. Sayer.

[52283.]—**Surveying Instruments.**—Get Heather's "Mathematical Instruments," by Crosby Lockwood and Co., 4s. 6d.—C. R. T.

[52284.]—**Telescopic Field of View.**—Mr. Webb in "Celestial Objects" says nothing about focus, aperture, &c.; but simply to note accurately the time taken by a star or planet on or near the celestial equator in passing centrally across the field of view. This, in minutes and seconds of time, multiplied by 15 will give in minutes and seconds of arc the result required by "E. M. R."—Arthur Mee.

[52284.]—**Telescopic Field of View.**—Mr. Webb in "Celestial Objects" says nothing about focal length, &c., in this connection; simply to note the exact time in minutes and seconds taken by a star as near as possible to the celestial equator in passing centrally across the field of view. This quantity multiplied by 15 gives diameter of field in minutes and seconds of arc. If "E. M. R." and other querists would procure the absolutely invaluable treatise referred to above, much space now devoted to astronomical inquiries might be saved. Arthur Mee.

[52286.]—**Observatory Instruments.**—"E. M. R." will find what he wants, I think, in Mr. Lockyer's valuable book, "Stargazing, Past and Present"; in Dunkin's "Astronomy," one of Lardner's series; and in "Chambers' Descriptive Astronomy."—C. R. T.

[52289.]—**How to Leave my Property.**—I should advise this querist to see a solicitor, as his affairs appear to be too complicated for a reliable reply to be given here.—G. Russell Pridham.

[52289.]—**How to Leave my Property.**—Is not this question rather "too too"? Surely, it is the duty of every good citizen to pay any tax legally levied, and not seek to evade it. If the tax is unjust, by all means get up an agitation and seek its abolition; but while it is the law, I think it is scarcely honest to seek to evade it. I make these remarks because I see it stated that a certain very rich nobleman (save the mark!) has evaded a payment to the State (that is, the nation) which, according to the law, would have been due if the law had not been evaded.—Nun. Dor.

[52294.]—**Legal.**—B. having become security to the bank for £50, can be compelled by the bank to pay. B. has his remedy against A. if he is compelled to pay. If B. at the time had not got his bankruptcy annulled, and the bank were cognisant of the fact, they acted most improperly in accepting him as security; but if they were not told this, then the money was obtained by fraud, for which they could prosecute A., as, no doubt, he was aware of the fact; which, however, they would first have to prove.—G. Russell Pridham.

[52296.]—**Nearest Fixed Star.**—Alpha Centauri is stated to be the nearest, and its distance over 200,000 times that of our sun. The estimate in *Girl's Own Paper* is obviously a slip—it may be a printer's muddle. "Stellarius" is surely somewhat severe on the conductors of an excellent journal which does not pretend to be scientific.—Arthur Mee.

[52296.]—**Nearest Fixed Stars.**—If "Stel rius" will refer to page 480 of "Chambers's D scriptive Astronomy," he will find a table [illegible] stars with their parallax, &c., which may interest him, a few of which, with the Editor's permission, I give below:—

Star.	Parallax.	Distance.	Time of Light Reaching the Earth.	Observer.
		Miles	m. s	
Sun	[illegible]	[illegible]	[illegible]	
		Sun = 1.	Yrs.	
[illegible]	[illegible]	[illegible]	[illegible]	Maclear
[illegible]	[illegible]	[illegible]	[illegible]	Auwers
[illegible]	[illegible]	[illegible]	[illegible]	O. Struve
[illegible]	[illegible]	[illegible]	[illegible]	Von Gylden
[illegible]	[illegible]	[illegible]	[illegible]	Brunnow
[illegible]	[illegible]	[illegible]	[illegible]	C. A. F. Peters
[illegible]	[illegible]	[illegible]	[illegible]	C. A. F. Peters

—[illegible]

[illegible]—**Bunsen Battery.**—Will "Electrician," who replied to this on p. [illegible], kindly tell me the size and number of the chromate cells required to [illegible] of platinum wire, No. 26 B.W.G. [illegible], and the relative proportions of the inner and outer cells that they may become connected together, and the relative areas of the two elements to produce the best results. Also the best plan of keeping the battery in good order when it is only occasionally used, as it would not be required for more than half an hour at a time. What are the red and white salts of the Fuller battery composed of? "Electrician" says "the same position of the elements are retained as in 'Bunsen,'" and then says "the bichro. solution is to be placed in [illegible] vessels, and the dilute sulphuric acid in the inner one." Now, as in all Bunsen cells that I have seen the carbon is in the inner, and the zinc in the outer, does he mean that the bichro. solution is to be put with the zinc, and the sulphuric acid with the carbon? Or is it a misprint?—[illegible]

[illegible]—**Bunsen Battery—Altering Form.**—If the fumes are the only objection, why not place the battery out of doors? To alter the form, take out the nitric and sulphuric acid, wash cells and buy some gas-retort carbon, which is sold at [illegible], and coarsely-granulated oxide of manganese, [illegible]. Break carbon into small pieces about [illegible] and with an equal part of the oxide of manganese fill up the porous cell to within [illegible] of the top, after placing in the carbon block; then cut a piece of cardboard to fit the top of the porous cell, with a hole to allow slipping over carbon block and a hole at side about ¼in. diameter [illegible]. Now remove clamp from top of carbon block and wind round a piece of copper wire twice, twisting tightly with pliers, leaving about a foot attached. [illegible] pitch [illegible] porous cell, and, with a [illegible] brush [illegible] carbon block, [illegible] porous cell [illegible] all round. It is now finished, and may be set aside to harden. [illegible] bottom and [illegible] a piece of copper wire [illegible] brush with hot pitch [illegible] inside and outside. When this is dry place with porous cell in jar, which three-parts fill with water; add [illegible]. Let it stand an hour or two, and you will have a capital constant battery. [illegible] without giving the slightest trouble.—Harry [illegible].

[illegible]—**Ice and Skating.**—My opinion is that the safest way is to break the ice at the edges, and to allow [illegible] the water. It is not so [illegible] if it were secured tightly to the [illegible].—W. [illegible].

[illegible]—**Ice and Skating.**—If my memory is correct this question was discussed in "[illegible]" a considerable time ago. I think that the ice will be [illegible] when water [illegible] rather than when [illegible] to the [illegible].—[illegible], Newcastle-on-Tyne.

[illegible]—**Methylated Spirit.**—Absolute alcohol may be obtained [illegible] with caustic lime or [illegible]. The distillate [illegible] either [illegible] water [illegible] from the air.—William [illegible].

[illegible]—**Methylated Spirit.**—The water in methylated spirit may be partially removed by treating it with carbonate of potash in the following manner: Place a pint of the spirit in a good stoppered bottle with about a couple of ounces of well dried carbonate of potash; the mixture is to be shaken occasionally for two or three days, and then allowed to stand; the carbonate is insoluble in the spirit, but having a great affinity for water, abstracts most of it, forming a dense layer at the bottom, from which the spirit can be decanted. The spirit thus obtained has a small proportion of water, which may be entirely removed by digesting it in a closed glass flask or retort, with about half its weight of fresh quicklime in coarse powder, for two or three days, and then gently distilling by immersing the flask or retort in a water bath, so as not to exceed a temperature of 200° F. The first ounce or so of the distillate should be rejected, as it contains the moisture of the apparatus. The absolute alcohol thus prepared requires to be carefully stored in well stoppered vessels, as it readily absorbs water from the atmosphere. Possibly the first part of the process would suit the requirements of "Solvo."—W. E. Haden.

[52301.]—**Locomotive Engine Cylinders.**—Inside cylinders, with valves between them, should not be made larger than 17in. to 17½in. diameter. Much larger cylinders are actually in use—18in., 18¼in., &c.; but I object to them very much, as the crank webs are dangerously thin, the bearings very short, and the valves are so crowded that the exhaust is throttled. If valves are placed either above or below, cylinders of even 22in. can be used without difficulty. I hope to see 20in. cylinders soon in use for express work, as I have no doubt that large cylinders in an ordinary engine will give better results than compounding. The "Gladstone," on the L.B. and S.C., is doing quite as good work on even less coal than the compounds on the N.W. The Midland is building 19in. cylinder engines for its Scotch traffic.—Historian, M.I.M.E.

[52302.]—**The Cheapest Food.**—There is a small book, price 6d., called "How to Live on Sixpence a Day," which, perhaps, might contain some of the information you require. I do not know who the publisher is; but a short time ago it was offered for sale at most of the stations on the Metropolitan and District railways.—Machina.

[52302.]—**The Cheapest Food.**—Dr. Nichol's "Food of Health," and "The American Breakfast Cereals" might meet the wants of "S. R." I have used both, and find that, if carefully prepared, they are most nutritious, wholesome, and cheap. Eaten with milk these foods are delicious, and quite capable in themselves of supporting the system.—Arthur Mee.

[52302.]—**The Cheapest Food.**—The cheapest foods I know of at the present time are haricot beans, boiled or baked with cuttings of fat bacon and flavoured with herbs, &c.; oatmeal and skim milk prepared in the way described by Dr. Edmunds. The latter is admirably suited to growing lads and children; the former may form the midday or principal meal of the hardworking labourer. Vegetables are, as a rule, very dear (as food) in towns; but the great aim should be to vary the diet as much as possible, though oatmeal and skim-milk (porridge) would form a better standing dish than the present bread-and-butter. Much depends on the nature of the work done by the eater, and it is nonsense to talk of the beef-eating habits of the Anglo-Saxons being the cause of the immense number of diseases. The poorer classes here get too little beef, while the Esquimaux live almost entirely on animal food, and don't want many doctors.—Common Sense.

[52303.]—**Faulty Ports.**—I think your ports are too small. I had one cylinder 3¼in. by 2½in. bore. It would just drive my 4½in. lathe, taking a light cut, at 50lb. per sq. inch. I got a stronger boiler and tried it at 100lb., and it was not much stronger, owing to the small ports and exhaust. If you cannot have any more pressure on your boiler, fix a smaller pulley on engine shaft, and run the engine from 100 to 200 revolutions per minute.—W. W. W.

[52304.]—**Legal.**—Without your permission the man has no right whatever in your timber yard: he is, in fact, a trespasser. He can, however, advertise over his gable end if he chooses, and you can't stop him. If you build on your yard and the bills are posted on his property so as to be an annoyance to you, no doubt you then could come to some arrangement in the matter; but you certainly could not make him take them down.—G. Russell Pridham.

[52306.]—**Volt Meter.**—To "Sigma."—A volt meter is merely a galvanometer wound with a great length of fine wire, which may be of German silver to give resistance. In Ayrton and Perry's, which is inquired for, the magnetic field and direction power is obtained by placing the galvanometer coils between the poles of a powerful permanent magnet. I cannot undertake to give the details of construction, which would require drawings, for which I have no time. But all that is necessary is a small coil with a sharp point outside it, mounted between the poles, the needle working on the outside of the coil. The graduation can be effected by means of several Daniell cells put into circuit one after the other, so as to mark the deflection each addition makes, which is a little over one volt of E.M.F. For large currents the matter is more difficult, as the resistance must be a little over one thousandth of an ohm. The best way is to make one with stout wire, and graduate it by comparison, or by a Daniell cell and resistances, and then shunt it off to the required amount. But it would be cheaper to buy than to make.—Sigma.

[52312.]—**L. and N.W. Locos.**—136 (Crewe) and 1107 (Birmingham) are Mr. Webb's 4ft. 7½in. 8-wheeled 4-coupled wing tanks; cylinders, 17in. by 20in. 303 Hydra, one of Mr. Webb's compounds. 373 Snake (Shrewsbury) is one of Mr. Trevithick's 6ft. 6in. outside-cylinder single-wheel engines; cylinders, 15in. by 20in. 395 Scotia (Crewe), 1489 Brindley (Peterborough), and 2006 Princess (Shrewsbury) are Mr. Ramsbottom's 6ft. 6in. 4-coupled express engines: cylinders, 17in. by 24in. 463 (Stafford), 569 (Birmingham), and 1506 (Longsight) are Ramsbottom's 5ft. 2in. 6-coupled goods engines; cylinders, 17in. by 24in. 675 Ivanhoe (Longsight) is one of Ramsbottom's 7ft. 6in. outside-cylinder singles of the "Lady of the Lake" class; cylinders, 16in. by 24in. 829 Turk (Nuneaton) is one of Mr. Ramsbottom's 6ft. 4-coupled passenger engines; cylinders, 16in. by 20in. 1009 (Birmingham) and 1015 (Birmingham) are Mr. Webb's 4ft. 3in. 6-coupled wing tanks; cylinders, 17in. by 24in. 1364 (Longsight) is one of Mr. Ramsbottom's 4ft. 4-coupled saddle tanks of the 1437 class. 2401 (Chester) is one of Mr. Webb's 4ft. 3in. coal engines; cylinders, 17in. by 24in.—J. E. Spencer.

[52313.]—**Trigonometry.**—This query is one of a class seldom suitable for these reply columns. 1st. Add together equations 1 and 2.

$$a \sin.^2 \theta + a^1 \cos.^2 \theta + b \sin.^2 \phi - b^1 \cos.^2 \phi = a^1 + b.$$

Or—

$$a \sin.^2 \theta - a^1 (1 - \cos.^2 \theta) - b (1 - \sin.^2 \phi) + b^1 \cos.^2 \phi = o.$$

Or—

$$(a - a^1) \sin.^2 \theta - (b - b^1) \cos.^2 \phi = o;$$

$$\text{that is, } \frac{\sin^2 \theta}{\cos.^2 \phi} = \frac{b - b^1}{a - a^1}, \text{ put this} = m.$$

The third equation (divided by 3) is equivalent to—

$$\text{Sin.}^2 \theta - \sin.^2 \phi = \frac{b^1}{b}, \text{ put this} = n.$$

In these two equations for brevity, let $x = \sin. \theta$ $y = \sin. \phi$; then we have—

$$x^2 = m (1 - y^2)$$
$$x^2 = n + y^2.$$

From which—

$$y^2 (m + 1) = m - n.$$

Or— $$y = \sqrt{\frac{m - n}{m + 1}}$$

And from this—

$$x = \sqrt{\frac{m (n + 1)}{m + 1}}.$$

By substituting the previous values of m and n, we shall get the answer in terms of a, b, a^1, b^1.—Orderic Vital.

[52319.]—**Telescope.**—"J. P. R. A." does not give the amount of his highest magnifying power; if, however, as he says, it defines badly, there does not seem much hope of 120 doing better, and, indeed, his 1¾in. o.g. must be good to bear this on planets. With so small an aperture one can hardly advise a stop, yet "J. P. R. A." might try the effect of aperture reduced to an inch; also his astro. eyepieces with the field lenses (those nearest o.g.) removed. What does he mean by the "shadow" of Jupiter's belts?—Arthur Mee.

[52321.]—**Faulty Sewing Machine.**—One, or a combination of the following causes will account for the machine missing a stitch:—Needle not set right height; needle being broken at point, or not set right way about. Shuttle being worn generally on the face, or having caught against the needle sometimes and blunted the *nose* of shuttle, or needle and shuttle are a little out of time with each other. Examine and report further, and I will tell you how to remedy, if you find any of the above defects.—J. I. S.

[52323.]—**G.W. Engines.**—821 (806—825) are 6ft. 6in. single framed 4-coupled passenger engines, were built at Swindon in 1873 (May to September); 931 (927—946) are 5ft. double framed 6-coupled goods engines built at Swindon in 1874; 1036 (1016—1075) are double framed 6-coupled saddle tanks, built at Wolverhampton from 1867 to 1871; 1142 (1134—1153) are 5ft. 6-coupled double framed saddle tanks, built at Swindon in 1874 and 1875; cylinders, 17 by 24; 1808 (1801—1812) is a 4ft. 6in. 6-coupled saddle tank, cylinders, 17 by 24; 2201 is a 6ft. 6in. 4-coupled single framed passenger engine: cylinders, 17 by 24.—J. E. Spencer.

[52327.]—**Gong.**—Simply a piece of round steel wire bent in the form of a watch spring, fastened another for nothing. I do not like them in use, and always prefer a common blacklead pot for hard work. They are valuable for hurried experiments, but the glaze gets exceedingly sticky at high temperatures, and the crucibles rapidly foul. If "R. W. F." knows any crucible material which has not some serious objections, I should like to be informed about it.—Thos. Fletcher, Warrington.

[52360.]—**Integrals.**—(1) Multiply numerator and denominator by $x - \sqrt{(x^2 - 1)}$. We have

$$\frac{dx}{x + \sqrt{(x^2 - 1)}} = [x - \sqrt{(x^2 - 1)}]\,dx = x\,dx - \sqrt{(x^2 - 1)}\,dx$$

Integrating

$$\int\frac{dx}{x + \sqrt{(x^2 - 1}} = \frac{x^2}{2} - \int\sqrt{x^2 - 1}\,.\,dx$$

Integrate the last term by parts,

$$\int\sqrt{(x^2 - 1)}\,dx = x\sqrt{(x^2 - 1)} - \int\frac{x^2\,dx}{\sqrt{(x^2 - 1)}}$$

but

$$\frac{x^2}{\sqrt{x^2 - 1}} = \frac{x^2 - 1}{\sqrt{(x^2 - 1)}} = \frac{\sqrt{(x^2 - 1)}}{1}$$

$$= \sqrt{(x^2 - 1)} + \frac{1}{\sqrt{(x^2 - 1)}}$$

Therefore

$$\int\sqrt{(x^2 - 1)}\,dx = x\sqrt{(x^2 - 1)} - \int\sqrt{(x^2 - 1)}\,dx - \log.\,[x + \sqrt{(x^2 - 1)}]$$

or

$$2\int\sqrt{(x^2 - 1)}\,dx = x\sqrt{(x^2 - 1)} - \log.\,[x + \sqrt{(x^2 - 1)}],$$

and

$$\int\frac{dx}{x + \sqrt{(x^2 - 1)}} = \frac{x^2}{2} - \frac{x\sqrt{(x^2 - 1)}}{2} + \frac{1}{2}\log.\,[x + \sqrt{(x^2 - 1)}].$$

(2.)

$$\sqrt{(2ax - x^2)} = \sqrt{[a^2 - (a - x)^2]},$$

Put $a - x = z$. Then $-dx = dz$.

$$\int\sqrt{(2ax - x^2)}\,dx = -\int\sqrt{(a^2 - z^2)}\,dz$$

$$= -z\sqrt{z(a^2 - z^2)} - \int\frac{z^2\,dz}{\sqrt{(a^2 - z^2)}}$$

$$= -z\sqrt{(a^2 - z^2)} - \int\frac{a^2\,dz}{\sqrt{(a^2 - z^2)}} + \int\sqrt{(a^2 - z^2)}\,dz$$

$$= -\frac{\sqrt{z(a^2 - z^2)}}{2} - \frac{a^2}{2}\sin.^{-1}\frac{z}{a}$$

Now, the limits $x = 2a$ or o, give $z = -a$ and $+a$, therefore,

$$\int_o^{2a}\sqrt{(2ax - x^2)}\,dx = \frac{\pi a^2}{2}$$

—Nabla.

[52366.]—**Skates.**—Skates made with a toe and heel plate are very good, but I do not recommend having a fanciful curve on the toe part of the steel. Many accidents have arisen from them. A skate made with a steel, same pattern as the Acme, has the plates you mention, looks nice, and is very useful. You can have a curve to any shape you fancy, but avoid a long shape curve, especially a pointed one.—T. P.

[52367.]—**H.P. of Engine.**—"Ignoramus" does not say whether he requires the nominal or the indicated horse-power of his engine. I have supposed he requires the latter, as the term "nominal horse-power" is now seldom used except for commercial purposes. An engine with a cylinder 28in. diameter, stroke 6ft. 3in., pressure of steam 40lb. per square inch, and making 24 revolutions per minute, should develop 223 indicated horse-power. The rule for working this out is as follows:

$$\text{Indicated H.P.} = \frac{2\,A\,P\,R\,S}{33000}$$

or—

$$\text{Indicated H.P.} = \frac{2\,A\,P\,r\,S}{550}$$

A = Area of piston in square inches.
P = Average pressure of steam in pounds per square inch in cylinder.
S = Length of stroke in feet.
R = Number of revolutions per minute.
r = Number of revolutions per second.

—T. R. Saxton.

[52368.]—**Red and Blue Photographs.**—I am afraid I can tell you nothing about red photographs; but you can take blue prints from a negative in the following manner. Immerse a piece of paper (ordinary writing paper will do) in a solution of ammonio-citrate of iron, and allow it to dry in the dark. Use this to print your positive copy from the negative, in the same way as you would the sensitised albumenised paper. Print it until a faint image appears; this usually takes about ten minutes or a quarter of an hour in the sun, or about an hour in the shade; be careful not to overprint it—a faint image is all you require to see. Then take it out of the frame, and in a darkened room immerse it in a solution of ferro-cyanide of potassium; then well wash in cold water; then immerse it in a solution of bichromate of potash, which will cause it to turn to a fine blue; after this well wash it and let it soak for a few minutes. The picture is then finished.—Machina.

[52373.]—**Polishing Brass.**—This is easily done with a little machinery; but I should think the cheapest and simplest plan would be a large and heavy grindstone, of, say, 8in. across, covered with several folds of tightly-drawn felt, and driven by a powerful foot treadle, the plates to pass between uprights adjusted to guide them, and to be pressed down on the felt and fed along by ths hands, being prevented from buckling by a temporary backing of strong board, which even if the plates were very thin would admit the polishing of all but the extreme ends, which could then be completed by being separately held on the stone for a moment. For curved plates this would, of course, require modification. The pumice stone in a powdered condition, or other polishing medium, might be applied by a pepper castor or flour dredger as often as necessary. Edward Conry.

[52379.]—**Banjo.**—I should say that oiling the vellum would spoil it. Keep it as tight as you can, so that the feet of the bridge hardly dent it. Always put the bridge down after playing, as, if left up, it will in time make two little "pits," which will not go away. On a damp day the vellum is always slack; but judicious warming at a fire has a very good effect. The strings should be the following (seven-stringed):—1st, tuned to D, an E violin; 2nd, tuned to B, an E, slightly thicker; 3rd, tuned to G, an A violin; 4th, tuned to D, octave below 1st, and 5th, tuned to C, one tone below 4th, a D violin, a *thin* American wire-covered string; 6th, tuned to G, octave below 3rd, a thicker wire-covered string; 7th, or "thumb" string, tuned to G, octave above the 3rd, an E violin, thin. For a six-stringed 'jo, the 5th string is done away with; for a five-stringed, the 4th and 6th; at least, this is my arrangement; but different players have different customs. I always use a seven-stringed instrument.—An Amateur Banjoist.

[52379.]—**Banjo.**—If it is the banjo pure and simple that "A Lunitick" wishes to play, the less he alters the quality of its tone the better; but if he would like in its place some nondescript instrument, he may, by either employing a thicker vellum, or by putting a slip of pine from rim to rim under the bridge, or even by substituting a wooden for a skin soundboard, modify the tone to any quality he pleases; though he would find that, as the tone improved (?) it would lose the rollicking "tum, tum" so characteristic of the banjo. Banjos as usually sold are rather gingerbread affairs, or I would recommend a covered fifth string and thicker gut throughout. It might, however, be well worth while to divide the finger-board into a scale of semitones, guitar fashion. This may be done by placing pieces of ivory or hard wood veneer just where the half-tones come, allowing for pressure by the finger, and testing by a correctly-tuned piano or harmonium. These pieces can be let into saw-kerfs and fastened with glue. For rapid execution they will be of the greatest service, as they not only make it impossible to stop out of tune, hut give a clearer ring to the stopped notes to afford greater facility to the fingering. I am afraid our old friends, "Fiddler" and Mr. Schucht, will think I also am somewhat of "a lunatick" when I say that the banjo deserves next rank to the piano for domestic music. The pity is that it has been so associated with nigger melodies that directly it is heard one naturally expects a clatter from the bones, or some outlandish conundrum that would be quite out of place in a drawing room. —W. H. Davies.

[52379.]—**Banjo.**—You may appropriate the following ideas, patented by Temlett, A.D. 1869, viz., improvements in banjos and certain other stringed instruments. In banjos the hoop (on which the vellum is stretched) is inclosed "in an outer casing or sound-box," and the back is made with double sides formed by the inner and outer hoop or casing. The inner hoop is, by preference, made of less depth than usual, so as to extend but a short distance within the outer box or casing. The perch of the neck, instead of passing through the inner hoop, is carried below it, and passes through the sides of the outer casing, to which it is secured in any suitable manner. The tailpiece is connected to the end of the perch as usual; the means of attachment, however, pass down between the inner hoop and casing, and serve to keep the latter securely in position. The tension of the vellum is regulated by screws taking into brackets on the inner hoep, and worked from the front by a key. Also another patent, A.D. 1867—viz., to render the instrument portable. The neck or finger-board is made in two lengths, united with a hinge. When played upon, the joint is kept extended by a hook, otherwise the player can pass an elastic band over the strings above the joint, and another just below the pegs, unfasten the hook, and fold over the top part of the neck on the front part of the tambour, &c. Don't oil the vellum, which should be dry and warm; and you might try very thin steel wire for some of the strings. Now, if you lay the banjo on a table, face up, it will sound better, proving that it wants more body, and to do this means a larger sounding surface, which we have in a guitar and violin. You can add a larger surface by adding a box, or a curved form of wood, to your banjo; it would have to be quite 8in. deep, including the present hoop. This would be awkward to hold, while 4in. would do very well to hold. Yet this might be got over by having two hoops or banjo bodies joined together at their sides, as a figure ∞ with the middle of the figure cut out, forming an indented oval. This would be a guitar without a back, and altogether too long; so there is no remedy, seeing that the banjo is only an initial instrument. Gut strings covered with silk are most in use, requiring constant tuning. I should try a deeper body, if I were you.—Fiddler.

[52386.]—**German Lacquered Mouldings.**—These appear to me to be covered with tinfoil. Try a coat of glue (hot and clear, and not thick) brushed over the plain moulding, and then lay on a sheet or strip of new pure tinfoil, and wipe with a rag or stipple with a soft brush into all the pattern. It would have to be done quickly. When it was quite set, say the next day, it would require to be washed very quickly and dried by heat, and lacquered whilst perfectly dry and hot, and in a hot room. I think you would not be able to make your own lacquer to your own satisfaction. It would be better to buy "gold lacquer for tin."—Murano.

[52387.]—**Absorbent Cotton Wool.**—This is made, I believe, by immersing ordinary cotton in a hot solution of weak caustic alkali, and afterwards thoroughly washing in a stream of water and drying. I have used large quantities, but never made any; the information is, therefore, only second-hand.—Thos. Fletcher.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

A New Otto Tricycle.—At a complimentary dinner given to Mr. F. S. Hunwicke, last Tuesday, at the First Avenue Hotel, to commemorate his remarkable ride from London to Edinburgh, 402¼ miles, in 4d. 15h. 5m., a new Otto tricycle was shown in model form. This machine is a centre driving front steerer, with several features of novelty and usefulness. The wheels, for instance, are much narrower than usual, and have a series of spokes in the plane of the rim, with the outside and inside spokes acting as stays. By this means remarkable strength, with great lightness, is obtained. The steering is effected by means of the usual bar with gearing through the tube supporting the front wheel, and is so arranged that the rider's body is naturally inclined in the same direction as the machine turns. The band brake is very powerful, and is applied by means of one of two studs on the steering bar worked by the thumbs, one being sufficient to apply the full power, while a handle behind the head applies the brake until it is released. The saddle and driving gear are mounted on a swinging frame, so that the rider takes automatically the best position for exerting his strength. The machine is mounted from behind, and can be left at a moment's notice. The Otto tricycle will undoubtedly attract much attention when it is introduced next season.

QUERIES.

[52388.]—**Warp Winding.**—Will some reader explain the drawing of a heart for a warp-winding machine ? or what lines are used to draw a heart right ? as I see they are not all the same.—An Apprentice.

[52389.]—**Sulphuric Acid.**—Will some kind friend show me where I have gone wrong in my method of finding the specific gravity of a mixture of sulphuric acid and water ? Let me take a mixture containing 76 per cent. of acid of specific gravity 1842, what is the specific gravity of the mixture ?—1842 × ·76 = 1399·92, say 1400 ; this added to 1000 × ·24, the quantity of water in the solution, gives 1640 as the specific gravity of the mixture ; whereas in Thorpe's "Quantitative Analysis" I find the specific gravity for this percentage is 1686.—Chemical.

[52390.]—**Dynamo.**——I have built a dynamo somewhat after the style of the Lumley machine, with pole-pieces top and bottom, and wire wound on each side in four sections ; F.M.'s are wound with No. 14 B.W.G. double c.c. wire, 9½lb., each layer varnished with shellac. The armature is built of two rings of iron wire with three crossbars equidistant from each other in the form of a drum, and the wire wound on longitudinally outside and inside of the ring. The A. is wound with 30 sections of 8ft. each No. 18 B.W.G., the inner end one coil and the outer end of the next connected together. When charged by two bichromate cells, I get a very slight deflection of the needle. When connected so as to charge itself, I get none at all. Speed 1,000 revs. per min. I have tested the A. and F.M. for insulation, and there is no defect. Can any of our kind readers tell me where I am wrong ? Inside pole pieces 4in. ; diameter of armature 3⅜in.—Faulty Dynamo.

[52391.]—**The "Kewanee" Windmill.** — Can any of "ours" kindly inform me where I can find a fully illustrated description of the "Kewanee" American windmill, made at 35, Broadway, New York—patented December 23rd, 1873 ? as I have come into the possession of one (or rather the parts), and I wish to put it into working order. The wheel is 11ft. diam.—E. R. Dale, Godmanstone, Dorchester.

[52392.]—**Gavitation.**—Would one of your correspondents kindly solve the following ?—In Newth's "Mechanics" occurs the problem :—"A ball is projected vertically upwards at velocity of 120ft. per second. At what height will it be at the end of four seconds ?" The solution is given as follows : 120 × 4 = 480, this less the space due to gravity in four seconds ($16·1 \times 4^2$ 257·6) gives 122·4 as the answer. So far good ; but in the same book the rule given for finding how long a body projected vertically upwards will ascend is to divide velocity by 32·2 and $\frac{120}{32·2} = 3·72$, so that the body would be ascending for only 3·72 seconds altogether. Now, further, for finding how high it will ascend Newth gives the rule—16·1 × time in seconds square and $(3·72)^2 \times 16·1 = 215·74$ft. In the short interval between this and the end of the fourth second the ball could not have descended to 122·4ft., as Newth gives it. How reconcile the two workings ?—Beginner.

[52393.]—**Water Consumption of an Engine.**—Can any of my brother-workmen give me any information ? How can I get the water consumption of an engine from the actual diagrams, as the same must vary from different points of cut-off ; that is, how much water should I have to evaporate to supply an engine with steam ? Please give the water-rate in pounds. The engine is a high-pressure engine. Initial pressure 73lb. ; absolute initial pressure 28·5lb. ; average pressure upon piston 39·75lb. ; area of cylinder 388·8 ; piston speed 450ft. ; dry steam per i.h.p. 23·74 ; scale 40lb. to the inch ; i.h.p. 210·6 ; steam at opening of exhaust 11·5lb.—J. N.

[52394.]—**Electrical.**—Will any of your electrical correspondents inform me if a zinc element would last longer (when in contact with caustic soda or potash) if gilt, than when amalgamated with mercury ? I do not object to the cost of gilding the zinc if it would render the element durable ; but the caustic potash acts rapidly on amalgamated zinc. Would our kind and obliging correspondent, "Sigma," kindly reply ? I have been experimenting lately with oxide of copper batteries, and hope soon to lay the results of my experiments before the readers of "ours."—Scrutator.

[52395.]—**Dynamo.**—I think of constructing one to be driven by a ½-horse engine ; but before doing so I should like to know what parts I must not touch when it is running. Can I touch the bearings to see if they are getting hot without fear of receiving a shock ? Suppose I supply four lamps, and I shut three lamps off when the machine is running, will it spoil the other lamp ? or what would it spoil if I shut all four lamps off when running ?—W. W. W.

[52396.]—**Legal.**—To Mr. Wetherfield.—A. sells to B. a quantity of coal under land which B. rents of A. as tenant from year to year. In three or four years B. purchases the land and house also from A. On the death of B. the whole passes to C., the eldest son and heir-at-law of B. C., at his death, gives the house and land by will to D., but nothing is said about the coal, or any appurtenances thereto belonging. At C.'s death D. claims the coal as legatee, and E. claims it also as only brother and heir-at-law of C. Which of the two has a right to it ?—J. S. Saddler.

[52397.]—**Raising Water.**—Wanted a definite rule as to how many feet in height 1lb. pressure of steam will raise water in a pump, whose diameter is half of that of the steam cylinder ?—A., Coventry.

[52398.]—**Astronomical.**—What will be the latitude and longitude of the earth's surface where the sun will appear vertical at 12 o'clock on the 21st of December at noon, and 12 o'clock on the night following ?—L. H. S.

[52399.]—**Governors.**—Would some of our mechanical friends kindly give me a formula that would enable me to get the speed per minute of the governors patented by C. T. Porter (makers, Omerod, Greison and Co., Manchester) ? and formula for the Buss's governor would oblige.—A. S. Hood.

[52400.]—**Reading Lamps.**—I have a gas reading-lamp with a black indiarubber tube. The latter emits an unpleasant smell of gas and indiarubber combined. Is it possible to cure this ? Would enamelling or varnishing the tube effect the purpose ?—G. C. G.

[52401.]—**Pianoforte Tuning.**—To Mr. Davies.—Mr. Davies, in answering a query on the above on p. 191, No. 918, refers the correspondent to p. 571, No. 830. On turning this up, I find he there states to tune C to the fork ; then G a fourth below ; then tune the remaining fourths and fifths in a similar manner. Their order is as follows : G to D. D to A, &c. Am I to understand him to mean to tune G to D up, then G to D down ; D to A up, and D to A down, and so on with the others ? or what ? (2) And also in answer on p. 571, No. 830, he says the G below C is one beat flat ; and then on p. 191, No. 918, it is given that each ascending fifth is to be one beat flat. How is this ?—A. D.

[52402.]—**Pulley.**—Will any of our practical readers tell me how to set the pulley so as to drive a machine set at right angles from the line shaft, what is termed a half-cross belt, and how to set carrier pulleys ?—J. W. S. B.

[52403.]—**Repairing Dies.**—Part of my occupation is repairing dies for screwing bolts. They are solid dies, and are made from double shear steel, which I cannot temper satisfactorily ; for in the hardening of them they fly in the pillars, and if I give them a lower heat they are soft. Can any brother advise me on this point ? Also, which is the best steel for that purpose ?—Alpha.

[52404.]—**Strains.**—A span is placed on board a ship, between the fore and main masts, and a weight of, say, 10 tons is suspended on the centre of span for lifting. How can I find strain on each end of span, and is the strain altered by the angle of span ?—R. J. P.

[52405.]—**French Polishing.**—Will the author of "Carpentry Hints," or any other of our valued correspondents, kindly give me instructions ? I have made several articles—brackets with spindles, &c.—in pine and birch, which I want to be black and polished. I have tried the effect on a piece of wood of painting in black and varnishing ; but it does not suit. It gives the wood a common appearance, and not the nice smooth effect of polish with which the Early English styles of furniture are finished. Any information will be thankfully received.—J. Watkinson.

[52406.]—**Cylinder Electrical Machine.**—To Mr. Lancaster and Others.—I have made the machine as follows : Cylinder consists of a glass gas jar 8in. long and 4½in. wide, and open at the bottom : to which I have cemented a circular disc of wood fitted with a wooden axle, and I have gummed three strips of tinfoil 3in. long by 1½in. on the cylinder. The rubber is a piece of leather stuffed with horsehair and tacked on a thin lath of wood. As to the prime conductor, I cut a piece of wood about 4in. long off a broomhandle and covered it with two thicknesses of tinfoil ; one end I fixed a brass ball in connection with the foil, and the other a piece of brass wire in the shape of a  with eight brass points which I soldered on the wire. The whole is supported on a piece of glass tubing, the points being about ¼in. from the glass cylinder. When the machine is set in motion (the rubber in connection with the earth by means of a length of brass chain) I get no spark from it ; but on presenting my knuckles to the brass ball, I felt a sharp pricking, but observed no spark. How is this ? Have I constructed it right ? I should be much obliged for information on the matter.—A. N. A.

[52407.]—**Oxy-Hydrogen Lantern.**—As I am using the oxy-hydrogen lantern weekly in public, and am somewhat inexperienced in the use of the mixed gases, I shall be glad to know if danger is to be apprehended from any other cause than unequal pressure on the bags, and also whether equality of pressure must be exactly preserved—say to an ounce or a pound ? Will the use of double-pressure boards entirely remove the possibility of accidental explosion ? Does pure hydrogen help to produce a better light than when the carburetted is used ?—W. Hobbs.

[52408.]—**Skin Disease.** — A poor hardworking mechanic has had for some time a kind of eruption on his left leg, on the knee, and on the calf, which has somewhat the appearance of ringworm. It appears at first like a portion of a small red ring, between the size of a threepenny-bit, and a shilling. It yields to tincture of iodine, but again appears somewhere else, or perhaps in the same place. He says it is at times rather itchy. Can it be ringworm ? Does ringworm appear anywhere except on the head ? Would Dr. Edmunds kindly suggest a remedy ? Is it infectious or contagious ?—Mechanic.

[52409.]—**Legal.**—A. dies and leaves some of his property to B., at whose death the said property to go to her eldest son C. The son dies before his mother, but leaves two sons. Does the property at the death of B. go back to the estate, or will C.'s children take it, or the next son of B. ? Can B. will it to whom she likes ?—Brighton.

[52410.]—**Dynamo Machines.**—Can any of your readers tell me what relation the thickness of the wire on the armature of a dynamo-electric machine bears to the electromotive force and to the quantity of the current produced ? Is the relation constant or variable, and does it depend on the weight of wire or on its surface ?—A. G.

[52411.]—**Cheap Lathe.**—With reference to the last article on this subject : As there are many amateurs who, like myself, have not access to such a large lathe as would be required to bore out the headstocks in the way described, would the writer or some other competent subscriber say if there is not some other way of boring the heads, and explain how ?—Amateur.

[52412.]—**Painting Lantern Slides.**—Can any correspondent inform me how to mix or make colours for lantern slides that will dab deeply and evenly, and at the same time dry well ? I can get very good daylight effects with the ordinary artists' colours, but cannot get deep colours—as for moonlight. Moreover, they do not dry well, even with baking. I should also like to know if there is any mechanical means of taking out a moon so as to be sure of getting it round and clear.—E. W.

[52413.]—**G.N.R.**—Does Mr. Stirling continue to build 8ft. singles ? What are principal dimensions of latest class of four-coupled express ?—J. E. Spencer.

[52414.]—**G.W.R.**—Can any reader oblige me with the number and dimensions, &c., of (1) the 6-c. named and numbered B G. goods ? (2) 4-c. B.G. (3) 4-c. N.G. side tanks without condensing pipes. (4) A new class of 6-c. N.G. tender goods without dome (No. 2301, &c.). (5) 6-c. N.G. side tanks, without dome (No. 1815, &c.). With reference to railway speed, I think the G.W.R. holds a good place. On the 22nd ult. the B.G. train due at Paddington at 8.10 p.m. passed Hanwell at 7.50, or about 11 min. before time. As this train is due to leave Swindon at 6.42 p.m., it gives a speed of 61·764 (70 miles in 68 min.).—T. M. R.

[52415.]—**Rushton's Self-Acting Fountain.**—To "Glatton."—I want to make a fountain as described by you in letter 51577 ; but it seems to me that if the water is poured into C, it will fill C and then rise up the pipes E and F, and nearly fill B before it ceases to leave the basin A. Also, will not the pressure of air on the top of B and C prevent the water from flowing down the pipe D after it has passed through the jet ? If "Glatton" will set me right, I shall be greatly obliged.—Student.

[52416.]—**Holding Links without String.**—Would any reader assist me with any instructions as to how I may fasten three links on a drawbar while I repair the broken end ? For instance, I fasten the first link with a wedge through the hole in hook, and then fit a pair of tongues on the end of the link, and then put the end link on the hook, and tie the middle link to the tongues, which takes up a deal of time, and you need have a great many different sizes of tongues to fit every link, as they vary so, and I have a great many to repair. They run about 6ft. long, and are not very light to lift about, and you cannot turn them about on the anvil without you have them fast, and on a line with the drawbar. A sketch would enlighten me. I want it to be as light as I can, and a remedy that will do away with the string, and not take long. I don't want to cut them out.—Midland Subscriber.

[52417.]—**Siemens' Dynamo.**—I want to make a small armature (drum-shape) for the above dynamo. Kindly give size of wire, winding, &c., and oblige.—Constructor.

[52418.]—**Photographing in Natural Colours.**—A few years ago I asked in "ours" if this had ever been done. By a curious coincidence someone about the same time read a paper somewhere on the subject. Has this ever come to anything ? Hand-coloured photos are at best daubs : reminding one of the hand-coloured illustrated books children used to have.—Murano.

[52419.]—**Memorial to Home Secretary.**—Must this be presented by a deputatation, or can it be sent by post ? How should it commence ? Any particulars will will oblige.—M.

[52420.]—**White Fillings for the Teeth.**—On p. 216 I saw an account of "dentists' white fillings," and I procured the oxide of zinc and pyrophosphoric acid, but I cannot get it to set, and I have tried all proportions. Can anyone help me with a little knowledge ?—J. Morgan.

[52421.]—**Partnership.**—To Mr. Wetherfield or Others.—A. is a partner in two firms, A. B. and Co. and A. C. and Co. A. B. and Co. fail ; but before this the partnership of A. C. and Co. is dissolved to prevent any complication, and A. is paid out. A. receives his discharge from his private creditors, but in the liquidation by arrangement of the firm's affairs, the creditors turn and refuse discharge. Is it safe for A. to go back to A. C. and Co. if he can borrow sufficient capital, some two years having elapsed since his trouble ?—O.

[52422.]—**Legal.**—I took a house on a yearly tenancy, and paid the outgoing tenant for venetian blinds, curtain poles, &c., and gas fittings, for which he gave me a receipt. Can I legally take them away when I give up possession of the house ?—Tom.

[52423.]—**Paint for Machine Tools.**—Will some kind reader inform me how to obtain a hard, smooth, and durable surface ?—G. B.

[52424.]—**Red Casting Wax.**—Could any reader kindly give me a recipe for red wax ? It will have to be rather brittle. I want it for the purpose of casting stove grate panels.—Modeller.

[52425.]—**Gaiffe's Peroxide of Manganese and Chloride of Zinc Battery.**—Will "Sigma," or other correspondent, kindly give an opinion upon the beforementioned battery ? Outer cell contains zinc rod with a 20 per cent. solution of chloride of zinc. No inner cell, but the carbon is in shape of a cylinder in which holes are bored longitudinally and filled with granulated peroxide of manganese. It is claimed for this element—(1) No creeping up of salts, the oxide of zinc formed not adhering to the zinc rod, but falls to the bottom in a pulverulent state. (2) The affinity of the chloride for water considerably diminishes the amount of evaporation—Chloride of Zinc.

[52426.]—**Voss Electrical Machine.**—I should be much obliged if any reader would tell me me how to fasten the revolving plate of a Voss machine to the axle. We use a 15in. plate of common window-glass, with a 1in. hole in the centre. This we clamp between two brass plates 3in. diameter, padded with indiarubber ; but we find that the plates very soon begin to crack, the cracks spreading from the centre to the outside of the plates, and rendering them useless. Some seem to advise that the plate should be fastened with marine glue. If this is used, is it necessary to have any hole in the plate ? Does not the glue get soft when the machine is warmed, and so allow the plate to slip out of its proper position ?—C. W. A.

[52427.]—**Adhesive and Waterproof Paste.**—Will some of our chemists kindly try to help me ? I want a transparent, adhesive, and waterproof paste tissue paper which has to pass over a cloth satu with the paste (cold) on to a spindle, on which spirally coiled. There is a German recipe comp [illegible] and ammonia, full particulars and [illegible] will greatly oblige.—P. E. M.

[illegible]—**Battery.**—I am making a small medical coil, and want a [illegible] small battery to work it. Chloride of silver [illegible] generally used. Can any one tell [illegible] a small form? I want to be able [illegible] portable.—T. P.

[illegible]—**Electrical.**—Will some one inform me what amount of water will be decomposed into oxygen and hydrogen per indicated horse-power per hour from a dynamo of [illegible] efficiency? Wether a dynamo producing [illegible] of high or low tension would be most suitable. Whether ozone can be produced by electricity generated from a dynamo, and if so, how?—INQUIRER.

[illegible]—**Chemical.**—Will some chemist inform me whether it is possible to make chlorate of barium (used in pyrotechny) from fluoride of barium and chlorate of potash? It is desired to utilise some fluoride of barium, which is at present a by-product.—MANUFACTURER.

[illegible]—**Iron Railway Sleepers.**—Some years ago the Barlow iron sleepers were largely used. Can any readers state if any now exist?—as a party of engineers, including myself, desire to visit any part of the country to see them in actual use.—HISTORIAN, M.I.M.E.

[illegible]—**Railway Time Signals.**—Wanted, details of a railway time signal used some years ago at [illegible] to inform drivers how long the previous train had left. Are any of these still to be seen at work?—HISTORIAN, M.I.M.E.

[illegible]—**Midland Engines.**—Wanted some details of [illegible] 124, 132, 142, 145, and 149, and where they are stationed.—HISTORIAN, M.I.M.E.

[illegible]—**Gout.**—Would some medical reader kindly give me his opinion of *Physalis alkekengi*, which I have been recommended to take for gout? It is, I believe, the active principle in certain pills. Is there anything objectionable in its continued use, and does it injure the system in any way, as colchicum does? I have inherited, and not acquired, the gout, and have never had a fit of it. Mine is generally "misplaced or retrocedent."—FAL.

[illegible]—**Extraordinary Phenomenon.**—What is this light that makes so grand an appearance some time after sunset and before sunrise now? Every day that the sky is clear this week I have seen it. The most interesting part to me is that I have always seen it in the day whenever the sky is clear, extending about 18° from the sun, causing the blue sky to appear of a beautiful mauve tint. This would seem to dispense with the idea of its being "sunset glow," as indeed would also the fact of the phenomenon being seen in India and at the Cape. Are we to suppose that there is a mass of [illegible] matter now lying between us and the sun? and has there been any record of such appearances as are here seen having previously occurred? The sight is altogether new to me. I trust we shall get further accounts from clearer climes.—HERBERT INGALL.

[illegible]—**Lachnanthes.**—Any particulars respecting the above drug (said to be an unfailing specific for phthisis) would no doubt be interesting to many of "ours."—H. [illegible]

[illegible]—**Paper Ornaments and Toys.**—I want to cast a quantity of paper ornaments and toys like those we get from Germany, but I cannot get the castings [illegible] from mould, and in drying they shrink too much. Will any one kindly describe the process?—X. C. L. R.

[illegible]—**Ventilation of Rooms.**—In issue of [illegible] there is a reply by "Initials" to some question on this subject. He says, "Tredgold's rule is, multiply the number of people in room by four, divide the product by forty times the square root of the height of the tubes in feet. The quotient is the area of the ventilating tube in feet." It is quite evident the sum [illegible], the height of the tubes having [illegible] their capacity of admitting air. Their [illegible] number of square inches in [illegible] for fresh air, is surely what is wanted. Has any reader access to "Tredgold's Rule," or can anyone give a working rule for capacity of inlets to proper ventilation of living rooms?—R. W. J.

[illegible]—**Transparencies.**—Can any of "ours" [illegible] how to take off the film of an ordinary gelatine negative either in the case of a developed negative or a positive by contact, without injury to the picture? My object is to transfer the film on to a piece of porcelain ware, or as the case might be, on to opal glass plates. A line or two from some of our friends would be greatly esteemed, and would no doubt be a source of interest for others situated as myself. I am sure if [illegible] films can be successfully transferred, many pleasing decorations and pictures can be made. I might [illegible] that I have tried the formula of 1oz. [illegible] to the pint of water, but I find this does not [illegible] and seems to dissolve the gelatine, [illegible]

[illegible]—**Water Power.**—On a piece of land in my [illegible] is a very strong spring of water; it rises [illegible] 2ft. I wish to use that water for a [illegible] I propose to make an embankment, and run the [illegible] wheel or obtain power by any other means. [illegible] the best means for obtaining that [illegible] the reservoir would fill to the [illegible] the level of the field; therefore, I [illegible] fall. If the power was not sufficient to [illegible] constantly, it is desirable to run a [illegible] the reservoir empty, stop the [illegible] allow the reservoir to fill up again.—[illegible]

[illegible]—**Paper Bricks.**—Could any of ours kindly [illegible] by 7in. square, something of the [illegible] tough and leathery, some composition [illegible] into a mould, that would [illegible] affected by water.—N. B.

[illegible]—**Complementary Colours in the** [illegible]—[illegible] kindly explain why [illegible] when the polariser [illegible] are complementary to those in [illegible] parallel? I may say that I [illegible] produced, but cannot [illegible] why they are complementary, though I have [illegible] Tyndall and Ganot.—NICOL.

[52443.]—**Overworked Brain.**—I suffer from blood to the head when I read much, or have more than ordinary worry or work, with an increasing loss of memory. I am 52. I take a rest every summer, and often go to a hydropathic establishment, and a few years ago was abroad travelling for six months. I do not sleep well, and suffer from flatulent distention. I overtaxed my brain some years back, and have never quite recovered from the strain. Can any reader kindly suggest any simple remedies which do not entail absolute suspension of work or prolonged absence from home? I have been much interested in what has appeared lately in these columns on the subject of nervousness.—B. M.

[52444.]—**Electric Current.**—Will "Sigma" or Mr. Lancaster kindly inform me if an electric alternative current of high power could be obtained from eight coils of wire placed on the polar ends of eight steel permanent horseshoe magnets weighing over ½cwt., the armature being of iron in windmill form, rapidly passing the magnet ends. This principle of fixed coils is made use of in Wheatstone's A B C magnetic transmitters, but have soft iron cores (fastened to the steel) on which the wire is wound. I desire to know if same effects can be had by winding direct upon the magnets, as in the telephone?—ROMULUS.

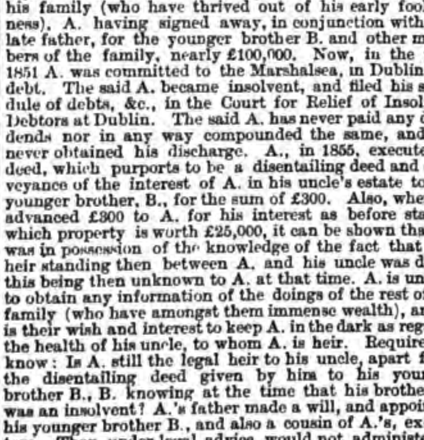
[52445.]—**Legal.**—A. is the next heir by entail to property of an uncle, now 80 years of age; but owing, unfortunately, to his not having a friend in the whole world, and hardly the means to exist, is unable to get right advice. A. is also estranged from every member of his family (who have thrived out of his early foolishness). A. having signed away, in conjunction with his late father, for the younger brother B. and other members of the family, nearly £100,000. Now, in the year 1851 A. was committed to the Marshalsea, in Dublin, for debt. The said A. became insolvent, and filed his schedule of debts, &c., in the Court for Relief of Insolvent Debtors at Dublin. The said A. has never paid any dividends nor in any way compounded the same, and has never obtained his discharge. A., in 1855, executed a deed, which purports to be a disentailing deed and conveyance of the interest of A. in his uncle's estate to his younger brother, B., for the sum of £300. Also, when B. advanced £300 to A. for his interest as before stated, which property is worth £25,000, it can be shown that B. was in possession of the knowledge of the fact that the heir standing then between A. and his uncle was dead, this being then unknown to A. at that time. A. is unable to obtain any information of the doings of the rest of his family (who have amongst them immense wealth), and it is their wish and interest to keep A. in the dark as regards the health of his uncle, to whom A. is heir. Required to know: Is A. still the legal heir to his uncle, apart from the disentailing deed given by him to his younger brother B., B. knowing at the time that his brother A. was an insolvent? A.'s father made a will, and appointed his younger brother B., and also a cousin of A.'s, executors. They, under legal advice, would not administer to the will, as the legacies made by A.'s father were much in excess of the value of his personalty. There is a quantity of jewellery, &c. A. does not know what they have done with it, and A. being the eldest son, is he not entitled to some portion of it, if not the whole? Also, would it be possible to obtain legal and other assistance, and how? A SUBSCRIBER FROM THE 1ST VOL.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Bryn Rhedyn, Llandwrog, Carnarvon.

PROBLEM DCCCLXIV.—By D. MACKAY.

Black.



White. [5+6

White to play and mate in three moves.

SOLUTION TO 859.

White.	*Black.*
1. Kt-K B 3	1. K takes R (*a*)
2. Q-Q 4 (ch)	2. P takes Q
3. Kt mates	
	(*a*) 1. P-Q B 7 (*b*)
2. B-K 2	2. Anything
3. Mates	
	(*b*) 1. Q B moves (*c*)
2. R-Q 4 (ch) &c.	
	(*c*) 1. Kt moves
2. Q K B 4 (ch)	2. Anything
3. Kt mates	

SOLUTION TO 862.

White.	*Black.*
1. K-Kt 3	1. Q-Q Kt 3
2. Q-K 3	2. P takes Q
3. Kt mates	

If 1. $\frac{\qquad}{\text{Q-Q Kt 6 (ch)}}$ 2. B takes Q, &c. 1. $\frac{\qquad}{\text{Q takes B}}$ 2. Q-K sq (ch); 1. $\frac{\qquad}{\text{K-Q 6}}$ 2. Q takes Q P (ch) &c.

This problem has other solutions, overlooked by the author, beginning 1. Q-Kt 2 (ch) and Q takes P (ch).

NOTICES TO CORRESPONDENTS.

CORRECT Solutions to 860 by J. B. of Boxford (very good), R. A. Bennett and S. Seymour Follwell (a very pretty problem: several plausible attempts; and pieces all bear well on their work).—This problem should have been numbered 861. To 862 by J. B. of Boxford, Schmucke, and Dicky Sam (all second solutions).

GAME received with thanks from J. Jowett.

MISS F. F. BEECHEY's and T. B. Rowland's work, "Chess Fruits" (a sequel to "Chess Blossoms"), will shortly be published. It will contain 100 problems, poems, and humorous sketches. The price to subscribers is 2s. 6d. The Editor's address is 10, Prince of Wales-terrace, Merrion-road, Dublin.

Mr. J. P. TAYLOR's entertaining work, "Dot's Diary," to which we drew attention some months ago, has been kindly offered by the author to the solver who scores the most marks in the two-move problems published between January and June, 1884. We may mention that this book contains an admirable illustration by Faed, and that it has met with most favourable notices in the *Saturday Review* and other leading papers. There are still some copies left, which may be obtained of the author 63, Malvern-road, Dalston. The price is 2s. 8d.

WE also offer a copy of Baxter's "Chess Problems" to the highest scorer in the solution of the three-movers during the same interval.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

ELECTRIC RAILWAYS AND TELPHERAGE.

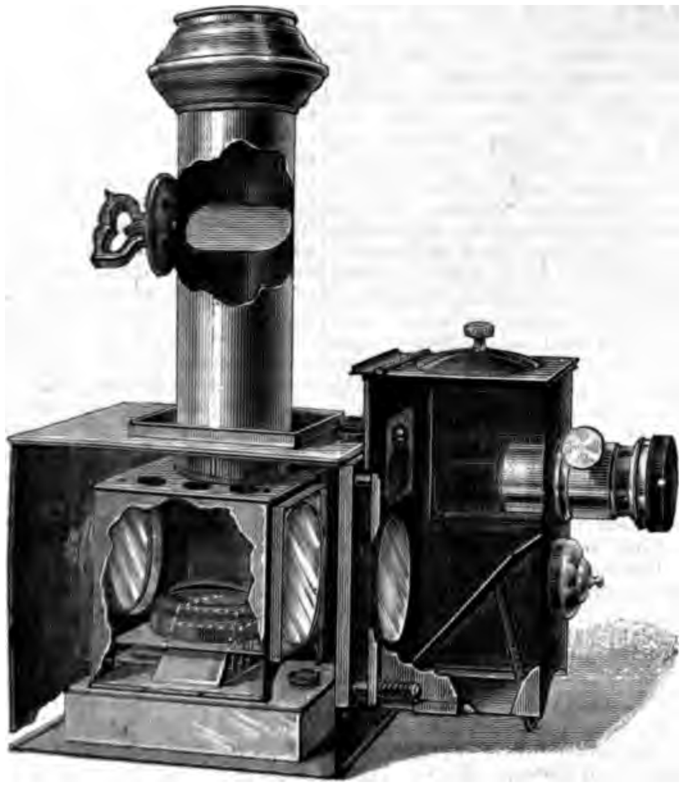
WE promised a few weeks ago to give an account of Prof. Fleeming Jenkin's system of electrical railways, which he has named Telpherage—a simple corruption of "telephorage," with the object of making a better-sounding word while retaining sufficient of the meaning to clearly indicate the nature of the new means of rapid conveyance. We have already given tolerably full accounts of the different electrical railways which have been inaugurated mainly by the brothers Siemens, and, as we mentioned at the time, Prof. Fleeming Jenkin commenced the present session of his class at Edinburgh with a lecture on "Telpherage," which is destined to play an important part in the inland carrying trade of the future. It will be in the recollection of our readers that Profs. Ayrton and Perry exhibited a large working model of their electric railway at the Royal Institution in the beginning of 1882, and Prof. Fleeming Jenkin, who had already put his ideas into definite shape, sought their co-operation. The result was that the three gentlemen named, although taking out separate patents, have combined their interests, and hold equal shares in the Telpherage Company, Limited, which is carrying out a series of practical experiments on the estate of the chairman, Mr. M. R. Pryor, of Weston, near Hitchin. For tolerably obvious reasons these experiments are confined mainly to discovering the best means of working a sort of light rope railway by electricity, which would convey parcels and light goods generally at a high rate of speed. On p. 233 of our last volume, we gave an account of some ideas put forward by an enthusiast, who thinks it possible the passenger trains may be propelled at the rate of a hundred miles an hour by means of electricity; and lately we notice that, electric light companies being at a rather low ebb, electric railways are receiving patronage which they could very well dispense with. Prof. Jenkin's idea is to transport passengers as well as goods; but he, and those who are acting with him, are well aware that in matters of this kind it is advisable to move slowly and make sure of every step, if any lasting results are to be attained. For this reason the experiments at Weston are being carried out on a working scale, with the view of perfecting the system by a natural process of evolution, before introducing it to public notice. In the simplest arrangement of the system patented by Prof. Fleeming Jenkin, there is a break of continuity at each post supporting the cable, the sections being insulated from each other and the earth; they are, however, capable of being connected by movable coupling pieces, actuated by the train, so that all the sections receive the exciting current and form part of the general circuit. Current is supplied to the cable by a stationary dynamo, and in circuit with the cable is an electric locomotive, which is provided with a governor to check the speed if it should become excessive. The line being elevated on insulating posts, leakage is reduced to a minimum, and like most lines of the kind which have not a separate insulated conductor the sections are short—so that a train always spans at least one of the junctions. The sections are connected by bridge-pieces automatically thrown over by the advancing end of the train, and put into the circuit again by the rear end. The *coupling pieces may be* replaced by an automatic telegraph, which is also used to insure that one train shall not overtake another. It is unnecessary to describe the exact mechanical details adopted; but the principle will be readily understood, and it will be seen that the current can pass in series through any number of trains on the line; but the more there are, the greater will be the demand made on the generating dynamo. In the experimental line at Weston, the supporting posts are 60ft. apart, and carry two lines of rods on crossheads fitted with cast-iron saddles so shaped as to facilitate the passage of the cars; there is thus an up and a down line. Square and round steel rods and steel ropes are all in use; but at present it seems likely that the round rod will be adopted as the standard rail of the Telpherage system. The line is divided into electrical sections of 120ft., insulated from one another, and the train is the same length as a section. The alternate sections are insulated from the ground, and are in electrical connection with each other, as are all the uninsulated sections. The insulated sections are supplied with electricity from a stationary dynamo, and the current passing from them to the uninsulated sections through the motor drives the engine or locomotive. A wire connects one pole of the motor with the leading wheel of the train, and the other pole is connected by similar means to the last wheel, the other wheels being all insulated from each other. Thus a train, wherever it stands, bridges a gap between an insulated and an uninsulated section. The train consists of seven buckets or skips, each weighing with its load 3cwt., and a locomotive which also weighs about 3cwt.—the gross load being 24cwt., and the paying load 17cwt. The skips and the locomotive hang below the line, and resemble in some of the details the devices adopted on wire tramways as they are termed. The skips hang from one or two V-grooved wheels; but the engine is supported by two broad flat wheels, and is driven by a couple of horizontal gripping wheels, the connection between these and the motor being made by the new design of friction gear which Prof. Jenkins calls nest gear. The skips are evenly spaced, and coupled by ash bars and iron pins. The locomotive is capable of exerting as much as 1½ horse-power, and the grip is almost frictionless, the gear running silently and easily; but other motors made on the plan devised by Profs. Ayrton and Perry give 1½ horse-power, with a weight of less than 100lb. Thus far a general description of the line and its stock as it exists: it is very short, and can show only one train each way; but it has already demonstrated the fact that a cheap and readily constructed line of electrical "permanent way" can be erected which will convey a paying load of 15 cwt. on each alternate span of 120ft., or 16½ tons per mile, which, at five miles an hour for 20 hours, gives 1,850 tons per day. It will be seen that there is nothing about 100 miles an hour in that estimate, and as a matter of fact, the arrangements are not suited for high speeds; but sufficient has been done to show that Telpherage will be a valuable means of conveying all kinds of goods, produce, manufactures, and minerals from outlying districts to factories or towns, or to existing railway stations for despatch in the usual way. In new colonies, as Prof. Jenkin points out, the Telpher lines will often be cheaper to make than roads, and will transfer goods more cheaply; in short, the Telpher line will do whatever the wire tramway does, and more besides. The steel rods used for the existing line are 1in. in diameter; but a smaller type, with a line only ⅝in. in diameter, is in course of construction, having smaller spans, which will probably be extended for a mile or so. At present the company does not contemplate working any lines extending more than five miles from a station; but one station could, of course, work any convenient number of lines radiating in all directions. Where it is necessary to go beyond five miles, an engine station would be needed at about every ten miles. The company is not yet in a position to fit up Telpher lines, because many details, such as sidings for loading and marshalling trains, have yet to be devised and tested, as have the arrangements for governing and blocking; but the directing spirits of the enterprise are convinced of the feasibility of their plans, and in a short time will submit them for public patronage.

The arrangements we have described are obviously unfitted for high speeds, because, to mention only one point, the buckets, if travelling at a high velocity, would be shot up into the air at every support, and might not always come down upon the line again. The line itself does not provide a sufficiently rigid road-bed for the passage of even moderate weights at high speed; but it shows that all that is needed can be done when it is required. Thus, instead of a mere rod of steel as the rail, with a carriage suspended from grooved wheels, the line for fast traffic would be a practically rigid bar of iron, and wheels so arranged that they could not by any possibility leave it, while for passenger traffic it might take the form of the letter A in section, the carriage body hanging down on each side, as suggested for light railways in mountain districts. There is, in fact, no difficulty in devising the requisite mechanical details, when the electrical arrangements are perfected; it is simply a question of which plan is the best, taking into consideration economy in construction, durability, and efficiency. The method of conveying the current above described, is that known as the series system; but Profs. Ayrton and Perry have devised one known as the "cross-over parallel," in which the insulated and uninsulated lines cross one another at intervals, and thus furnish insulated and uninsulated sections for two lines—the up and the down. The governing arrangements and the absolute block devised by Profs. Ayrton and Perry, have helped to perfect the scheme of Telpherage invented by Prof. Fleeming Jenkin, which he modestly says is not likely to compete with railways or injure their traffic. At first the Telpher lines will no doubt be used mainly as feeders for railways, and as a simple and rapid means of conveying articles from one part of a large works to another; but they will not stop there, for with the growth of the parcels post it is not unlikely that the Post-office will eventually possess a Telpherage system, and become altogether independent of the railways.

A NEW MAGIC-LANTERN.

MR. J. B. MEDLAND, of 12, Borough, London Bridge, is introducing a new lantern, the lamp of which has no fewer than five wicks (an engraving of which we give), to which he has given the name of the "Pentaphane," or fivefold light. Besides the improvement in the lamp, there are some others not before met with in the ordinary lantern. As will be seen, the shape is somewhat different—the square front carrying the objective being an arrangement for exhibiting opaque objects, which has hitherto been accomplished by a separate piece of apparatus, the aphengescope, the use of which necessitated altering the position of the lantern, whereas in this case it is effected almost momentarily. For exhibiting transparencies, the objective is screwed into the bottom flange, shown in the engraving, with a cap screwed in to exclude the light when not in use. The light from the lamp passes through the condenser in the ordinary way to the objective. When required for opaque objects, such as a C.D.V., medal, works of a watch, &c., &c., all that is required to be done is simply to screw the objects

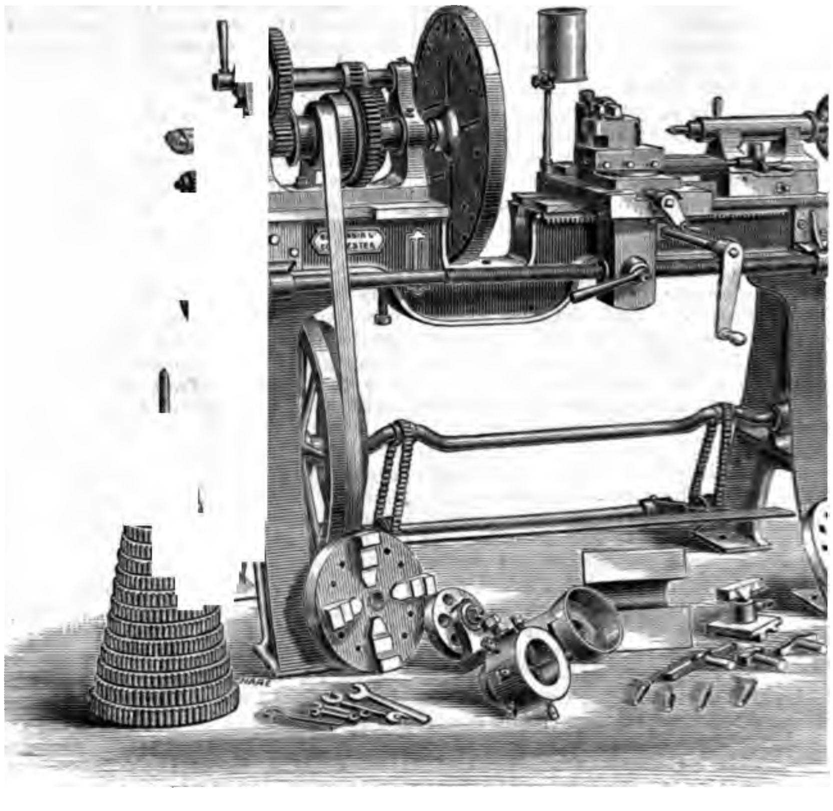
VOL. XXXVIII.—NO. 977.



into the top flange, as shown in the engraving. The flat mirror shown at the bottom is then brought into use, and fixed at a proper angle to throw the light from the condenser back on to the object by a piece of metal drilled with a number of holes, and a pin fixed beneath. The object is then reflected through the objective on to the screen. This arrangement will be found very serviceable for introducing many interesting objects in the course of an exhibition, which otherwise could not be done without first having them photographed and made into slides in the ordinary way. The five wicks of the lamp are arranged parallel, and the light given is, certainly, one of most intense brilliancy and, for transparencies, all that can be desired for schools or moderate sized lecture rooms. The difficulty of the accurate adjustment of the wicks, so as to avoid smoke, &c., from so many burners, is obviated by a very simple but, at the same time, very effective arrangement of a fan or shutter placed in the iron chimney of the lamp, as shown in the engraving, which regulates the current of air so that, when the flames are left at a moderate height all level, by turning the fan the current of air is increased, and the combined flames drawn upwards and towards the centre, where the greatest amount of illumination is, of course, required. The lantern appears to be well made in all its parts, is fitted with 4in. condensers and portrait combination objective; and is made exceedingly portable, packing into a light iron case only [illegible]in. by 7½in. by 13in., and we should think, leaves nothing to be desired by those who wish for a compact and complete instrument ready at a moment's notice.

BRITANNIA COMPANY'S NEW "NAVAL" LATHE.

THE Britannia Company, of Colchester, are introducing a new extra strong lathe for [illegible], especially designed for the British [illegible]. The bed is [illegible] long, 8½in. on face, [illegible] height of centre, 6in.; size of gap, [illegible] will swing 2ft. diameter, [illegible]. It has three speeds on cone, 9in., [illegible] band. The head is fitted with [illegible] pitch, 1¼ face; two [illegible] to alter the speed to either single, [illegible] Steel leading screw is [illegible] pitch. These lathes [illegible] to do very heavy work by [illegible] where [illegible] are [illegible] cannot be obtained [illegible] in., [illegible] 9in. bed, [illegible] do [illegible] for [illegible] ships where space is limited. They are fitted with a full assortment of chucks and tools of corresponding strength; longer beds when required. As an instance of the work, a 24in. wheel or plate can easily be turned by foot-power by use of the treble gear. By using the double gear this will take a ½in. cut off a 2in. or 3in. shaft. The treble gears are used on larger articles up to 24in. Total weight of lathe and tools, 14cwt.



HOW TO MAKE A CHEAP LATHE.—IV.

Mandrel Details.

IN our last, we left our headstock castings prepared ready for the reception of their fittings. Taking now the headstock proper, "the last headstock," as it is usually termed, le make its mandrel (Fig. 25).

Get a piece of 1in. round steel rod : on this have two collars welded out of ¼i rod, and at a distance of 1¾in. betw inside of the first ring being 1½in. dist the end. Centre pop each end, and in into which the back centre will run, d hole about $\frac{3}{16}$in. or ¼in. deep, using a archimedean drill for the purpose. insures concentric wear in the mandrel acting in the function of a guide to point of the dead centre (Fig. 26) whic absence of the hole, would grind the end eccentric (Fig. 27).

Chuck between dead points, using tl (Fig. 28), and turn the end which is t the rigger to ⅞in. diameter. Use a to like Fig. 29, taking a rough cut first, a: a fine one. Then change ends, putting just turned into the carrier, and turn th that runs in the brasses, the collars screwed part to dimensions (Fig. 25). your borrowed lathe is suitable for screw having the necessary change wheels, cu thread of 8 to the inch on the nose of drel, using a tool like Fig. 30. A cha run along half a dozen times will impar to it. If, however, no screw-cutting arra is available, better to have the man chuck-screws cut by a machinist, tha stocks and dies

Now slip the front collar or the nos mandrel into one of the holes of a cc (Fig. 31). Put a drill ⅜ $\frac{1}{32}$in. diameter slide-rest, and drill a hole with it 1¼in. c the mandrel nose; cut a ½in. thread with taps, the taper one first, and the stum wards.

Now file a flat ¼in. wide for the ke rigger, reaching to within an ⅛in. of the and hand the mandrel over to the smitl hardened where the point of the back centr

For the back centre, turn down a piece to ½in. diameter by 2¾in. long, tapering which forms the centre to an angle c thereabouts. Screw it about ¾in. from c then have the point hardened. Provide of nuts for it (Fig. 32).

Make the rigger of hard wood—a piece dry hard wood will do—oak, ash, or beecl pare two metal discs, either cast brass or of plate (Fig. 33) 2¼in. diameter by ⅛in. thick, drill a ½in. hole in the centre of ea three holes, countersunk for wood screw circle 1¾in. diameter. File a keyway i ¼in. wide by ⅜in. deep, or rather $\frac{1}{32}$i than ⅜in. in one plate, and ⅛in. in eeth

SCALE HALF SIZE

in the other, to give the necessary taper for the wedge. These plates will be let into the block of hard wood intended for the rigger. Prepare the stuff to 6in. diameter by $2\frac{3}{4}$in. thick in the rough, screw it on the face plate, bore a $\frac{7}{8}$in. hole through it, using the gouge and the corner of a side-chisel. Turn a recess $2\frac{1}{2}$in. diameter to a depth equal to the thickness of one of the discs, hammer the disc into place, and screw with $\frac{3}{4}$in. or 1in. screws. Rough down the wooden block to $5\frac{5}{8}$in. diameter, take it off the plate, and rechuck by the finished face. Let the second disc into the other side, keeping the keyways in line with one another, remove from face plate, drive tightly on a mandrel, and turn the two speeds to dimensions, not forgetting the slight rounding (Fig. 34). Cut keyway through the wood from plate to plate, file a key out of $\frac{1}{4}$in. iron or steel rod to dimensions (Fig. 35), and key rigger in position. Place in headstock, of which Fig. 36 now presents a sectional appearance.

For the poppet mandrel (Fig. 37) get a piece of thick $\frac{3}{8}$in. wrought-iron tubing, 6in. long and not less than $1\frac{3}{8}$ diam. outside—what is known in the trade as "hydraulic pipe"—and instruct the smith to weld a short bit of $\frac{5}{8}$in. bar, about $\frac{3}{4}$in. long, into each open end, in which to cut the necessary threads for the traversing screw, and the dead centre. In a small mandrel this is a readier method than drilling up a solid piece of metal, and fitting in a nut for the back screw. When welded, centre pop the ends, chuck in the dead centres with carrier, and turn to a sliding fit with the bore of the poppet head. Remove the poppet centre, replace with the cone plate, and drill at one end a $\frac{3}{8}$in. tapping hole for the dead centre, then re-chucking, drill at the end opposite a $\frac{1}{2}$in. tapping hole for the traversing screw. Remove from lathe and cut the screws.

Make a slot in the mandrel 4in. long by $\frac{1}{4}$in wide by $\frac{1}{16}$in. deep (Fig. 37, *a*, *a*) for the tightening screw. To cut the slot, get a cold chisel $\frac{1}{4}$in. wide, keep it sharp, and chip as near to size as possible, just cleaning a little with the point of a file afterwards; but the revolving cutter of a slotting machine, if at our service, would almost run it out while we are talking about it.

For the traversing screw, get a piece of $\frac{5}{8}$in. rod $5\frac{3}{4}$ long, have a collar $1\frac{1}{4}$in. diam. by $\frac{1}{4}$in. thick, welded on at a distance of $3\frac{1}{2}$in. from one end. Turn in lathe to dimensions (Fig. 38), trying the collar in the corresponding recess in the poppet to get an easy fit, and keeping it just a shade thinner than its recess is deep, so that it may not run tightly when the back plate is screwed on. The screw may then be cut either in the lathe or with stock and dies. If the latter are used, care should be taken to keep the stock square with the axis of the traversing screw.

For the back plate (Fig. 39) make a disc of wrought iron or brass, $1\frac{7}{8}$in. dia. by $\frac{1}{4}$in. thick, drill a $\frac{1}{2}$in. hole through its centre, and three holes in a diameter of $1\frac{1}{4}$in. to take three small $\frac{3}{16}$in. screws. Slip this over the end of the traversing screw, thrust the screw collar into its recess in the poppet, and mark three holes with a scriber point on the back of the poppet, corresponding with those just drilled in the plate. Centre pop, drill $\frac{1}{2}$in. deep, and tap these three poppet holes with any convenient tap about $\frac{3}{16}$in. in diameter. If you have a screwplate, one of the taper taps of the set will do for entering, and you can either make, or get a fitter friend to make for you, a stump tap cut with the same thread to finish with. Get some lock screws, mushroom-headed, such as carpenters use, cut them off $\frac{3}{8}$in. from the bottom of the head and screw with plate, so that they will fit the tapped holes (Fig. 40).

Now bore the hand wheel to $\frac{1}{2}$in., slip the disc over the end of the traversing screw, then the hand wheel against the disc, followed by a tightening nut. Then drill a $\frac{3}{16}$in. hole through boss of wheel and spindle, and drive in a bit of steel wire—or, neater still, tap a $\frac{3}{16}$in. set screw through one side of the boss into the spindle (Fig. 41).

For the dead centre get a piece of $\frac{3}{4}$in. steel, and turn down to dimensions as shown Fig. 42.

The part A simply indicates a surplus length for the attachment of the carrier, and is cut off on removal from the lathe. Screw with ⅜in. dies, chuck in a block of hard wood, and file the centre to a nice point in the lathe, giving it afterwards to the smith to harden.

Make a set screw to dimensions (Fig. 43) for tightening the mandrel. Put in the mandrel, make the traversing screw take into it, screw the backplate in place, also the hand wheel and tightening nut, and run the mandrel backwards and forwards with oil several times till it goes easily. The poppet, now in section, has the appearance of Fig. 44.

Have a small forging made for the tightening screw of the rest (Fig. 45). Let the looped portion be forged solid, and drill a ⅜in. hole through it. Cut the ½in. thread, and drill and tap similarly the boss on the rest socket.

DARWIN'S ESSAY ON INSTINCT.

THE so-called "posthumous" essay of the late Charles Darwin, which it appears was written thirty years ago, was read at the recent meeting of the Linnean Society by Mr. G. J. Romanes, in whose forthcoming work on the "Mental Evolution of Animals" it will form an appendix. The essay was, it seems, penned by Mr. Darwin as a preliminary to some chapters for his "Origin of Species," and the following is an outline of the paper, arranged under the several topics to which it relates:—

Under the head of migration the main points with which Darwin is concerned are—(1) That in different kinds of birds there is a perfect series, from those which occasionally or regularly shift their quarters within the same country to those which periodically pass to far distant countries; (2) the same species often migrates in one country, and is stationary in another, or different individuals of the same species in the same country are migratory or stationary; (3) the migratory instinct is made up of two very distinct factors — viz., an impulse to travel periodically and a faculty of knowing the direction in which to travel; (4) savage man shows a sense of direction which may be analogous to that shown by migratory animals; (5) certain cases are on record of birds or domestic animals having truly migratory instincts—a fact which is specially pronounced in the case of a breed of Spanish sheep. Such being the *data*, substantiated by a number of facts, Mr. Darwin proceeds to consider the problem of the origin of the migratory instinct. This theory is that the ancestors of migratory animals were annually driven, by cold or want of food, to travel slowly southwards, and that in time this compulsry travelling would become an instinctive passion, as in the case of the Spanish sheep. In the case of birds the wings would be used, and if in the course of many successive generations the land over which they flew in their annual journeys were to become slowly submerged, the line of flight would remain unaltered, and thus we should have the state of things which we now perceive—viz., migratory birds flying over wide stretches of ocean. In regard to instinctive fear, an accumulation of facts are given to show that the fear of man has always first to be acquired in a state of nature, and that under domestication it is merely lost again. The feigning death of insects and spiders is shown to be merely an instinct of remaining motionless, and therefore inconspicuous, in the presence of danger, there being thus no idea of death or of its similation on the part of the animal. A great array of facts is given to show that the instinct of nest-building is subject to variations, both on the part of the individuals and, in the course of time, on that of species. Hence it is argued, "If it be admitted that the nests of each bird, wherever placed, and however constructed, be good for that species under its own conditions of life, and if the nesting instinct varies even so little when a bird is placed under new conditions, and the varieties can be inherited, of which there can be little doubt, the natural selection in the course of ages might modify and perfect almost to any degree the nest of a bird in comparison with that of its progenitors." Applying a similar class of considerations to these as to the nests of birds, Mr. Dawin shows that variations of instinct have occurred in rats, which now uniformly inhabit roofs of houses instead of hollow trees, &c; in the hyænas of South Africa having ceased to make burrows, and so on. He also shows how the lodge of the beaver might have been developed out of such a habitation as is made by the musk rat. After adducing severally unusual striking instances of variation of instincts, Mr. Darwin observes:—"As there is often much difficulty in imagining how an instinct could first have arisen, it may be worth while to give a few, out of many, cases of occasional and curious habits, which cannot be considered as regular instincts, but which might, according to our views, *give rise to such." After adducing* several such cases, the essay goes on to consider cases of special difficulty presented by sundry instincts to the theory of natural selection.

Prof. Huxley said he could not but think that this was not a matured work of Mr. Darwin's, but consisted simply of a series of notes made for his own use out of the immense stores of information which he had acquired, and which he intended to digest and bring into complete harmony with his great scheme as published in "The Origin of Species." Prof. Huxley would not have been sorry had the paper been left in the unfinished, unpublished state in which Mr. Darwin left it. It had added nothing to the ideas which already obtained on the nature of instinct, and the illustrations were not of so unknown, rare, and unheard-of a character as to help them to any further comprehension than they already possessed of the extraordinary phenomena which had been grouped together under the name of instinct. He knew of no subject more interesting than this, from its bearing upon the intellectual phenomena of the higher animals, man in particular. Any discussion of this subject from Mr. Darwin would have been profound and valuable, and would have thrown light on one of the greatest chapters of scientific inquiry; but the paper was simply a series of statements, many of which were familiar to most of them, and many cases were difficult to reconcile with the view of creation, or the world of life, which was a phrase he preferred which proceeded upon the hypothesis of use either individual or special. In regard to some of these it might be said that there was not a clearer illustration of the view that the world was not constructed upon any plan which did, upon any attentive consideration, produce amiable feelings in the breast of the philanthropist. The world was hard, full of struggle and pain; it was a world in which the weakest went to the wall; where there was a waste of life and of suffering absolutely incommensurable with the results obtained. Mr. Darwin would, no doubt, on careful consideration have modified may of the views expressed in the paper, and he rather regretted that in this unfinished state it should have been given.

Prof. Allman expressed the opinion that the great value of the paper lay in the fact that the different cases of instinct mentioned in it had been accepted by Mr. Darwin from observations of his own and others. They knew his judgment and skill in observation, and what a truthful record he made of his observations; they might, therefore, accept without hesitation both the instances noted in the paper which were the result of Mr. Darwin's observations and also of those which he had accepted from others.

Mr. A. R. Wallace said there was, to his mind, a considerable amount of obscurity about what was really meant by instinct. It included a considerable number of phenomena, some of them mere results of muscular and nervous co-ordination, and in other cases simply the results of observations and experience. Referring to the supposed instinct guiding the migration of birds, he said the present state of facts tended to show that there was no such power at all, but rather led to the belief that this migration was one of the means of getting rid of the enormous surplus of bird population, as it had been proved, especially by the observations promoted by the British Association at lighthouses and Heligoland, that of the vast numbers of birds which sought to pass from one region to another only a small proportion survived.

Prof. Ray Lankester wished to know whether Mr. Wallace abandoned the supposition of instinct altogether. He thought there were many instances which might be adduced which could not be accounted for on the theory of observation or of having learnt from others, and referred especially to certain habits of the caddisfly in support of his contention. He asked, also, why birds, for example, should go to the west and not to the east in their migration. These things required further investigation, and they must not draw any conclusion from what had been brought before them, as that the phenomena referred to were, if necessary, to be explained by instinct or the reverse.

FRAME FOR PRINTING LANTERN SLIDES.*

TO print transparencies for the lantern by contact when the negative is of a larger size than the picture required necessitates some special kind of printing frame, if the negative is to be kept free from scratches. The following may be simply made, and will be found a great convenience where a number of pictures are required alike:—Take an ordinary printing frame, say a 12 by 10, of the kind made to use without a plate-glass in front, and in the rebate where the negative is usually placed fasten, with strips of paper all round the edges, a piece of very flat glass; turn the frame over, and on the other side of the glass fasten a mask of paper or cardboard having an opening 3¼ by 3¼in. exactly in the centre. Now, in place of the ordinary hinged back, make a frame of the same size and thickness, with an opening in the centre about 6 by 4in., and cover all over one side, with the exception of the opening, with a piece of velvet. This frame, when placed in position, will be held by the springs that originally held the hinge back. To complete the arrangement, cut out a piece of dry mahogany an inch thick, and exactly 6 by 4in., to accurately fit the opening in velvet-covered board, and on this block draw a square 3¼ by 3¼in. exactly central. At one end of this square glue down a very thin slip of hard wood—that is, rather thinner than the glass plates to be used—and at the other end cut a mortice 3¼in. long, and about an inch wide, right through the block, beginning just within the 3¼ line, say a sixteenth of an inch less. Into this mortice fit a piece of wood 3¼ by 1 by ¼in. On to one side of this piece glue a similar strip of hard wood to that placed on the end of the block only, projecting ¼ of an inch each end, and on the other side screw a similar piece so that it can be removed. Place the piece in the mortice and screw on the back slip of wood; there will then be left a space of half an inch at the end, just room to put a piece of bent steel clock spring, sufficiently strong to clip the 3¼ plate in position. The sides of the block may be rebated down half an inch at the 3¼ line to allow the thumb and finger to adjust the plate in exact position. To complete the frame, place the block in the opening of velvet board, and arrange an ordinary brass pressure frame spring to keep it in position. For use, take the frame, remove the board, and adjust the part of negative required over the 3¼ opening, then place over the velvet-covered board, and fasten down the springs. The 3¼ plate is now clipped in the block, and dropped carefully into the opening over the negative, and after exposure is lifted out in the same way, so that any number of exposures may be made exactly registered in the same position, without the chances of injury to the negative which often occurs unless some such arrangement is adopted.

USEFUL AND SCIENTIFIC NOTES.

Lubricating Oils.—According to a German technical journal, the manufacture of machine oils is simple and very easily carried out. Any fine non-drying oil can, after refining and purifying, be used as a lubricating material. Cotton oil takes the first place among all the fatty oils, and but for its price would be employed much more frequently than it is. Poppy oil, croton oil, radish oil, &c., are comparatively little used. Sesame oil, almond oil, earth-nut oil, and rape oil are better fitted for the preparation of machine oils, and the last named, being the cheapest, is more used than all the others. It is never perfectly pure as met with in commerce, and must therefore be refined. Various more or less satisfactory methods of refining it have been employed—for example, those in which sulphuric acid, oxide of zinc, oxide of lead, potash lye, potassium bichromate, and sulphuric acid are employed. An oil almost as clear and transparent as water is obtained in the following manner: 100lb. rape oil are heated to 167° Fahr., and washed with 3lb. of potash lye of 30° B.; after about 10 to 12 hours the oil is transferred to a clean vat, left to cool down to 116°—99° Fahr., stirred and mixed with a solution of ¼lb. potassium bichromate, 1¼lb. hot water, and 1½lb. of sulphuric acid (22° B). The mixture is then washed with a sufficiency of hot water, left to stand for some hours, and the purified oil is filtered off from the impurities present. An excellent machine oil consists of 50 parts of rape oil mixed with 100 parts of mineral lubricating oil.

Preserving Iron Surfaces from Oxidation.—Pulverulent zinc is mixed with oil and a dryer, and the mixture is applied with a brush. For ordinary exposure, one coating of this mixture is affirmed to be sufficient, but a double coat, it is claimed, will afford a sure protection against both the atmosphere and sea water. A good formula for this zinc paint is the following: Zinc in powder, 8 parts; oil, 71 parts; driers, 2 parts. The mixture should be prepared freshly, and only so much made as is required for the time. The zinc coating imparts to the iron a steel-grey colour, and does not interfere with the application of another coat of paint.

THE owners of the railroad up Green Mountain on the Mt. Desert in Maine, U.S., propose building an electric railroad for summer pleasure travel on the island from Bar Harbour to Eagle Lake, where connection will be made with the steamboat running across the lake to the terminus of the Green Mountain Road. The distance is three miles.

AT the Swiss Congress recently summoned to discuss the subject of the Patent Law, resolutions were passed, by 110 votes to 52, recommending the Government to adopt some measure for the protection of inventions. No opposition was offered to the introduction of a "Trade Mark" law.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

THE second meeting of the session of the above society was held on the 14th ult. at King's College, Strand; the President, Prof. P. Martin Duncan, F.R.S., in the chair.

Mr. Stewart exhibited his simple safety-stage, a small contrivance intended to remedy a want which he had often felt of some simple method of preventing slides from being broken by careless focussing down upon them during class demonstrations. Having frequently lost valuable slides in this way, he had thought of a simple plan which Mr. Curties had carried out for him, and which he described to the meeting by means of a drawing on the blackboard. It consisted of a piece of wood the size and thickness of an ordinary glass slide, with a hole in the centre sufficiently large to admit the light to the object. Between this hole and the sides of the slip of wood two small strips of wood were fixed, and on the top of each of these a thin strip of brass was fastened, the brass being longer than the wood, and so overhanging it at each end. A couple of indiarubber rings were then passed over these projecting ends, so as to lie crossways to the slide, and on these, suspended in a kind of hammock, the slide it was desired to protect was placed. If, then, the objective was brought down upon the cover glass the indiarubber yielded to the pressure, and the object was saved from destruction. He was aware that there were other safety-stages in use, but thought this supplied a want which had been felt for something quite inexpensive, and yet perfectly efficient for the purpose.

Dr. Anthony said he had for the last 30 years, in the course of his microscopical observations, attained the same result by simply having the stage of the instrument made narrower than usual, so that the slide slightly projected beyond the edge. When a high power was used, all that was necessary was to tilt the slide with the finger, and it could be at once felt or heard when the objective came in contact with it whilst focussing down. Ross had somewhat improved upon this plan by having a very thin plate made, by means of which the slide could be raised in a similar manner.

The President said there was no doubt that in exhibiting objects to a class of medical students something of this kind was very necessary; and as they were not particularly careful or experienced, the plan of tilting the slides was not of so much use; but he thought the admirable little plan described by Mr. Stewart quite met the difficulty. For his own part, he could say that he had some slides which he had never ventured to show because of the danger of getting them broken in this way. One idea which appeared to be useful was to have a piece of cork fitted on the slide, so that the shoulder of the front of the objective would come in contact with it before it touched the cover.

Dr. Matthews said he had much felt the want of something of this kind, for it was only during the previous week that he had demolished a slide in that way, and this not from any particular carelessness on his part, but from inadvertence, the microscope being shaded and the lamp turned down, so that he was almost in the dark at the time the accident occurred.

Mr. J. Mayall, jun., said it appeared to him that the inventors of "safety-stages" had hitherto claimed for their devices far greater practical utility than they really possessed. It had been suggested some time ago that the use of a safety-stage secured practical immunity from breakage of slides, however short might be the working distance of the objective. Without doubt, so long as the operator limited himself to illuminating the object by the mirror or equivalent means, the safety-stage would protect the slide during careless focussing, or from injury by accidental concussion of the eyepiece. But when high powers were in use, just when the safety-stage might appear to be of service, a new factor had to be considered—in the majority of cases it became necessary to use some form of condenser, which had generally to be racked up in contact, or very nearly in contact, with the base of the slide. The slide was thus in danger of being squeezed between the objective and the condenser, and this applied equally whether the safety-stage were used or not. In such a case, the action of the safety-stage was practically nil as regarded the protection of the slide. As he understood Mr. Stewart's intention in devising his new form of safety-stage, its use was expected to be limited to class demonstrations where sub-stage condensers would not be applied, and where the students were only too apt to regard the breakage of a slide as of no moment. With that purpose in view, he thought Mr. Stewart had hit upon a very simple and effective device.

Mr. Stewart said it was intended entirely for rough purposes when exhibiting slides to students and others who were not very careful in such matters.

Mr. Crisp said that it was not unusual to hear derision of these safety-stages; but it came from Fellows who were all experienced workers, and to whom any such contrivance was superfluous.

Dr. Coffin said that he had employed a similar contrivance for some time; but it was simply made of a piece of brass wire bent into a fork somewhat wider than the slide, the two ends of which were bent back again, and across which the two indiarubber bands were stretched.

The President inquired if any Fellow had tried to meet the difficulty which Mr. Mayall had mentioned with regard to the condenser? Perhaps a piece of brass projecting so as to catch on the shoulder of the objective might answer the purpose.

Mr. Watson's nose-piece adapter and those of Dr. Matthews were exhibited by Mr. Crisp.

Dr. Matthews, in reply to a question as to the firmness with which his adapter would hold an objective, said that, as a proof of how firmly this kind of connection would grip, he might say that a 1in. bolt could be screwed in a lathe at one operation in a chuck which was only fitted to the head stock by a coned joint.

Mr. Ingpen thought that in the case of the lathe chuck the screw pressed strongly against it during the operation, and that this pressure of course increased the cohesion of the surfaces; but in the case of an objective there would not only be no such pressure, but the weight would act the other way.

Dr. Anthony inquired if any provision was made as regarded the centring of the objective, supposing that it was interfered with, by this mode of connection.

Mr. Ingpen said that coning was the nearest approach to perfect centring that could be obtained.

Dr. Matthews said that all objectives were open to the difficulty of centring because each had its own centre, and no two of them were alike. To get accuracy they must be fitted to the instrument on which they were to be used. Those which were coned were no worse in this respect than others; possibly they were better.

Prof. Abbe's analyser was explained by Mr. J. Mayall, jun., by means of a blackboard diagram.

Mr. J. Mayall, jun., exhibited and described a pocket lens of 1in. focus on a new formula by Dr. Schröder.

Mr. Ingpen asked if the lens was considered to be superior to those of Steinheil.

Mr. Mayall said he had recently the opportunity of comparing a 1in. of Steinheil with the new 1in. of Dr. Schröder, and the latter was superior both as regarded length of working distance and more perfect achromatism.

Mr. C. Beck remarked that the working distance of the new lens was nearly an inch.

Mr. Crisp read a paper "On Optical Tube Length: an Unconsidered Element in the Theory of the Microscope."

Dr. Anthony said that the important point to ascertain in future was the value of Δ or the "optical tube length," and he thought this was a matter which might be easily got at.

The President said it followed from the paper that in consequence of the variation in the optical length, they could not formulate any table of magnifying powers which would be of general service. The data for a correct table must be obtained by actual measurements of the focal lengths of the objectives and eyepieces employed.

Prof. Abbe's paper "On the Relation of Aperture to Power," Part III., was read by Mr. Crisp.

Mr. J. Mayall, jun., said he could not agree with the statement contained in Prof. Abbe's paper—that eyepiece power beyond six or eight diameters was of little or no service. He thought Prof. Abbe had fixed upon too low a limit. In viewing double stars, for instance, with a fine telescope, it was unquestionable that eyepiece power far beyond six or eight diameters was of service, for it was in everyone's experience who had used such an instrument, that eyepiece power of 40 and more was, in many cases, required before the separation could be discerned. So also with the microscope. It was a fact that, with a deep eyepiece—and by a deep eyepiece he meant a power of 10 to 40 diameters—many images, such as the resolution of Nobert's lines or the finest diatoms, were rendered visible which could not be seen with one of less depth. He might mention, too, that this point could hardly yet be said to have been settled by theory, for, in discussing the subject recently with M. Prazmowski, of Paris, than whom he did not know a higher authority, that gentleman stated that not only did he regard the question of the useful limit of eyepiece power as still an open one; but he also considered the absolute relation of the aperture to the resolving power required the confirmation of experiment before he could give it his unqualified adhesion. He (Mr. M.) might safely bracket Dr. Schröder's authority with that of M. Prazmowski, between whom these subjects had been discussed any time during 20 years past. Dr. Schröder considered the questions still open, and he was actually engaged in computing a formula for an eyepiece for the microscope to give 40 diameters; whilst, with regard to the limit of resolving power of objectives of a given aperture, he considered the theory too incomplete to warrant any definite limit being assigned. Mr. Mayall thought he might appeal to the experience of English and American microscopists in general, in proof that eyepiece power far beyond the limit assigned by Prof. Abbe—six or eight diameters—was of service in bringing to view microscopical details which could not be seen with less eyepiece power. From his own experience in testing some of the finest objectives hitherto made, he was bound to say the useful eyepiece power was very much a question of the real perfection of formula and workmanship of the objective.

Dr. Anthony said he could emphatically endorse the remarks which had been made. Every microscopist knew by experience which of his battery of eyepieces suited his purpose the best, according as he wanted to see the relative position of the parts of a structure, and if he wished to see through several planes he would go on using his eyepieces until his objective "broke down"; but if they had an objective which would bear the deeper eyepieces, C, D, and so on, they knew that they were able to get a great power of separation, and then found that there were thousands of lines which could not be appreciated before, because they were not grasped by the eyepiece.

The meeting was then adjourned to the 12th inst.

The following exhibits were made:—

Mr. C. Beck exhibited "Beck's Pathological Microscope and Condenser."

Mr. Crisp exhibited (1) Microscope made by the "Société Genevoise pour la Construction d'Instruments de Physique," a movable table for drawing with the Camera Lucida; (2) Swift and Sons' Pocket Microscope; (3) Harris's Pocket Microscope; (4) Zeiss's Micrometer Eyepiece; (5) Millar's Multiple Stage-plate; (6) Bausch and Lomb Optical Co.'s Compressors; (7) Valentine's Hot Stage.

Mr. Curties exhibited Aylward's Collecting Apparatus.

WESTERN MICROSCOPICAL CLUB.

THIS club held its usual monthly meeting on Dec. 3rd, at the house of Dr. B. Thompson Lowne, F.L.S. The subject for illustration was "The Microscopical Structure of Eyes," more especially the wonderful "compound" eyes, as they are called, which are found in insects, crustacea (crabs, lobsters, spiders, &c.), and other members of the order Arthropoda. When it is borne in mind that each of the two eyes of insects is an aggregate of smaller eyes, amounting in the case of the dragon-fly to at least 25,000 separate lenses, it will be seen that some interesting questions arise as to the kind of picture which is presented to the possessor of this astonishing plurality of visual organs, the chief problem being whether or not the picture presented to the insect is a multiplication of the objects of visions corresponding to the number of the lenses in each eye. To illustrate this part of the subject, the host gave some interesting demonstrations of the views he has set forth in a paper contributed to the Royal Society. The specimens exhibited by Dr. Lowne and other members were curious and interesting. Different stages in the development of the compound eye were exhibited, the earlier structure in the pupa of a moth, and of the more advanced and perfect insect, being among them. Microscopes were brought by Messrs. E. Bartlett, L.D.S., J. Dolleymore, B.Sc., J. W. Groves, F.R.M.S., G. Karop, M.R.C.S. S. P. Moore, LL.B., E. M. Nelson, H. V. Tebbs, and A. W. Stokes, F.C.S. Among the objects exhibited were sections of eyes of dragonfly, blowfly, "jumping spider," and a fly of the species Syrphus. Passing from the compound eye of insects, there were specimens of the eye of molluscs or shellfish, which have their eyes on their backs and other parts of their bodies, developing them in the most sporadic manner. It was mentioned that the common scallop of the fishmongers' shops has no less than ninety separate eyes along the fringe of its "mantle," and a case was mentioned in which a mollusc which is preyed upon from above by a fish has (according to Semper) developed eyes on its back as a precaution against such enemies. The cornea and retina of frog, together with the stellate pigment of the human choroid, variously stained, were also shown. Mr. W. J. Milles, F.R.C.S., brought some exceedingly interesting sections of the human eye in various forms of disease.

THE AMATEUR MECHANICAL SOCIETY.

THE annual conversazione of the Amateur Mechanical Society took place on Wednesday, the 5th inst., at the Gallery of the Society of British Artists, in Suffolk-street, Pall Mall. A large number of members and their friends attended, and in addition to the work shown by them, there was an unusually good display of professional exhibits. Amongst the amateurs General Clarke, C.B., brought a beautifully executed cup and cover in ivory, which worthily sustained his well-earned reputation; Mr. Phillips showed a looking-glass frame, composed of turned oak, designed in the

the ancient Egyptian lattice work, used to [illegible]lows in place of glass, some illustrations of [illegible]ill be found in Vol. IV. of Mr. Holtzapffel's [illegible]late I. [illegible] Mr. Inwards had an elliptograph, [illegible] instrument to show the trisection of an [illegible] practical demonstration of the 47th proposition of the First Book of Euclid, and other [illegible] curiosities. Colonel Sandeman, an ingenious contrivance, intended, we believe, for the [illegible] in the shape of a small box, from [illegible] anyone desiring a post card could obtain it [illegible] in a penny—any other coin being [illegible] returned to the owner without the [illegible]. Ellis illustrated the use of celluloid for [illegible] of dental instruments, the colour [illegible] distinguish at a glance the character of [illegible]. Seyd proved the ability of an amateur [illegible] quantities of brass and iron in excellent [illegible] by means of Fletcher's gas furnace and [illegible]—the whole outfit weighing but a few [illegible] and many other gentlemen gave evidence [illegible] more or less successfully mastered the [illegible] of mechanical manipulation. Amongst [illegible] Messrs. Holtzapffel and Co. had an [illegible] large selection of their beautiful work, [illegible] a powerful [illegible] screw-cutting lathe, a [illegible] lathe, with slide rest, and a complete [illegible] of chucks, the whole, by clever packing, [illegible] in the drawers beneath. The slide-[illegible] lathe was furnished with a driving-[illegible] receive a band from the overhead drum, [illegible] as to be put out of gear by the pressure [illegible] against either of a pair of stops [illegible] rod fixed parallel to the main slide, thus [illegible] stops generally in [illegible] Evans showed a handsome lathe combined, and having in addition to the usual [illegible] an ingenious device for the equal [illegible]—a necessary adjunct for all [illegible] elliptic surfaces produced [illegible] "oval" chuck. Besides this and [illegible] other tools, he had a case full of ex-[illegible] specimens of turning, which seemed to have [illegible] attraction for the ladies. Mr. Syer [illegible] a watchmaker's bench, which we noticed [illegible] back—amongst the merits of which [illegible] be reckoned its moderate price [illegible] as other tools. Messrs. Churchill [illegible] large assortment of American tools, the [illegible] and excellences of which are now too [illegible] to need description, and the Aluminium Metal Company exhibited a number of [illegible] of their new alloy, the colour of which [illegible] that of silver. It is said to turn well, to [illegible] for lock fittings for yachts, railway [illegible] door-handles, locks, and other articles [illegible] freedom from corrosion is an advantage. [illegible] forming the Exhibition of the Society [illegible] Artists decorated the walls, and proved [illegible] to those who were not wholly [illegible] in admiration of the various mechanical [illegible] exhibited. In addition to those whose [illegible] have been incidentally mentioned, we [illegible] amongst the company Sir Lewis Pelly, Sir [illegible] Mr. Sant, R.A., Lieut.-Colonel [illegible] Dr. Edmunds, the Rev. S. B. Burnaby, [illegible] Mr. Livingston, and many others, [illegible] hon. secretaries, Mr. Bord, M.P., and Mr. Smith.

[illegible]following are the questions which have [illegible] addressed to the members of the society on [illegible] question of screw threads. Comparatively few of the members—not more than a third—[illegible] yet replied, so that the decision of the [illegible] will probably have to be postponed for [illegible] yet:—

[illegible] been accustomed to use a lathe furnished [illegible] the thread known as Holtzapffel's [illegible] for what description of [illegible]

[illegible] experienced any of the inconveniences [illegible] do you think that they [illegible]

[illegible] the present and future conveni-[illegible] desirable that the [illegible] the adoption of a standard [illegible] in the construction of their [illegible]

[illegible] the present system [illegible] what [illegible] you wish [illegible] to make in these [illegible]

SCIENTIFIC NEWS.

THE great comet of 1882 does not seem to have been observed lately, and it is doubtful if any "position" has been estimated later than that for May 26 last, at Cordoba, where the comet was also detected on June 1. So lengthened a period of observation ought to enable the period of the comet to be calculated with more than usual accuracy, but at present Fabritius makes it 823 years, and Kreutz 843 years, the former being most probably the nearest.

In his address as President of the Royal Society, Prof. Huxley, speaking of Sir W. Siemens, said that "hardly any living man so thoroughly combined an extensive knowledge of scientific principles, with the power of applying them in a commercially successful manner; and that the value of his numerous inventions must be measured, not merely by the extent to which they have increased the wealth and convenience of mankind, but by the favourable reaction on the progress of pure science which they, like all such inventions, have exerted, and will continually exert."

Owing to increasing age, Prof. Owen has resigned the post of superintendent of the Natural History department of the British Museum, which he has held with much distinction for more than a quarter of a century.

Prof. Sylvester, it is said, is about to return to this country, having accepted a professorship at Oxford.

Besides the extraordinary phenomena witnessed during sunset and sunrise lately, we learn that a real blue moon was seen last week. The sky was red and the moon aquamarine on one occasion; and on another, the sky was orange and the moon a perfect sapphire blue, which we suppose means a deep blue.

According to the *Times*, though the dust of the dead mountains could not subjugate the sun in its strength, it has had force to "prolong its setting" and to determine the tone of the afterglow.

Referring to a paragraph in our Scientific News (p. 279), Dr. R. A. Hayes, physician to Dr. Steevens' Hospital, Dublin, sends us a brochure containing four microphotographs taken by him to illustrate Dr. Stack's paper on replantation and transplantation of teeth. The photographs are printed in colour by the Woodbury Co., to represent the staining of the sections, and are good examples of the skill of the photographer, and of the value of such photographs in illustrating papers of the kind.

At a visit recently paid to the Ben Nevis Observatory, the observer and his assistants were found in excellent spirits, and "quite at home." The visitors had to cut a path through the snow in parts, and on the summit found it six feet deep on the levels.

The Scottish Meteorological Society will shortly publish the observations of Messrs. Herdman, Beddard, and Hoyle, on the fisheries at Loch Fyne, Eyemouth, and Peterhead, together with the results of Mr. Norman's investigations as to the *food* of fishes in the Scottish lochs.

The inventor of the hot blast, Mr. J. B. Neilson, has now a monument to his memory, which has been erected by his son on Barstobrick Hill, near Kirkcudbright. It is in the form of a pyramid, 55ft. in height, on a base of 20ft. square.

The "standard time" has now been adopted on nearly all the railways in the United States, and has been followed, in one instance at least, by the further reform of reckoning the time of day from 0 to 24 o'clock. The Cleveland, Akron, and Columbus Railroad is the pioneer in this movement.

The standard time is sent from the Observatory at Washington at "75th meridian mean time," which is 8m. 12·09secs. earlier than Washington time, and when received at places belonging to the 90th meridian the clocks are set to 11 a.m. The "standard time" has already been adopted by many of the chief towns, and the "town clock" is now set in accordance with railway time.

M. Pasteur has shown that the bacillus of "rouget" as found in pigs can be attenuated by passing it through rabbits. The inoculated rabbits are all rendered very ill or die, but pigs inoculated with the bacillus, after the virus has been passed through a series of rabbits, have "rouget" in a mild form, and enjoy immunity from further attacks. A series of inoculations carried through pigeons, on the other hand, increases the virulence of the disease when a pig is inoculated from the last of the pigeons.

MM. Mouchot and Pifre have obtained a patent in this country for their solar engine; but it may be doubted whether they will find many infringers here until the climate is altered very materially.

M. Cartailhac has communicated to the French Academy of Sciences a description of some old flint mines in Miocene strata, near Mur-de-Barrez, Aveyron, which appear to have been worked by Neolithic miners. This is stated to be the first discovery of prehistoric mines in France.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

γ VIRGINIS—β 607 AND ARG. (—0°) 2,600—γ CASSIOPEIÆ—41 ARIETIS—β DELPHINI, &c.

[22120.]—MR. GEMMILL (letter 22036, p. 239) is correct in supposing that measures of the pos. angles of γ Virginis (and cognate stars) are not fairly indicative of the comparative brightness of either component; for this, the original observations must be consulted. His observations, if reliable, seem to point to rapid variability in either Arg. (—0°) 2,599 or 2,600. The former (β 607) was discovered to be double at Harvard in 1867, and has been observed at Cincinnati; the mags. agree very fairly. In remarking that "faint coarse pairs are not worth cataloguing," I referred, of course, simply to their being included as *double stars* in catalogues. I do not know of any particular authority for the variability of γ Cassiopeiæ; but Mr. G. is, doubtless, aware of its remarkable and almost unique spectrum, some recent observations of which he will find in *Ast. Nach.*, No. 2548. Smyth says, on page 21, of the *Bedford Catalogue*, "γ is suspected of variability," and then follow the words quoted by "F.R.A.S." on p. 290 of Vol. XXXVI. Flammarion gives the mags. of γ β and α Cass. on March 29th, 1880, as 2·0, 2·2, 2·5 respectively. Secchi seems to imply that it is *not* variable. I am not able to refer at present to other observations. The following are the principal measures of 41 Arietis other than those of Smyth, cited by "F.R.A.S.," on page 264:—

A—D	H.		125·58 :	1781.79 ;		1
	Sh.	226·6 :	127·56 :	1821·95 ;		1
	Σ.O.	228·7 :	127·40 :	1852·16 ;	9·0 mag.	1
	β.	230·2 :	125·90 :	1879·93 ;	8·5 mag.	2

The magnitudes are expressed in Σ.'s scale. The change is probably due to the proper motion of A, which, according to Mä. is 0·134″ annually in the direction of 158°. Smyth, in the MSS. calls B. indigo, C. and D. pale grey, and in the "Cycle" he says: "My friend, the Rev. W. R. Dawes, re-examined this object at my request in October, 1842, with results very similar to my own." I am not aware that Da's results have ever been published. Smyth quotes H's angle of A.C. as 188° 12′, but it is evidently 189° 12′, as the MSS. and printed catalogues agree; H marks his measure "very imperfect." Of A B, O.Σ. says, "Comitem exiguam primus Smythius conspexit." Is this a fact? [illegible] am unable to look up authorities at this moment, but I should be glad if Mr. Burnham, if he sees this, would say whether he knows of any measure of A B, other than Dawes's unpublished one, anterior to the publication of the "Cycle." Possibly Challis may have observed it; but it is a pity that the measures of double-stars made with the Northumberland equatorial have not yet seen the light. Ward has seen B steadily with averted vision with 2½in. Wray, but most observers would require a much larger aperture. In answer to Mr. Gaudibert's inquiries (letter 22099, p. 302) the following are β.'s most recent measures of β Delphini (182·5°: 0·23″: 3 nights; 1883·55) and δ Equulei (307·6°: 0·21″: 3 nights; 1883·55), from which it would seem that Mr. Gaudibert has actually succeeded in seeing δ Equulei also with 8½in. aperture—a feat upon which I must congratulate him. When at or about its greatest distance Dunér found it "oblongue, je suis bien sur" with the fine 9·6in. Merz, power 739, and this is the smallest aperture with which it has ever been seen. No one has ever succeeded in seeing the *comes* in the present quadrant before. Mr. Gaudibert should try the very unequal pairs η and τ Geminorum, and the exceedingly close equal pair 126 Tauri. The following are the most recent measures I possess of γ^2 Andromedæ; Hl. 99·4°: 0·33″: 3 nights; 1880·04; for comparison we have Hl. 101·90°: 0·38″: 5 nights, 1878·21; β 102·1°: 0·43″: 2 nights, 1878·65; β 107·9°: 0·36″: 1 night; 1880·06.

H. S.

MARE CRISIUM — REPORTING—FRACASTORIUS—JUPITER—DARK SPOTS IN ALPHONSUS—SATURNIAN DETAIL AND OBSERVATION.

[22121.]—I suppose it is the circumstance of my sketches of the Mare Crisium and Plato, in letter 22036 having been done in pencil, which is to blame for certain mistakes in their reproduction, which I will now enumerate.

Mare Crisium.—The ring of the crater marked D was seen complete. The ridge east of Picard was much more bent, curving westward just opposite the ridges marked B. The two craters west of the Pass were joined by a straight high ridge. The two mountains north of Picard E cast pointed shadows.

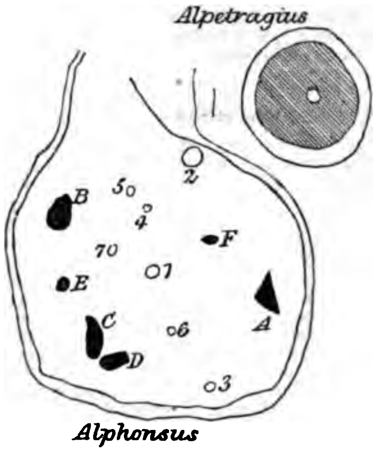
Plato.—The markings indicating the crater-cones can hardly be seen.

After reading Mr. Elger's letter concerning Fracastorius, and examining his beautiful drawing (which makes the "E. M." which contains it quite an artistic treat*), I made up my mind to look at this formation on the first opportunity. On the 18th, about 14h., I found one. Moon's age 19d. 2h. Terminator through Römer and a little W. of Fracastorius. The air was pretty clear, but the definition was very unsteady. Had it been steadier I have no doubt that I would have seen more detail; as it was, a great deal of that shown in Mr. Elger's drawing was visible with the 3¼in., and a power of 145. Of the objects designated by M. Gaudibert by the certainly appropriate, and as certainly infelicitous, name of "swellings," *p* and *y* were distinctly seen. But south-west from *p*, under the S.E. side of the wall of the formation, a rising-ground seemed to trend. Out of this rising ground an object which seemed to be p^1 appeared to rise as an eminence. The existence of an elevated surface here was plain, though none is shown in Mr. Elger's drawing. It stretched from the S.W. edge of *p*, and narrowed until it came to a point, and ended just east of the place of the craterlet shown by Mr. Elger upon the W. wall. An object occupying the place of *c* was visible, and was distinctly the brightest object on the floor. W, the object midway between it and *a*, and the ridge S.W. of it were easy. S.E. of the latter were seen two parallel objects running S.W.—N.E., and casting shadows. The heart-shaped mountain *b* was visible. Westward from, and parallel with, the southern spur from the E. wall, ran a spur not shown in Mr. Elger's drawing. West of this lay what appeared to be a deep, elongated, crateriform object.

In the remarks on Jupiter upon p. 240 (letter 22036), there is a mistake in punctuation, perhaps due to myself, which alters the sense. I *meant* to say that the brilliant equatorial spot was roughly circular all round *except* on the following side—where it was not quite so; but have said the reverse. I speak in the place referred to of a projection northward from the S. equatorial belt, as being distinctly the darkest marking visible. On the 28th of October I got, for a short time, an excellent view of Jupiter. The projection referred to was then so dark as to present the appearance of a dark spot. *Preceding* it, appeared a second bright spot, not, however, so bright as that *following*. A *lane* of light crossed the N. equatorial belt, running from the spot *p*, and was a curious and interesting feature. While I was observing, the eclipse of I. took place. It was rapid, but not instantaneous. The satellite seemed to me of a dull bluish-green or greenish-blue, and this hue seemed to become plainer during immersion. The satellite seemed to brighter slightly just before disappearance. This, as it appears to be, hurried extinction of a heavenly body is a startling and rather a weird sight, at least, when witnessed when not being watched for. IV. was much the brightest. III. was a little brighter than I.; and I. a little before II. IV. appeared to be white, and II. I thought bluish; III. was distinctly reddish. On the 16th, about 15h. 30m., I observed the bright spot again. It was distinctly the brightest portion of disc. The projection was not so large, but a point upon it was certainly the darkest point upon the disc. I did not see the *p* bright spot. Definition, however, was not good. IV. was much brighter than III.; III. was reddish-yellow, or yellowish-red.

Alphonsus.—In his description of this crater, Webb says, "Under a high light two bright specks, and several defined blackish patches, vary the surface, in those places perfectly level. Lohrmann drew 6 dark spots; Schmidt found but 3 dark and 1 faint." On the 17th instant, about 14 hours, I observed this formation. 3¼in.; e.p. 145. Definition not specially good. I inclose a sketch, in which are marked 7 bright and 6 dark markings. The bright spots are *numbered*, in order of brightness; and the dark spots *lettered*, in order of distinction. F was visible only by glimpses; E was plain and steady; C and D were certainly distinct. Spot 2 was larger than spot 1, and gave perhaps more light; but it was diffuse, and its outline not very well defined, while 1 was steady and sharp. A and B are marked on Webb's map. I would like much to know how the spots are marked in Lohrmann's map.

The appearance of the comparative drawings of Saturn by Mr. Franks and "F. R. A. S." may form a convenient opportunity for bringing forward a matter of some consequence. I refer to the giving of more systematic attention to the detail visible upon the *ball* of the planet. In a valuable paper upon planetary observations printed in *Nature* for October 18th, Mr. Denning remarks: "Though sketches of Jupiter are frequent enough, we rarely see attempts to delineate Saturn, and thus we have comparatively few records as to the arrangement of his belts. . . . No doubt the rings of this planet monopolise observers to such a degree that they neglect other phenomena which, though less attractive, may be of greater significance and interest." This seems to express a fact commonly overlooked, for while no astronomical phenomena *can* be, *in themselves*, of *greater* "significance and interest" than the rings of Saturn, it may well be doubted whether the representations of them which appear in ordinary sketches of the planet are in the least degree fitted to advance our knowledge of the system. What is left to learn concerning the rings of Saturn will have to be learnt either by scrutiny of them with great apertures, or by persistent observation of details, and not by the occasional drawing of their general aspect. In a letter in the *Astronomical Register* for September, the Rev. T. W. Webb takes notice of those phenomena of the system which require elucidation—such as the continuous visibility of Encke's division, the existence of minor subdivisions, the absolute blackness of Cassini's division, the shading of the brightest ring, and the phenomena of the gauze ring. But investigation upon these points, except perhaps the last, is beyond all ordinary instruments. It would be a good thing if the visibility of the gauge-ring in instruments of small aperture was made the subject of careful observation. It would be interesting to know whether any changes take place in the visibility of that portion which crosses the disc. Of course, there is nothing to prevent the disc behind being covered with a material of higher reflecting power at one time than at another, and so throwing out the ring with greater distinctness at such times. Any inquiries as to variability are, of course, always attended with the uncertainty due to the state of the weather and of the eye, and it would be well if, when any object is either unusually easy or unusually difficult, observers could always make observations as to the visibility of other faint and difficult objects. More care and caution, with less anxiety to see marvels, would no doubt reduce the number of extraordinary observations. It is, however, to the phenomena of the belts, zones, and spots upon the ball that I would direct attention. I do not, of course, know whether the engraver has *exactly* reproduced the drawing made by "F. R. A. S.," but if he has, it strikes me as curious and interesting that a 4½in. should not have shown detail revealed by my 3¼in. The difference is this: in the drawing by "F.R.A.S." the entire southern hemisphere is shown as almost *equally* shaded, and without subdivision into belts or zones of any kind; but on several occasions lately I have distinctly seen, when definition was good, at least two dark belts. Now, we know that the belts have been seen with 2in. of aperture. The only explanations of these discrepancies are these: the belts may be variable in distinctness, they may be variable in form and persistence, or they may be more readily visible upon one portion of the planet than upon another. Upon the first hypothesis it would be necessary to assume that the material of the belts varies in light-reflecting power—a point worth investigation. The second is the most probable; but unless we can unite with it one of the others, we are driven to suppose that the surface of the planet changes with a rapidity for which we are not altogether prepared. Of course, it is quite possible that clouds may be deposited and dissipated with great rapidity in the higher regions, above the locality of the belts. If these phenomena took place, we would, of course, at times not be able to see the details of the belts. The third hypothesis suggests an interesting possibility. Of course, though it *should* be proved that the belts are apparently discontinuous, or in some other way different in different parts, it would still remain possible that the apparent variations were due to obscurations by clouds formed as suggested above. But one thing is clear: to settle such a point we must compare sketches according to the period of the planet's rotation to which they relate. The period of axial rotation of Saturn is brief, and not commensurable with that of the earth; consequently, if we inspect the planet at about the same hour each night, we must inspect on each occasion a fresh part of its surface, and if we vary our times of observation we must still very probably do the same thing. Therefore, not only ought all sketches of the planet to be carefully dated, but we ought, in comparing one sketch with another, to take care that we notice whether we are comparing representations of the same, or of different, portions of the discs. The hypothesis which suggests *change* is the most interesting, and it would be all the more interesting were there any suspicion of *periodicity* in the changes. In describing the planet, Mr. Webb says: "The globe is diversified by darker and lighter bands, changeable, but usually parallel to the equator, though Sir William Herschel noticed occasional deviation. His 'quintuple belt' of alternate light and shade is now seldom to be seen; usually there is a strong central whitish band, the brightest part of the ball; on each side of it a broad brown or somewhat ruddy zone, with many streaks and markings, generally parallel, and, according to some authorities, reaching to the limb; to the principal of which the Washington achromatic gives wavy edges: then a similar greenish or bluish grey region extending to the poles, which are capped by a darker patch of the same tint, with sometimes a pale central space. Sir W. Herschel found the brightness of the polar regions variable. Browning describes the colours in 1868, with a 12½in. mirror, as light cinnamon and bright azure blue." To find in how far this description holds good *at present*, and to discover what changes, if any, make themselves visible from time to time, would be excellent objects for possessors of telescopes to place before themselves. It would be very interesting to know what change, if any, takes place in the *colours* visible upon the ball. Of course, this latter inquiry could only be conducted with instruments of considerable aperture, and preferably with reflectors; but there are plenty such lying idle. It will be seen that it is the making and comparing of drawings of the ball, care being taken to record carefully the times at which the drawings are made, that I urge; and if the sketches are made, I would suggest that some, at least, should be published. Inasmuch, however, as a sketch of Saturn takes up a considerable amount of space, and you, Sir, might object to give up so much to the subject, I would suggest that the sketches when published should be limited to the ball. Representations of the ball alone would not take up so much space, and would not cost so much to engrave as representations of the entire planet. I would especially like to see, and I am sure all your astronomical readers will agree with me, sketches by Messrs. Webb, Denning, Franks, Perry, Williams, Bruce, and Barnard.



---

* The credit is entirely due to Mr. Elger, and correspondents who complain of the bad reproductions of their sketches may take a hint.—Ed. E.M.

The subject is one of great interest and importance; at present the planet is well situated for observation. I do hope to induce some of the numerous owners of large telescopes to attack the problems involved. Cannot the able and energetic heads of the Liverpool Astronomical Society do something in the way of setting amateurs to work at the elucidation of these matters? Certain points seem to me worthy of special attention. First. The occurrence of belts lying oblique to the planet's equator. These seem to be very rare. One is shown in a sketch in the E. M. by Mr. [illegible], taken with [illegible]in. [illegible] October, 1877, but it is comparatively small. Second. The character of the belts. They are generally represented as equal and continuous. That they are, perhaps, not always so is, of course, one of the points raised above. In Mr. G. F. Chambers' "Descriptive Astronomy" there is a drawing by Bond in which the markings on the disc are shown in a way utterly different from that in which they are usually shown. In this, not only are the belts discontinuous, but their ends and [illegible] are [illegible]. The possible discontinuity, [illegible], and variability in brightness, [illegible], and colour, of the various belts are all matters well worthy of investigation by those who have telescopes which will carry them through the work.

In this connection, a point relating to the notes and drawings of Saturn furnished in these columns may be mentioned. In the drawing by [illegible] we find the northern edge of the shaded portion of the S. hemisphere rather more [illegible] than the rest. In Mr. [illegible] drawing we find the corresponding border [illegible] with the best definition —a [illegible] circumstance, if the engravings are [illegible] on these points. In neither case have we [illegible] suggested. But in letter [illegible] p. [illegible] Mr. [illegible] says "The wavy edge of the [illegible] of the bright equatorial belt was well seen." This I take it comes to the same thing as [illegible] of the dark equatorial belt already referred to. [illegible] Mr. Perkins' [illegible] Mr. Franks [illegible] the boundary of the dark belt and the bright zone [illegible]. The recurrence of spots, [illegible] says "Spots and streaks [illegible] easily enume- [illegible] observers to keep [illegible] they come they do not [illegible] observations of spots on [illegible] they would throw [illegible] of the planet [illegible] within it and they [illegible] of the [illegible] planet's [illegible] about Saturn. I [illegible] between [illegible] that for [illegible] between the ring and [illegible] a star [illegible] between the planet [illegible] Taurus [illegible] Sagittarius in [illegible] the new [illegible] however, that [illegible] of the [illegible] He remarks [illegible] unfavourable [illegible] certainly [illegible] occurrence of [illegible] of estimation [illegible] different parts of [illegible] with [illegible] but proper [illegible] of their [illegible] not fail to be [illegible]

[illegible] Baird Gemmill.

MÄDLER—THEOPHILUS—HORROX—FRACASTORIUS.

[illegible] I first observed [illegible] I was not [illegible] what it was; but in 1880—Feb. 28th and March 17th—with a 4in. telescope, I saw it plainly to be a crater, and marked its position at the south-western end of Mr. Neison's short ridges. This corresponds with Mr. Gaudibert's position. I thought that it was nearer to Mädler than to Theophilus. I have seen it since that time, once in 1881, and three times in the present year. April 25th of this year is the only occasion on which I noted it as a *white* crater. In 1880, March 17th, and 1883, Oct. 20th, there was a second crater W of it. On these and other occasions a ridge was seen W. of both craters, springing from the N. wall of Mädler and bending to the east, partially inclosing the ground on which the craters are situated. Some small hills are also to be seen on this ground. Neither the ridge nor craters are shown by Mr. Neison. Two craters N. of Theophilus, which are shown by him, were also seen on the two dates in 1880 above mentioned.

I have been watching for the crater in Horrox. At the last moon the weather was unfavourable. On the 7th of this month at 4h. 30m. p.m., though there was not much shadow remaining in Horrox, it was sufficient to hide the crater; the shadow bulged out on the floor, however, at this point. By 8h.30m. the shadows had considerably lessened under the wall S. of the crater, while there it was a large round, dense patch exactly like a hole without walls. Clouds prevented anything more than this momentary glimpse. The next night also, the moon was not to be seen even for a moment.

I thank Mr. Elger for his reply about the rings N. of Fracastorius. I have many sketches of them, in all of which they appear perfect: but this is no doubt owing to my having used a smaller telescope. Only on one occasion did I note that the ring A was broken. The ridge which Mr. Gaudibert mentions as inclosing B, C and D, I have also seen; a sketch of Fracastorius in the *Selenographical Journal* by Dr. Richards also contains it. Y has generally appeared to me as a dark patch very similar to N; but it is much more rarely visible, while N, with one crater in it, and A with one crater, are very generally to be seen. The cleft ρ^1 must, I think, be rather easy to see sometimes, for I saw it in 1878 with a 3¼in. telescope, when I had not observed Fracastorius before.

M.A.

SELENOGRAPHICAL—FRACASTORIUS.

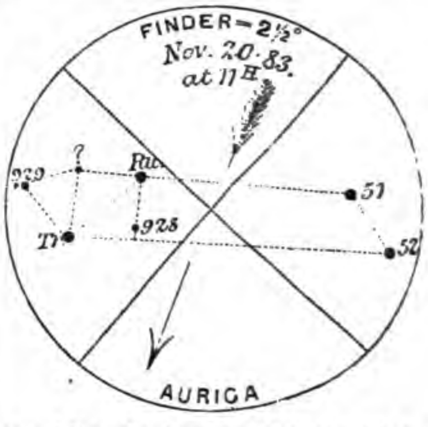
[22123.]—In reply to Mr. Gaudibert (letter 22093), allow me, in the first place, to assure him how highly I appreciate the very complimentary remarks he makes regarding my drawing of this formation, which, emanating from so diligent an observer as himself, are of more than ordinary value. With respect to the principal cleft shown in his sketch (English Mechanic, Vol. XXIII., p. 495), the want of agreement as regards position and direction between the western portion of it as there depicted, and my cleft ρ can perhaps only be accounted for on the not improbable supposition that they are two distinct features. September 20th was not the only occasion on which I have been favoured with a satisfactory view of this cleft. On referring to my observatory book I find, under date 24th January, 1882, 5h. to 6h., that it is shown almost precisely as in my recent drawing, and is noted as "an undoubted cleft traceable from the west side of *a* to a crater cone not far removed from the foot of the inner slope of the west wall." On the same evening another short and delicate cleft was observed south of ρ (and distinct from it), making an angle of about 45° with it, and trending in a S.W. direction. I note with very great interest the cleft shown in Mr. Gaudibert's drawing on p. 302, crossing the semicircular formation A, and terminating on the south at the craterlet 41. The latter, by the way, is double, the component craterlets lying in the direction of the cleft. I usually find the peaks on the low narrow ridge which extends from A to the eastern wall, very easy objects under a low sun. This ridge seems to be made up of three distinct portions, as clearly shown in Mr. Gaudibert's sketch. On October 1st and 2nd, 1870, with a power of 200 on a 4in. achromatic by Cooke, I saw these peaks very plainly, and describe them as "bright and conspicuous." The floor of Fracastorius falls rapidly towards the S.W. side of this ridge, thereby forming a deep ravine or wide valley, which runs parallel to it throughout its length. The "fine ridge," *m*, has been frequently observed, though on the date of my drawing not a trace of it could be distinguished. It is of so moderate a height that I cannot see that it affects the question as to the possible incursion of the Mare from the north towards the objects B, C, and D. On January 24th, 1882, three large craterlets were observed on the outer slope of the E. wall of Fracastorius, the most southerly of which seems to agree in position with Mr. Gaudibert's *e*; the remaining two were more to the north. The two minute craterlets shown in my drawing immediately north of *f* are distinct from the craterlet 47, which I generally find an easy object, though it was not seen on September 20th. I should like to say a word or two respecting the object numbered 18 by Mr. Gaudibert, and lettered C in my drawing. Under a high sun, it has the appearance of a large round nebulous spot, with an ill-defined outline; while under very oblique illumination it accords perfectly with Birt's description, "A round-topped tableland." Schmidt shows a *large* crater here; and Grover, on 1st July, 1865, records it as a crater. But my experience of this object, extending over some 15 years, induces me to regard it as very difficult to make out as a craterlet. On 24th January, 1882, with a power of 350 on my 8½in. mirror, it appeared to be surrounded by a peculiar nebulous light or glow, very different from the tone of other spots on the floor; and it was only after careful and sustained attention, that I could just detect in the midst of the brightness a delicate craterlet of the minutest type, which would certainly not have been distinguished had not the definition been exceptionally good—so good, in fact, that 29 craterlets were, more or less, easily seen in the interior of Fracastorius, without taking into account isolated mounds or craterlets visible on and about the north border. The extreme difficulty of seeing 18 as a craterlet seems so inconsistent with Schmidt's representation of it as a large crater, and Grover's observation of it with, I believe, an achromatic of very moderate aperture, that I shall be glad to learn from Mr. Gaudibert or other observers whether my experience with respect to this object is peculiar or not.

Thos. Gwyn Elger.

Kempston, Beds, Dec. 8th.

AURIGA.

[22124.]—The following note may perhaps have an interest to some of your astronomical readers. There exists in Auriga a quartette of objects very near together, and each of them I think will be allowed a tolerably good specimen of its class. There is a red star, a tolerable close double, a pretty triple, and another double, with a charming greenish *comes*. All these may be seen together, with the least turn of the screw, in the field of 60, on a 3in. ach. I observe them with this power in a first-class 3in. Wray, and really the view is one of great interest, and, so far as I know, not to be met with elsewhere. The positions and details of these objects are given in Prebendary Webb's invaluable "Celestial Objects." May I beg the favour of your insertion of the accompanying sketch, if you can find room?



51 and 52 Aurigæ (see Proctor's Large Atlas) are roughly, 8° below β and θ Aurig., but a little nearer θ. Without any very mathematical exactness, I may describe the principal stars 52, 51, Ru., and Tr., as forming the half of a hexagon. These four stars are prominent in the finder, and stretch pretty well across its field. Having secured this half-hexagon, the other stars are easily identified—*e.g.*, 928 is at a right angle to Ru. and the Triple, and 929 is on the left of, and forms a triangle with, Ru., and the Triple. The *comes* of 929 is a charming object.

Whilst writing I may add that 51 and 52 point twice their distance to 941, which is below them on their right, but is not shown in the sketch. I think 941 a good test for a 3in. ach. It has also what I think is a good light test in a very faint comes, perhaps 80 *s.f.*

If you can find room for the following details, it will help to the clearness and completion of my communication.

AURIGA.

	Mag.	P. A.	Dist.
Ru.		Distinctly so.	
928	7, 8	134°	3·4
Triple	6¼, 8½, 9	—	—
929	7, 8	24°	6
941	7, 8	77°	1·2

Dec. 3. **H. D.**

SATURN.

[22125.]—I took advantage of what appeared to be a tolerably favourable evening on Wednesday last, the 28th ult., to compare the figure of Saturn given by your correspondent "F.R.A.S.," on page 263 with the planet itself, and it may perhaps interest some of your readers to learn what can be done in the neighbourhood of London with an achromatic of exactly the same aperture as that used by "F.R.A.S." All the features of the figure were at once seen without any effort whatever, and, except that the bands across the planet were somewhat different, everything appeared very much as there represented, even to the shade on the outer ring, which though not so dark as in the figure, was more apparent than I ever recollect to have noticed it. The division in the ring, however, appeared wider in the ansæ than given by "F.R.A.S.," and I thought it appeared better defined on the inner edge. With a power of 260, the great difference between the light of the two rings, together with the termination of the shadow of the planet at the outer edge of the inner ring, gave the idea that they were not in the same plane, the inner ring appearing to be raised above the other. With a power of 140, the difference in light was not so apparent, and with 100, no difference could be perceived. The dusky ring was very indistinct, and of a bluish-grey colour, and only the half of it nearest the earth could be made out. I do not know whether this is intended to be represented in the figure of "F.R.A.S."; but it is rather remarkable that the other portion could not be seen, for Hind in his "Solar System," p. 110, says:—"The more distant portion of the new ring is seen much more distinctly than the corresponding portion nearest the earth." Perhaps some of your correspondents who have larger apertures will give us their experience. Five satellites were visible with powers of 260, 140, 100, and a lower power—I think about 60 or 70. They were perhaps brightest with the lowest power; but the whole system was of course very much reduced, and two of them were brought very near the outer edge of the ring. They were seen easily with all the eyepieces.

At 10·35 a brilliant white fireball became visible between Xi and Eta Draconis at about a third of their distance from the former star, and made a direct course towards the horizon, leaving in its wake a train of small sparks. It vanished about 15° above the horizon. **Henry T. Vivian.**

SPECIALISM IN ASTRONOMY—CHINESE WHITE—SATURN.

[22126.]—The remarks of Mr. Maitland Baird Gemmill (on p. 239), on the advantage of not working only at one branch, are certainly true; but the difficulty is that if we would do good work at any branch, we must concentrate ourselves upon it, and the nights and days are too short to concentrate ourselves on much more than one branch. My own experience is this: last winter I worked at three branches, with the result that for four or five months I was up, for several days together, 22 or 23 hours out of the 24, then getting three or four hours sleep for a night or two when it was cloudy, then only one or two hours again.

Through the summer I have worked at two branches. The short nights gave me more sleep: but then and now I often do not go to bed for fifteen nights together, sleeping between times as I can. This is the result of working at more than one branch. I suppose every one has not time to sleep in the day. I have not.

Mr. Franks and "F.R.A.S." have observed that Saturn bears a higher power than Jupiter. Have they also noticed that the focus for it is different to that for Jupiter? I have always observed this to be the case.

A short time back some one stated, in reply to a query, that glycerine should be put to Chinese white to soften it. I did so with mine, with the result that I have spoiled three elaborate drawings. It certainly softened the Chinese white; but nothing that I can do will make it dry on the drawing. I think people ought not to recommend things without knowing what they answer, unless they do it with a warning. **Brickwall.**

LIGHTNESS OF WINTER NIGHTS.

[22127.]—I have often wished to draw attention to a curious fact which I have long noticed—viz., the brightness of the nights sometimes when the moon is not above the horizon, and there is nothing to account for it. It happens on both cloudy and clear nights, and the light being sufficient to make out the various things in the observatory; and out of doors it is a strange contrast to the intense darkness of some other winter nights. The amount of light is generally greater on cloudy than on clear nights, being then equal to what the moon sometimes gives. Perhaps it can be better explained on cloudy nights; but I can see no reason for it on clear nights. Have any other correspondents noticed it; and can anyone account for it? **M.A.**

LOCOMOTIVES.

[22128.]—Mr. Wm. John Grey (page 305) expresses "*surprise*" *that I have not written a reply* upon this subject. He is, perhaps, unaware that in back volumes of the English Mechanic I have discussed the question very fully, and given the necessary formulæ. In my opinion, the information for which Mr. Grey asked has been fully and ably furnished by Mr. A. Luis and "Historian." The rules for resistance and tractive force have been clearly and correctly given by both these gentlemen. I am at all times happy to give assistance; but I really cannot see any useful object in taking up valuable space simply to repeat rules which have already been furnished by two correspondents. **Clement E. Stretton.**

Glen Magna, Dec. 8th.

CONTINUOUS BRAKES.

[22129.]—"Imprimatur," in letter 21991, makes a statement that air brakes cannot be used for shunting purposes. "Imprimatur" evidently knows little of the Westinghouse brake. I see it used every day for shunting purposes. Before the coach to be shunted is detached from the train, the taps at the end are closed, the reservoirs being charged with air. A man riding on the step can open the tap when required, and the brakes are applied with full force. I see coaches on the N.E.R. running at a considerable speed stopped in two or three yards by this means.

Again, "Imprimatur" seems to forget that with the Westinghouse brake there are gauges in the vans, which the guard sees before the train starts; so that, if the cocks have not been opened, the omission is at once rectified. On the North-Eastern Railway no train is allowed to start until the guards have looked at the gauges and tested the brake.

I repeat, with Mr. Stretton, that there is always a danger of the brake connections freezing in winter, in the case of mechanical brakes. Take the case of Fay's brake on the L. and Y.R., which I have known to freeze several times. In the case of this brake (applied by the guard), the connection is a rod, which turns in a socket. This is used in the case of every stop made, and one would think that there was no chance of it being frozen, owing to the frequency of use. The chain brake (L. and N.W.R.) is often frozen. Mechanical connections are also often clogged up with dirt in nasty weather. This has also proved a source of failure in the case of Fay's and the chain brakes.

In the Westinghouse brake, very little dirt, if any, enters the pipes, owing to the use of a drip-cup for drainage. Such dirt, &c., as enters is often blown out again by the compressed air.

Simplicity is all very well, *provided*, as "Imprimatur" himself says, *the efficiency is secured*. As a matter of fact, in the case of the existing brakes, the brakes (e.g., Smith's vacuum) which fail most are the most simple. This looks well for "simplicity," though this is the point on which the arguments of the upholders of the vacuum brake are based.

"Imprimatur," and also your correspondent "Traffic" (letter 22060), seem to consider that the best plan is to use the momentum of the train to create the power by which that momentum is to be destroyed. This looks well theoretically, and may have arguments in favour of it. But let us take a practical illustration—viz., the G.W.R. vacuum brake. The vacuum is maintained on this line by a pump worked *mechanically* from the cross-head of the engine. Thus the amount of stopping power stored up in the train is proportional to the velocity; and it would seem that the brake was practically perfect owing to this system. But let "Imprimatur" look at what Col. Rich says in his report on the Portskewet Pier accident. (This I quoted on p. 85, Vol. XXXVII.) Most engineers would prefer a constant brake power of, say, 30,000lb. per carriage to a power varying from 0 upwards with the speed of the train.

Otherwise the letter by "Traffic" (22060, page 265) is very good. It would be interesting to know how the inconveniences stated by him are got over.

I must thank Mr. Parker-Smith for the interesting description of his brake.

To answer "Imprimatur's" letter, page 265. He lumps together all the "failures" (so-called) of brakes, irrespective of their nature. A train running into the buffer-stops and injuring the passengers counts just the same (according to "Imprimatur") as a few minutes' delay, the latter possibly arising from the negligence of a servant. But let "Imprimatur" give us a list of failures under headings 1, 2, and 3 of the Board of Trade, and the difference will be strikingly shown.

Let us look at "Imprimatur's" figures. He gives 16 as the number of failures of the Midland Clayton Automatic Brake. I have before me a record of considerably more failures of this brake, many of which were not reported.

The Midland Railway report 29 failures of the Westinghouse brake. I may say that this brake is scarcely looked after at all on the Midland, and a great fuss is made when it (naturally) fails, even when the failure is a few minutes' delay. On the other hand, great care is taken to keep quiet about the vacuum brake failures, and the drivers scarcely dare risk their position by reporting anything against it. Engine 814 has just come out of the shops, and the Westinghouse donkey-pump looks as if it had scarcely been seen to, and the air-pump formerly on engine 902 was in a shameful condition for several years. No wonder this brake fails on the Midland Railway. "Imprimatur" says that Clark and Webb's chain brake shows very satisfactory results. "Imprimatur" has peculiar ideas of "satisfactory." The L. and N.W.R. Company are removing this brake because they find it unsatisfactory. The brake is only an emergency brake, and is rarely used. I have heard several drivers say that they would far rather rely upon the hand brake.

Of the Smith's vacuum brake little need be said. Most of your readers know that it is unreliable. Taking the Board of Trade returns from 1878 to 1881 inclusive—

Number of cases of overrunning owing to failure of brake itself: Westinghouse 9, Smith's vacuum 216; other cases where stopping power was affected owing to brake itself: Westinghouse 7, Smith's vacuum 340.

In the above 556 cases of failure of Smith's vacuum brake, there are 5 accidents due to the failure of the brake, or which the brake proved useless to prevent. Five *other* accidents reported on by the Board of Trade inspector were *not* included.

"Imprimatur" shows a great deal of inconsistency in his arguments. From them it seems that he argues *in favour of* automatic brakes when advocating the cause of the Parker-Smith brake, and *against* them when he has a fling at the Westinghouse. For instance, he makes a great deal of the point that automatic brakes (of course, only the Westinghouse) go on unexpectedly and stop the train, and possibly another train runs into the first from behind. He seems to forget that the Parker-Smith brake is also automatic, and the same thing is also liable to occur. He does not seem to think it better for the brake to show automatically that there is a defect somewhere; but he prefers the train to run on until, when the brake is required, it is found, when too late, that there is none. He claims for the Parker-Smith brake that it is automatic. If it did this sort of thing, I should like to see what "Imprimatur" would say. Again, in support of his statements, he records a failure of the Westinghouse on Long Island Railroad, U.S. Before "Imprimatur" records failures he had better make sure of correctness. The brake failure in question was one of Smith's Vacuum Brakes. This is the brake in use upon this line, and the Westinghouse is not employed at all. I never heard of the St. Alban's case. Will "Imprimatur" give full particulars instead of the vague uncertain statement in his former letter? It is all very well to make a long argument because the Westinghouse stops trains automatically, thereby endangering it. Let us look into the case.

The Brighton Railway Co. ascertained the number of stops made upon their line on two separate days. On 5th April, 1883, 16,460 stoppages; on 26th July, 1883, 17,747 stoppages. Of these, about 7,000 on each day were extra stops (signals, &c.). Therefore, "Imprimatur's" one great argument entirely breaks down, as here were 7,000 cases of trains "endangered" by unexpected stops. **Meteor**

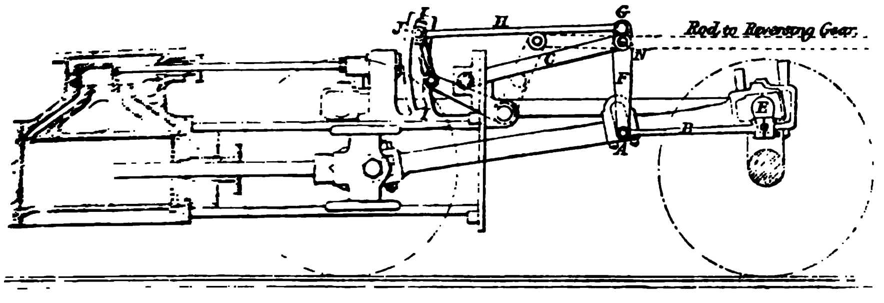
THE MORTON VALVE GEAR.

[22130.]—On page 411 of last volume, I gave a diagram and description of Joy's valve gear, I now send similar details of Morton's gear to which a correspondent (p. 273) refers.

The inventor read a paper before the "Institution of Engineers and Shipbuilders in Scotland" about a year ago, and since that time the practical working of the gear confirms all he said in its favour. It will be seen from the accompanying copy of Mr. Morton's diagram, that the motion of the connecting-rod of an eccentric or overhung crank, are combined and communicated through levers and radius-rods to a curved link attached rigidly to the valve-rod, and sliding in a suitable guide, the motion of which is given by the rod attached to a pin in the die of the link; the reversing and expansion depends upon the position of the die in the link.

Your readers are aware that a fixed point on the line of a connecting rod, actuating a crank describes the path of an irregular elliptical figure resembling the outline of an egg, the larger end being nearest the crank, so that any lateral motion derived therefrom must be irregular. This difficulty is not a new one, as it has presented itself to every engineer who desired to obtain valve motion from a point in the connecting rod.

To overcome this source of error, it will be seen that Mr. Morton adopts a simple means to convert the irregular lateral motion into a regular motion. The movable point (A) is actuated by an overhung crank (E), through the link (B); the link (C) vibrates and carries the fulcrum (N) of the lever (F) through its circular arc, but the lever F



[illegible] an extended over-end centre (G) so far distant from N as just to give it horizontal travel equal to amount of the "lap" and "lead" of the valve, whilst the vertical travel agrees with the minor axis of the elliptical figure described by the movement point A. The link (H) is connected at its end to the centre (G) of the lever (F), and thus follows a through the small elliptical path; the upper end is jointed to a slide block or die (J), capable of adjustment in the curved link (I).

The Morton gear is now fitted to a bogie passenger engine on the Caledonian Railway and appears to give satisfaction.

Clement E. Stretton.

[illegible]-street, Dec. 1st.

KEY CHARACTERISTICS OF MUSIC.

[illegible] by itself a key has nothing independent [illegible] other keys. It has a major and minor mode [illegible] with some others, and is affected by [illegible]. A shifting keyboard [illegible] are all alike. Play the [illegible] the only difference is [illegible] again in a minor mode and [illegible] a melancholy ditty. [illegible] obtained by suddenly [illegible] part, half a tone [illegible] gradually returning to [illegible] the "Bohemian [illegible] would be pro- [illegible] A peculiar effect is [illegible] by having a slight [illegible] and out of tune. [illegible] of a violin, when [illegible] is moved from side to side. [illegible] organ, but not so [illegible] be varied to suit [illegible] all you see, [illegible]

TRICYCLE.

[illegible] their various [illegible] say a few words in [illegible] I have ridden it now [illegible] since September [illegible] steadily, easily, and [illegible] for brickbats. [illegible] a bicycle, and that [illegible] I want to know [illegible] out of it? Being [illegible] this. For those [illegible] motion, having [illegible] and speed. The gear- [illegible] without stop- [illegible] free running, which [illegible] Its disadvantages are: [illegible] its weight is 95lb., [illegible] very glad if other [illegible] give their experience.

I would also bring before your tricyclists the pleasure of [illegible] frozen road, and particularly on a moonlight night. It is a great mistake to think that the frost stops the tricyclist's enjoyment.

John Alex. Ollard.

MICROSCOPIC TEST OBJECTS.

[22134.]—Having worked at these objects for some years, and having also kept pace with the times in objectives and apparatus, I will, in answer to Mr. Carr's request (22076), give the results of my experience. 1st, the total abolition of oblique illumination if one wishes to see the true structure of an object; 2nd, object mounted dry on cover.

I use a P. and L. achromatic condenser, accurately centred to the optic axis. The edge of the flame of a paraffin lamp, with $\frac{1}{4}$in. wick, exactly focussed on the object, without bull's-eye or mirror. This illumination, with a P. and L. oil $\frac{1}{12}$, N.A. 1·43, easily resolves A. Pellucida, dry on cover, *with direct light*—i.e., without slot or stop.

If S. gemma is examined by this means, the hemispherule theory is at once exploded, and the true structure (which is far more beautiful) is revealed. It is something like a most delicate skeleton leaf. This, however, is very difficult for a beginner. The P. formosum is, perhaps, the best one to try first. Work away at that until the hemispheres, which are so easily seen, give place to a *square* grating! To see this, with a $\frac{1}{4}$, N.A. 74, will severely test the lens and the observer's manipulative skill. A coarse Nav. lyra and a Tryblionella punctata, both have square apertures, and are very easy. N.B.—If the objective is much out of correction, the square apertures will blur round. The next one to try is P. angulatum. In this, a fracture should be distinctly seen to pass *through* the apertures. The apertures will take a *rose* tint if the glass is properly corrected.

It is manifestly absurd to test an objective by a fine diatom seen with oblique light, for only a small portion of a narrow marginal zone of the objective is used. The central, and by far the more important, part of the glass might be stopped out.

By the central illumination, however, the whole of the objective is used; the centre by the dioptric beam, the margin by the diffraction pencils. In former days one used to hear this sort of thing said: "This $\frac{1}{12}$ is a beautiful diatom glass." "This $\frac{1}{10}$ is splendid on 'Podura,' but not good at diatom resolving." (What a fine thing for the opticians! One had to buy two glasses, one for Podura and one for diatoms.) The explanation is very simple: For Podura a glass must be good in the centre, and for diatoms, with oblique light (the only light used in those days), good in the marginal zone. So then the $\frac{1}{10}$, which was good for Podura, and the $\frac{1}{12}$ for diatoms, could neither of them have been thoroughly corrected from their centres to their margins. I have a glass in my collection which is very fair on Podura when the screw collar is in one position, and also is a good diatom resolver with its collar in another position; but when all its zones are tried at *once*, by the direct illumination, it utterly breaks down.

With regard to A. pellucida, the *strongest* resolution is obtained with P. and L.'s vertical illuminator. The long striæ can only be seen by this method. Spurious long. striæ may be easily seen; but the true lines are very difficult, and may be estimated to be 120,000 to the inch at the lowest. The transverse I have counted repeatedly, and find them, in Van Heurck's specimens, very constant at 95,000 per inch. The best picture of the trans. striæ is obtained with oil imm. $\frac{1}{12}$, N.A. 1·43, or oil imm. $\frac{1}{8}$, N.A. 1·38, and P. and L.'s oil immersion condenser, *used dry*, with single slot, edge of flame direct, valve being dry on cover. The lowest angled glass, with which I have seen the trans. striæ, is a water imm. $\frac{1}{16}$, N.A. 1·08, and the lowest power $\frac{1}{4}$, N.A. 1·17.

December 4th. **Edward. M. Nelson.**

OPTICAL.

[22135.]—I regret that we are to have only the results, not the method, of Dr. Hastings, and still hope we may obtain the original. I trust, Sir, you will advertise the want as widely as possible, that some of our American friends, perhaps even Dr. Hastings himself, may be induced to let us have an outline of his analysis; the notion of "light energy" sounds well, but is somewhat Greek to most of us. I am glad Littrow's papers are coming, and shall hope to see Gauss's follow.

As regards dispersion, I would not have troubled "O. V." but that I thought his remark had some deeper meaning. Of course, a substance has as many dispersions as there are wave-lengths between red and violet—perhaps more; but fixing on the index of refraction of any one length as a standard the dispersion for light of any other wave-length is definite enough, and for their colour the ratios of dispersion of crown and flint are also definite enough, and but for the irrationality of the spectra would be very definite indeed, and the same for every pair of colours in the spectrum, till we get glasses with the colours of their spectra arranged proportionately; we only attempt to unite two colours, and which two seems a trouble. C and F, D and F, and perhaps (for three colours) C E G are mentioned in theory, because the most brilliant and most nearly complementary; but whether these are used in practice I should doubt. I should think experiment would decide the best ratio of dispersions to use for any kind of glasses more conveniently than theory; but it just strikes me that merely picking the two brightest complementary colours is perhaps inadvisable for this reason—that the ratios of dispersion for so many other colours may be alike, though not quite the same, as that for C and F, that it might be worth while to let go perfect accuracy of union of C and F in order to bring the collective weight of these others to bear on the side of achromatism.

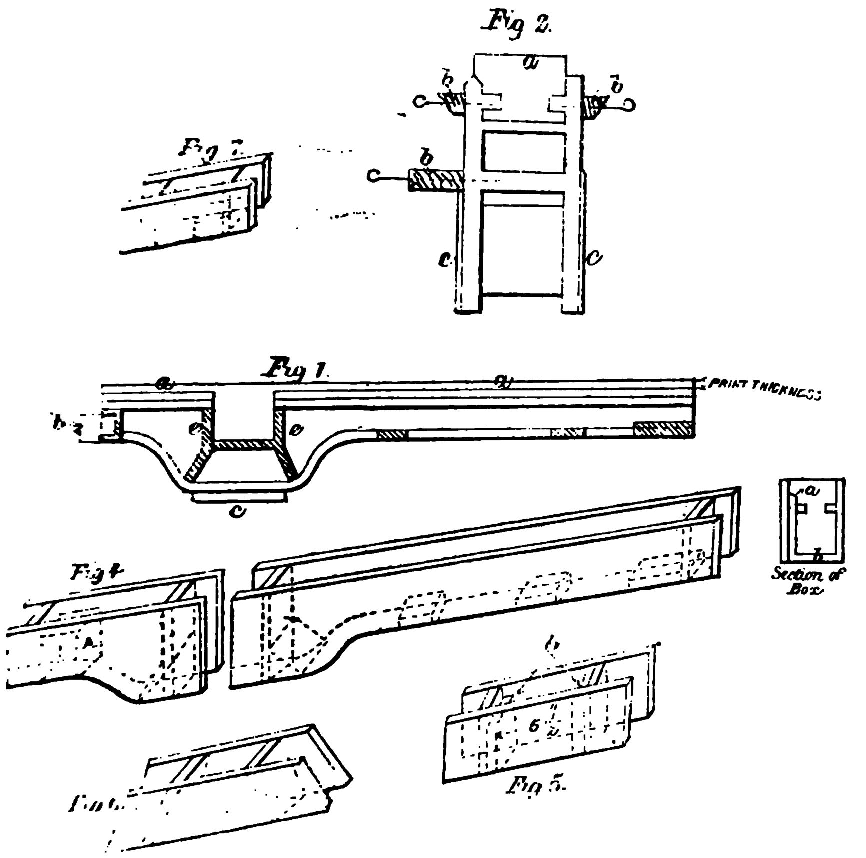
There is no book on the "Construction of the Achromatic Object-glass, in Theory and Practice," as far as I know, in any language. I beg to state my belief that one giving the pith of Coddington, Barlow, Littrow, Gauss, Herschel, and "O. V.," with the working processes of Dollond, Tulley, "Prismatique," and others, would not be of limited interest: it would be on the hobby of thousands, and we should "sell the farm to buy the horse."

Can any one give a list of papers on the working of o.g.'s by Dollond, or others since his time?

Bow.

COMPOUND ENGINES OF TWO CYLINDERS.

[22136.]—Seeing that the interest taken in compound engines is growing among your readers, I think a few words upon the variable results which may be obtained from a given quantity of steam may here not be out of place. I think few of your readers will have failed to notice the description given by some querists of their way of cutting off steam in both cylinders of their compound engines, and especially in the low-pressure. So varied are their arrangements that we find the cut-offs are arranged for one-third, one-half, and two-thirds of the stroke, regardless of the relative ratios that the cylinders bear to each other. I need scarcely say that with some of these arrangements the power of the compound will be less, theoretically, than that of a single cylinder engine using the same measurement of steam. Now, in my opinion, the cut-offs in the low-pressure cylinder of a compound engine should be constant. When I say constant I mean that the cut-off should occur when the low-pressure piston has traversed a sufficient distance for the cubic capacity within its cylinder to equal the whole cubic capacity of the high-pressure cylinder. This being so, the volume of steam contained in the high-pressure cylinder would not have to be increased, but would only have to be transferred from one into the other cylinder. Its volume not being increased, its pressure would remain the same, providing there was no loss of heat in its transmission, and, in this case, I shall suppose that no such loss does occur. If this mode of cutting off steam be adopted, the same theoretical power may be obtained with a compound as is obtained with a single cylinder engine; for I believe it has never yet been shown that a compound engine would give a higher theoretical power than a single cylinder engine with the same number of expansions, pressure, and measurement of steam; but it is easy to show a loss in the compound compared with the single, if the cut-off in the former be not properly arranged. From this I hope it will not be thought that I am opposed to the compound principle, for I am not, and I should be surprised to find anyone that is, knowing the practical advantages that it has over the simple engine. Now the greatest object of me writing this letter is to show that a fixed point of cut-off in the low-pressure cylinder is highly necessary, otherwise loss may be the result of compounding: and it has been stated that what cut-off is good for one cylinder is good for two, and this is borne out by the law of proportion given by Mr. Sutcliffe, which is, that the proportionate areas of the cylinders are to each other as the square-root of the number of expansions, and as the root is to the square so must be the cut-off in each cylinder, and I have no doubt but that this is the only proper way of obtaining the best results from the compound engine. To compare the power of a compound with that of a single-cylinder engine when a given volume of steam must only be used, I shall proceed by taking a simple engine, with a cylinder of 300 sq. in. area and a 3ft. stroke, making a piston speed of 400ft. per minute, with an initial pressure of 72lb. absolute, and a terminal [illegible]



[illegible], and the ends of the bed in the longitudinal view, Fig. [illegible], and with the plain sides in the transverse view, Fig. 4. Make a print, say ¼in. thick [illegible] continuous from end to end, [illegible] the recessed portion, and [illegible] cut underneath the gap. The [illegible] Fig. [illegible], b b b, will be wired on loosely, so that they may be drawn into the mould after the [illegible] of the pattern itself. The border or [illegible] Fig. [illegible] which you are troubled, will [illegible] for the planed faces of a [illegible] downwards, and the strips will [illegible] with brads or screws. [illegible] pattern [illegible] on the face side than on the opposite one. The rest of the work [illegible] core-box for [illegible] Fig. 7, end recess. [illegible] strips from [illegible] of lines, but [illegible] In that section the [illegible] Fig. 2, and [illegible] which may be [illegible] box. In Fig. 4, [illegible] the end recess [illegible] In Fig. 5 are shown [illegible] in this [illegible] continuous, and [illegible] from the top of [illegible] shouldered [illegible] desired to [illegible] themselves. [illegible] from one [illegible] Observe [illegible] box, that the [illegible] continued [illegible] they shall reach just [illegible] further, Fig. 7 is [illegible] that is, the core made [illegible] at the end of [illegible] with the top [illegible] that trouble. [illegible] I should say [illegible] of the film. [illegible] Half that [illegible] the work it has to [illegible] inherently [illegible] J. H.

[illegible] If this querist will [illegible], he may [illegible] early, [illegible] by the con-[illegible] the latter is to be [illegible] The power of [illegible] depends on the surface and [illegible] the quantity of [illegible] ESSAR.

[52121.]—**Scribing Block.**—I would recommend this querist to see a catalogue of engineers' tools. A scribing block is really so very common a tool, that he would find one in any toolshop; but if he cannot see one or a sketch, I will send a description.—ESSAR.

[52122.]—**Phosphor Bronze.**—I believe rolling is the best, as the metal is liable to become brittle; but no doubt the company would tell your correspondent the best method. I surmise that they issue instructions for working this really valuable alloy.—ESSAR.

[52126.]—**Microscopical.**—I think the question of the best camera lucida is one purely of personal taste. There are three illustrated in the last volume; but Mr. Limont would find a collection at any of the dealers who advertise in your columns. —F. R. M.

[52131.]—**Boiler Query.**—No reliable method of calculating the strength of such a boiler. Fill it with water, as much as it will hold, and load the valve to four times what you would like to work at. Then light the fire, and if the valve lifts without the boiler showing signs of strain or leak, you may safely work at one-fourth of the pressure indicated by the weight on the valve. The rationale of this is, that water expands as it heats, and there is no risk in the experiment. A pound pressure is a pound, 16oz., or whatever you may please to call it.—ESSAR.

[52136.]—**Galvanising Wrought Iron.**—There is nothing to do but to clean the iron thoroughly, and pass through the bath of zinc. The dipping in water is to cool the zinc, if anything. GALVANOPLAST.

[52137.]—**Electro-Magnet.**—Perhaps the bell is not really louder, although two inches larger in diameter.—E. G. M.

[52145.]—**Springs.**—Simple coiled springs would be best. You can see them in the music-turning machines, which your instrument seems to resemble.—S. M.

[52147.]—**Chilled Roll Turning.**—This query is incomprehensible. What is it Mr. Wilkinson wishes to know? As query reads, one can only say it depends on the gauge.—MECHANIC.

[52149.]—**Cotton Spinning Spindles.**—Some are made of Bessemer steel, and would probably not be of much use for chisels and drills. Still, the only way is to try: but see that you get hold of a real tool-smith who understands his business, and is not above trying another method because the first failed.—ESSAR.

[52151.]—**Ammonia and Alcohol as Sources of Motive Power.**—There is an ammonia engine (Dr. Lamm's) at work, I believe; at any rate, your correspondent will find full information in back volumes. Ammonia, ether, alcohol, bisulphide of carbon are objected to, because they are so liable to leak, and so very unpleasant when they do. Ammonia and ether are both used for ice machines. ESSAR.

[52154.]—**The Ross Battery.**—If querists would but look up their back numbers, they would find many questions answered. For instance, the Ross cell was described on p. 260, Vol. XXXVII.; but surely, it was described in Lord Bury's article—or did his lordship fail to give this most important information? If so, why? Let those interested answer the question for themselves. A fuller account of the Ross cell, apparently an earlier patent, will be found on p. 492, Vol. XXXV.: but I see, from a recent announcement, that it is claimed to give a horse-power for every three-quarters of a pound of cast spelter per hour, the price of which is said to be under twopence a pound. It is also claimed that the zinc is recovered in the form of a solid oxychloride, which is said to be a valuable product because it forms an ingredient of a new insulating material. Of the other cell I know nothing, except that it is a carbon-zinc excited by "oxidone;" but if the querist will look through articles and notes on batteries, he will, no doubt, find something about it. It seems to be a modification of the Holmes patent. About new batteries, just now, it is as well to believe nothing at all without trial.—NUN. DOR.

[52157.]—**Legal.**—I think the lawyer who could answer this question as it appears would deserve rather more than 6s. 8d.—THE OWL.

[52159.]—**Speed of Dash Wheel.**—This is purely a matter for experiment.—J. C.

[52161.]—**Spectacles.**—All short-sight spectacles make type appear smaller. It is useless to appeal to opticians, as they, none of them, seem to know much about the matter, and even the published writings of experts are contradictory. My advice is, Go to the stores, select a pair of specs that suit, and don't trouble yourself about the bogey stories.—VIDEO.

[52164.]—**Leather versus American Cloth.**—The statement is nonsense; but as you wish to re-cover, use indiarubber cloth of good quality. Or if you must have leather, you will probably get a suitable skin at a shop where bookbinder's materials are sold.—B. T. K.

[52166.]—**Engine Power.**—It seems a strange thing that no two of the correspondents of the "E. M." agree as to the h.p. of "C. C.'s" engine. According to "Firer" the initial pressure is 65lb. ("C. C." states the boiler pressure to be 50lb.), and the average pressure when cut of at half to be 52lb. I had an idea that the average pressure was less than the boiler pressure; according to "Firer" it is higher: how does he explain this? No wonder he gets a higher power. "Sabata" supposes that the steam loses 10lb. pressure in passing from the boiler to the engine: it is only in a very bad arrangement that such a terrible loss as this could occur. Doubtless in "C. C.'s" engine the pressure in the engine is very nearly the same as that in the boiler. I think the following figures are correct:—

When cut off at ½ h.p. = 16·93
" " [illegible] " = 18·30
" " [illegible] " = 14·69

When the steam is admitted till end of stroke h.p. = 20·01. These figures give only the theoretical power; the actual power is what remains after subtracting the back-pressure, friction, etc. If "C. C." has a friend to indicate his engine, his friend can instruct him better than I can, being able to see the engine. A hole will have to be drilled in either of the cylinder covers, and a screw thread cut in it, into which to screw the steam pipe of the indicator. There will also be required some arrangement for producing a reduced copy of the stroke of the piston; this may be done by a lever about 40in. long, one end fixed on a centre, and the other end attached to the crosshead of the piston. The cord of the indicator is attached to this lever at a suitable distance from the fixed centre. If "C. C." has an indicator card taken, I should very much like to know the result.—GOSSAX.

[52175.]—**Perspective of an Interior.**—It would appear from "Murano's" remarks at page 308, that his actual case is somewhat different from that treated by me at page 270; but I think if he will work out, on a large scale, and study the solution I gave, he should be able to apply the methods to his own case. If, by "point of disappearance" he means vanishing point, he should remember that there are often two or more such points in a perspective picture. If he means the point of sight in a picture—that is, the point directly opposite to which the eye must be put to view the picture—then, as I formerly stated, that point should always be in the middle vertical line. If he wishes the point of sight P, to be on the north wall, he must, in the preparatory plan (Fig. 2) draw a line (X N, for example) through the station point X, and the point he wishes in D H. Next, draw a line at right angles to X N, [illegible] present the picture plane instead of the line V L in my figures. Then place the plan with this new picture line in a vertical position, draw a new line G G at right angles to it to form the base line for the new elevation instead of Fig. 1, and proceed to make the elevation corresponding to Fig. 2 as in its changed position. The perspective drawing can then be deduced from the new Figs. 1 and 2, in the manner previously explained by me. As regards the shape of the ceiling, I understood "Murano" to say at first, that it was not like a tunnel: but now it appears that it is like a tunnel except near each end. To show on my Fig. 3, what I now understand to be the form of the ceiling near the north end, all that is necessary is with a line joining H and E as major axis, to describe a semi-ellipse of the same proportions as N A S in Fig. 1; then the part between H and the point of the semi-ellipse cut by the hyperbola N A, will be the junction line of the north and west parts of the ceiling, whilst the junction line of the north and east parts will be part of an ellipse of which a line joining D W is an oblique diameter, and which can be obtained by the method explained for the ellipse H A T F.—E. H.

[52190.]—**Copper Reduction (Wet Process.)**—There are many wet processes for the extraction of copper from pyrites. Longmaid's process, patented in 1842, consists in roasting the ground ore in a reverberatory furnace with common salt, by which means sulphate of soda is produced, and any copper which may be present is converted into soluble chloride. The copper was separated, either with iron or lime slaked in water. This process was worked at St. Helen's for many years. Bankart's process. The material was Cuban ore, containing 14 to 25 per cent. of copper. The ore was reduced by mechanical means to a fine powder and exposed in a furnace at a low red heat, with free access of air; most of the sulphur was driven off, while a certain amount was converted into sulphuric acid, forming $CuSO_4$, which was then treated with water. The process is repeated until no more copper is dissolved out, and the liquor is drawn off and the copper precipitated by means of iron. This process was worked by the Bede Metal Company, at Jarrow-on-Tyne. At many of the Spanish copper mines the ores were roasted in heaps. The process consisted of five operations—viz., roasting, grinding, sifting, lixiviation, and precipitation. After roasting, the ore is ground in an ordinary Cornish crusher, and rock salt added in proportion from 12 to 15 per cent. Before grinding, it is necessary to ascertain the exact amount of copper and sulphur, because, on the ratio existing between these bodies depends, to a very great extent, the success of the operation. In the majority of cases the sulphur should exceed the copper by about ½ per cent.; if this is not the case, an addition of finely-ground pyrites must be made; if, on the contrary, the sulphur is in excess, more burnt pyrites must be added. *Calcination.*—The furnaces vary considerably in form. In many cases long open furnaces fired by gas are used. The furnace is something like an ordinary puddling furnace. The furnace is charged from the top by a high-level railway, as in a coke oven; and the mixture of ore and salt is at once evenly spread over the surface of the hearth, where it is kept at a dull red heat and frequently stirred by means of rakes until fit for drawing. This point is determined by taking a small quantity from every part of the hearth, and after being finely ground it is boiled with water; the residue is treated with HCl, poured off, and NH_3 added to the solution; finally, the residue from the HCl solution is boiled with HNO_3 and NH_3 again added. If it is found after these trials that the solution in HCl shows only a slightly blue tint, and the HNO_3 is free from any colour, the charge is ready to be drawn. If, on the contrary, nitric solution contains copper, it is not sufficiently roasted. During the process of roasting the sulphur combined with the soda of the chloride of sodium forming sulphate of soda, and soluble cupric chloride is formed: but, unless the process is carried on at a suitable temperature, a certain quantity of comparatively cuprous chloride is produced. The charge is about 3¼ tons, and the time required is about six hours. The HCl and chlorine which is evolved is conducted into a condensing tower, and the condensed acid and water utilised in lixiviating the calcined ore. *Lixiviation.*—The calcined mixture of ore and salt is raked out of the furnace, and whilst still hot charged into tanks which are about 10 to 11ft. square and 4ft. deep. These are made of wood and provided with a removable false bottom, either of perforated tiles or brick, supported on other bricks set on edge. Upon this is placed a layer of cinders 3in. thick, forming a coarse filter, on which is charged about 15 tons of the calcined ore. The weak tower liquors are now run in until the surface of the ore has been covered to the depth of several inches. This is allowed to remain for about two hours, when it is run into proper receivers and the tank again filled with hot water and tower liquors. In this way the tanks receive from 9 to 10 successive washings. About the seventh washing a little HCl is sometimes added. All the washings after the addition of acid are collected in separate cisterns and are employed with the next series of freshly burnt ore; the residue, which is called blue billy or purple ore, should not contain at most more than 0·15 per cent. copper. *Precipitation.*—In works in which the silver is extracted by Claudet's process, the first three washings, which contain practically the whole of that metal, are treated with soluble iodide, and the iodide of silver is allowed to settle. But when the silver is not separated the copper is run at once into precipitating tanks; these are about 12ft. square by 4ft. deep, and are partly filled with scrap iron, the precipitation of the copper being accelerated by the introduction of a jet of steam. Complete precipitation takes place in about eight hours. The operation may be considered to be finished when the supernatant liquid produces no stain on a piece of polished steel when dipped into the liquor. The precipitate contains about 80 per cent. metallic copper. In some works spongy iron is used for this purpose. In order to precipitate copper by a galvanic current, take the chloride of copper solution, and in it place a plate of copper and a piece of gas carbon, or any other suitable substance, to act respectively as a kathode and an anode, which plates are to be attached to the poles of a dynamo. If the current is properly regulated the copper will be precipitated upon the surface of the kathode; of course it is cheaper, if possible, to work the dynamo by water power. There are various other processes in use for the reduction of copper from its ores; but as I fear I have already occupied too much of the valuable space at your disposal, I do not feel myself justified at the present moment in entering into further particulars. As, however, it may possibly interest many of your readers, I shall be happy, on a future occasion, to give an account of a process which, from its rapidity, completeness, and the purely scientific principles upon which it is conducted, entitles it to a position as one of the best metallurgical processes in existence.—William E. Dawson.

[52237.]—**Soapery Joints.**—Nothing will make a good joint but actual contact. The fact that your couplings go on over the lead and hemp is palpable proof that they are too large. But granted that you could obtain, at a reasonable rate, properly-fitting pipes, you will find it far preferable to take off the couplings and use flanges, with fairly good rubber wheezes. Very great care should be observed in planning out and fitting pipes in soapworks, as alterations and breakdowns so often occur. Possibly your pipes were fixed and fastened without the slightest reference to the fact that hot leys would sometimes be used, and in a long length the expansion is an essential point to provide for. If you don't like the idea of flanges, you could use back nuts to the present couplings, jamming up five or six laps of good thread elastic; but I would strongly advise the flange joints with rubber, as each one becomes practically an expansion joint. Don't use the rubber too good, or it will, in time, squeeze over the bore of pipe, and stop flow. If you use the muriatic acid, as advised in last week's Mechanic, you will make what is practically a rust joint, and most likely have to get your couplings off with a warding chisel, with the nearly absolute certainty of spoiling the threads on pipes. All pipes in soapery, whether steam, ley, or water, should be laid with an incline to the low end, so that in frosty weather they can be thoroughly drained when work is knocked off. Steam should be turned on with extreme slowness when the pipes are cold, or the kicking will find out the weak parts, and either spoil joints or split pipes. The supply-pipe for each pan should rise from the main, so that lodgment of condensed water cannot occur. Insist upon having all nuts square; the others are pretty about an engine, &c., but utterly out of place where joints are likely to be often disturbed. Have standard sizes for the nuts, and as few different sizes as possible. Unless your boiler primes, you will find that the condensed water from your steam-pipes is practically pure. In one large soapery in Lancashire weak leys were used in place of water for the boilers, in order to obtain strong leys at a cheap rate. Will you excuse me for suggesting that some elementary knowledge of the part borne by caustic lime in making leys would prove valuable to yourself and employers, as lime is very slightly soluble, and is not dissolved as you seem to imagine. Don't be offended; but ask again if further information is required.—London Stone.

[52256.]—**Brush Dynamo.**—If Williams will supply the following details, I may be able to help him out of his fix. Resistance of A. from brush to brush, weight and resistance of F.M.'s, and the shape and construction of commutator. There are other means of increasing E.M.F. without re-winding. 2,000 per minute is quite high enough in practice.—W. H. E., Coventry.

[52268.]—**Will.**—I promised this querist an answer to the latter part of his query, viz., whether an executor can resign. Yes, he can be allowed to do so in the customary way.—G. Russell Pridham.

[52269.]—**Acoustics.**—The first of these questions is from the Honours Examination paper for May last, the word "steam" being, however, a misprint for "gas." The velocity of a sound in a gas is given by the formula—

$$v = \sqrt{\left(\frac{ghd}{D} \times 1{\cdot}4\right)}$$

Taking the temperature at zero, d in this equation is the density of mercury referred to water, which the student was supposed to remember. We have—

$$\begin{array}{lrl}
\log. g = & 2{\cdot}9916690 & \\
\log. h = & 1{\cdot}8633229 & \\
\log. d = & 1{\cdot}1335389 & d = 13{\cdot}6 \\
\log. 1{\cdot}4 = & {\cdot}1461280 & \\
\hline
 & 6{\cdot}1346588 & \\
\log. D & \bar{5}{\cdot}9493900 & \\
\hline
 & 2)10{\cdot}1852688 & \\
 & 5{\cdot}0926344 & = \log. 123770 \text{ c.m. vel. at zero.} \\
\log. \sqrt{1 + 003665 \times 20} = & {\cdot}0153605 & \\
\hline
 & 5{\cdot}1079949 & = \log. 128230 \text{ c.m. vel. at } 20^\circ.
\end{array}$$

If, instead of remembering the density of mercury, the student calculates what is the equivalent in C.G.S. units of 15lb. per square inch—namely, 1033 grammes per square centimetre, the same result may be arrived at by a slight variation in the process. With respect to the next question, which is from the Honours paper for 1880, I think the following will indicate method of solution: Assume that the length of the slip varies as the tension, then, if the tension was increased m times, the note would become $F_1 \times \sqrt{m}$ as regards change of tension, but would be altered also to $\frac{F_1 \times \sqrt{m}}{m} = \frac{F_1}{\sqrt{m}}$ by reason of variation in length. Again, the diameter would alter in the ratio $\sqrt{m} : 1$. This would make the note become $\frac{F_1 \times \sqrt{m}}{\sqrt{m}} = F_1$ or the same as before. Perhaps a numerical illustration will make this clearer. Suppose the slip originally = ·4in. diameter and 10in. long stretched by 1lb. and giving x vibrations. On increasing the tension to 4lb., the number will become $2x$, but the length increases to 40in., and this makes the number only $\frac{x}{2}$; the diameter diminishes to ·2in., which doubles the last expression, making it equal to x as at first. I am not quite certain about this string; but the above is how I would have tackled the question had it come before me in an examination.—Wm. John Grey, Newcastle-on-Tyne.

[52278.]—**Gas.**—Respecting query No. 1 of "W. A. S.," his surmise is correct; but, in No. 2, the coke produced from a comparatively short period of carbonisation would be a much less smokeless and incandescent fuel than ordinary coke is at present. Neither would it, for several reasons, be profitable to the gas manufacturer, whose chief aim is to make gas for illuminating and heating purposes, to produce a residual partially carbonised. The following suggestions, if acted upon, would, to my mind, contribute largely towards the thing desired:—1. The more general use of gas as fuel for cooking and heating purposes, the reduction of price consequent on the increased demand eventually causing it, for heating purposes—as it now is for cooking—to be more economical than coal. 2. The using of ordinary coke broken into small pieces—from 1in. to 2in. cube—burning it alone, or mixing it with coal, for domestic purposes. 3. The improved construction of stoves and fireplaces, to give more radiation of heat, combined with the better ventilation of our living rooms, whereby gas and coke, as fuel, could be more efficaciously used.—W. T.

[52281.]—**Boiling Frosted and Chased Silver Articles to Whiten Them.**—To H. J. Sayer.—I have boiled few alberts and necklets in strong solution of cyanide of potassium, and washed with soap and warm water, and dried in sawdust. All of them are a bluish colour, not white, like new. How long should they be boiled? Where do I fail? Got new tin saucepan holding a pint, and put 4oz. potassium in same, and boiled alberts about two minutes. Everyone has the same appearance. I should like to get the white colour of new articles.—Young Jeweller.

[52298].—**Bunsen's Battery.**—In answer to "S. I. M." I must say that I have not yet tried the experiment with the platinum wire you mention; but

I can give you some idea of what you might expect to get from this battery. One dozen chromate cells will be required to light [illegible] lamp for about 4 hours with one charging. [illegible] I daresay find it very expensive if you [illegible]. Why not rig up your own [illegible]. The above requires about 4lb. of sulph[illegible] of potash for each renewal. [illegible] are :- Outer cell [illegible] cylinder [illegible] containing a square [illegible] is then placed in [illegible] lasts depends entirely upon the amount of work done and the quality of the [illegible] in for two dozen cells you can produce a good steady light at a cost of about [illegible] each day [illegible] the carbon. A most convenient way of keeping them is to use the square cells, and they can be easily packed together [illegible] without any trouble. When not in use [illegible] the zincs and to place them in water [illegible]. I daresay the [illegible] chromate of potash [illegible] know that there was any [illegible] Fuller's [illegible] diluted with water [illegible] battery [illegible]—[illegible].

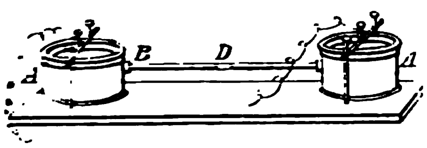
[illegible]—**Methylated Spirit.**—Break up some glue and put with it. The glue will absorb the water but not the spirit, [illegible] expense, [illegible]—[illegible].

[illegible]—**The Cheapest Food.**—I am obliged to those correspondents who have noticed my query [illegible] XXIX. [illegible] and elsewhere in back volumes [illegible] For working men, [illegible] beans [illegible] cheapest [illegible] a quart, and bacon [illegible] a pound. [illegible]

[illegible]

[illegible] the following [illegible] fitted [illegible] Brake was [illegible] Experiments [illegible] March [illegible] was sent to [illegible] London, and [illegible] 1874. [illegible] After [illegible] the automatic [illegible] St. Albans [illegible] 1875, till [illegible] has now been [illegible] The [illegible] a week after [illegible] It [illegible] Skipton, &c. [illegible] and [illegible] The [illegible] engine 156 [illegible] fitted to [illegible] Bedford [illegible] train [illegible] The next [illegible] brake were [illegible] and [illegible] to London, [illegible] the Pullman [illegible] London.—[illegible]

[52329.]—**Electrometer.**—I think that Lippmann's electrometer, as modified by Dewar, would answer your purpose. A glass tube rests horizontally between two glass dishes, in which holes have been bored to receive the ends of the tube. It is filled with mercury, and a single drop of dilute acid is placed in the tube. Platinum wires to serve as electrodes dip into the mercury in the dishes. An E.M.F. of only [illegible] of a volt suffices to produce a measurable displacement of the drop. The direction of the displacement varies with that of the current. See sketch: A A, dishes of mercury; B, tube of mercury; D, drop of dilute acid.—Ratio.



[illegible]—**Varnish for Baywood Tops of Carding Engine.**—Is not baywood the mahogany that comes from the Bay of Honduras? If "T. I." means mahogany of that ilk, let him take "M[illegible]'s" advice, and French polish. Don't use, however, but mix up tallow and whiting, and rub that in; then polish in the usual way, or apply with a brush, as I suppose you do not want a very high finish.—Nun. Dor.

[illegible]—**Legal.**—In case the widow dies intestate, you had better leave it to A.'s executor.—G. Russell Pridham.

[illegible]—**Legal.**—When a divorce has been made absolute—that is, after six months has elapsed since the hearing of the petition *nisi*—the parties have no claim upon one another. Neither are the children legally liable to support their parents; but putting aside legality in the matter—the mother, as such, and moreover being an invalid, should be shown some consideration by her children, although there be no legal responsibility on their part. Yet, whatever be the differences between husband and wife, it is certain that no child in a position to assist his mother, with a spark of filial affection left, would refrain from doing so simply because the law does not compel him.—G. Russell Pridham.

[illegible]—**Draughty Church.**—In your last week's issue, "[illegible] E. L." thinks the heating apparatus ought to be in use two or three days before the congregation meet. I think it could be heated with less expense (practically) by erecting a heating apparatus about [illegible]ft. high, or by laying an apparatus in the galleries, so that the air above will be quite as warm as the air below, and thus prevent the cold current coming down on their heads.—S. [illegible] Arrington.

[illegible]—**Fretsaw.**—The sketch illustrating this query is an absurdity. How can the small wheel pull saw properly when its centre is out of line with the saw? Let the querist either shift the saw or the wheel so that a line passes straight through their centres, and he will have no difficulty. Plenty of them in back volumes; and a dust-blower, which will give an idea, on p. 188, Vol. XXXVI.—Nun. Dor.

[52344.]—**Fretsaw.**—"A. D., Amateur" will never get his fret saw to work quietly and easily with so short a connecting rod. The whole sketch is wrongly worked out; ¾in. is throw enough for crank, giving saw 1½in. stroke. Let "Amateur" bring the crank close to the ground, directly under the saw, and with a long, light connecting rod his machine may go. The spring should be on the flat; the last I made did well. I approve of steel for working parts; but cannot approve of your arrangement which admits of too much friction.—William Hosken.

[52345.] — **Non-Condensing Horizontal Engine.**—The indicated horse-power will be 52·50, and as for the nominal horse-power, there are so many rules, all giving different results, that it would not be reliable.—Sabata.

[52345.]—**Non-Condensing Horizontal Engine.**—If you wish to know the actual or indicated power of your engine, have some diagrams taken when the engine is running with full load on. As "nominal horse power" varies considerably with different makers, the term ought to be abolished, and in speaking of an engine the dia. of cyl., stroke of piston, and revs. per min. stated instead. With the particulars given the engine would approximately indicate 136 horse-power.—Labor Omnia Vincit.

[52345.]—**Non-Condensing Horizontal Engine.**—Seeing that "Young Manufacturer" and a good few readers in "ours" is desirous of knowing the nominal and indicated horse-power of these engines, I will try and help them. The term "nominal horse-power" is of the vaguest description, as it really expresses nothing, as makers of small engines find it a convenient way for entrapping people, as a high nominal horse-power has powerful attractions for the general public. The term "nominal horse-power" was introduced by Watt, and in his time gave a fair means of estimating the comparative value of engines. But now, owing to the greatly varied conditions of engines, the term "nominal horse-power" forms no means of comparison. The following was Watt's mode of calculating the nominal horse-power of an engine: The area of cylinder for a 1 horse-power engine (high-pressure) is 10·75 sq. in., worked with an average pressure of 14lb. per sq. in. on the piston; length of stroke, twice the diameter of cylinder, with a piston speed of 220ft. per minute. The area of a cylinder for a 1 horse-power condensing engine is 21·5 sq. in., worked with an average pressure of 7lb. to the sq. in. on piston; length of stroke, twice the diameter of cylinder, and a piston speed of 220ft. per minute. So, taking "Young Manufacturer's" engine, with a cylinder area of 201 sq. in., the nominal horse-power will be 201 × 14 × 220 ÷ 33,000 = 18·77. The Admiralty rule for nominal horse-power was $\frac{D^2 V}{6{,}000}$ where D = diameter of cylinder, and V = velocity or travel of the piston per minute; then 16 × 16 × 220 ÷ 6000 = 9·4 horse-power nearly, or a difference of 9 horse-power in the two rules. Now we will deal with the indicated horse-power. The indicated horse-power can only be ascertained by the use of the indicator cards. But we will assume that your engine gets an initial pressure of, say, 75lb. gross on to the piston, that is allowing 5lb. loss from boiler pressure, which we will suppose is lost in friction and condensation in steam pipes from boiler to engine, and that the engine is perfect, that is allowing nothing for leaky piston and defective valves; the question of condensation in the cylinder we will not entertain; the indicated horse-power will be 127 nearly. The way to get the indicated horse-power of an engine is to square the dia. of the cylinder and multiply by ·7854. Then to find the number of expansions in the cylinder by dividing the length of stroke by the point of cut-off, or 42in. length of stroke divided by 14in. point of cut-off = 3 expansions, and 75lb. gross divided by 3 = 25lb. terminal gross pressure. The hyperbolic log. of 3 expansions is 1·099 + 1, so if we multiply 25lb. terminal by 2·099 = 52·475lb. average pressure throughout the stroke. But as the engine is a non-condensing one, we want the atmosphere deducting from 52·475 − 15 = 37·475 effective average. Then multiply by the piston speed 560ft. per minute, which is rather a high speed, and divided by 33,000 = horse-power

$$\frac{16 \times 16 \times \cdot7854 = 201 \times 37\cdot475 \times 560}{33{,}000} = 127$$

—Firer, Dewsbury.

[52347.]—**Vacuum Gauge.**—Your gauge showing 25in. (12½lb.) of vacuum is not at fault, because you only expected 15in. to 18in. Your engine is doing better than you gave it credit for. The indicator applied to the condenser would alone give you the correct vacuum, which is generally less than shown by the gauge.—J. F. W.

[52347.]—**Vacuum Gauge.**—If the Bourdon gauge is new and perfect, it only proves that you were wrong in your ideas of the quality of the vacuum in the condenser, as the 10ft. of ½in. piping would make no difference to the vacuum as long as the joints are sound. And if you have plenty of cold water for condensing, you ought, if the air-pump is in good order, to get a much better vacuum than 25in. For example, at the time I write, the condensing water of the engine now working is 54° temperature, barometer stands at 30·9in., and the vacuum gauge shows 28in. steady in the condenser. The vacuum gauge is extremely useful, and every condensing engine ought to have one fitted to the condenser.—Labor Omnia Vincit.

[52348.]—**Boiler Tank.**—The tank will hold 4632·398 gallons, and the weight of water will be 20·68 tons.—Sabata.

[52349.]—**Steam Mill Pump.**—You do not give sufficient data. You must state height the water is to be lifted, stroke of pump, and what quantity of water required per min. or hour. If you have an engine already fixed, state size and present work it is doing.—Labor Omnia Vincit.

[52349.]—**Steam Mill Pump.**—I take pleasure in informing "R. R. N." that the depth of the widest part of the pump (which will be double-action) is [illegible]in., and the width is 5in. I have no well, but have bends just beneath the surface. I connect pipes [illegible]in. diameter, and lay them in the clay pit, perhaps 30ft. long; but the lift is not above [illegible]ft. or [illegible]ft. I want to get all I can out in the least time.—Narva.

[illegible]—**Legal.**—C.'s remedy is by action against B. He must employ a solicitor. It is not the question of B. being justified: he would naturally sell the property for the best price he could get for it.—G. Russell Pridham.

[illegible]—**Water-Wheel.**—If you find you get enough power out of water-wheel, and such a loss of water as well, would it not be well to reduce the size of hole? Or else reduce driving-pulley and increase the speed of water-wheel, which would give you more power.—Sabata.

[52367.] — **Horse-power of Engine.**—The horse-power of "Ignoramus's" engine, according to the figures given, is 111·95, or 112 nearly.—Rollie.

[52367.]—**Horse-power of Engine.** — Find out what part of the stroke the piston is at when the slide-valve closes steam port, which is termed "cut-off," and I will work out horse-power.—Sabata.

[52367.—**H.P. of Engine.** — "Ignoramus" omits to state the point of cut-off in his engine, and also whether condensing or not. But we will suppose it to be a condensing one, with an initial gross pressure of, say, 55lb., and a back pressure of 2lb. in the condenser, and, for simplicity, to cut steam off at half of the stroke; then the horse-power will be 615·7536in. area of cylinder multiplied by 44·5lb. average pressure, multiplied by 350ft. piston speed per minute, and divided by 33,000, equals 290·6 horse-power, or thus:

$$\frac{615{\cdot}7536 \times 44{\cdot}5 \times 350}{33{,}000} = 290{\cdot}6.$$

—Fiber, Dewsbury.

[52368.]—**Red and Blue Photographs.**—I am much interested in "Machina's" reply to this query, although not the querist. If he will kindly give full directions for making the solutions—say, time the paper should be immersed in each, also if a non-actinic light may be used in the dark-room operations—it would probably be of use to others besides—Dozey G.

[52368.]—**Red and Blue Photographs.**—The sensitising solution for red or, more properly-speaking, light reddish-brown photographs, is bichromate of potash ½oz., water 16oz. The sensitising solution for blue photographs is ferricyanide of potash (red prussiate) 1dr., ammonio-citrate of iron 1dr., water 1oz. In sensitising the paper, take hold of it in the middle of each end, bend it so that you can place the centre of the paper on the solution, and gradually lower the two ends. Let the paper remain floating on the solution for about one minute, and then with your forceps take one end and slowly raise it from the solution, taking care not to get any on the back of the paper; then pin it by the corner in a dark cupboard to dry. When dry, put it in your printing frame with the negative or design which you wish to photograph, and place it in the light. On a bright day it will take from five to ten minutes to print; but you will require a little experience to get a nice colour. When printed, take it out of the frame and place face downwards in a bowl of clean water from ten minutes to half an hour, then take it out and dry. Never sensitise more than you require for one day's printing, and you should obtain some shallow dishes for your solutions. Keep your red and blue solutions in stoppered bottles, and take care to cover the bottle containing the blue solution with two or three folds of blue paper.—A. Laundy, Buxton-villas, Stratford, E.

[52381.]—**Power of Local Board in Water Supply.**—If you are willing to bear the expenses of laying down the pipes, I don't think the Board would refuse to supply the water; but if you lay the main without consulting them, you can't compel them to supply the water.—G. Russell Pridham.

[52382.]—**Plaster for Outside Walls.**—Can it possibly be clay? Surely not. It would wash off in "no time," unless the house were baked in a kiln, which does not seem practicable. I conclude that "S. B.'s" house is very old, and built in the Elizabethan style, as he speaks of it having a wooden "framework." If so, the best way would be to paint the wood red, and peck off the old cement where loose, and replaster with Roman or Portland cement, mixed with very coarse river sand, all the stones being sifted out and the very fine also.—Murano.

[52384.]—**Absorbent Cotton Wool.**—I am much obliged to Thos. Fletcher for the early answer to my query; but I am sorry to say I have tried many sorts of soda which are alkalis, but they all injure the colour and cause it to look grey, and after I have washed it well in cold water, it shows the alkali when tested. If I boil in clear water, or neutralise with a little acid, it brings it back to what it was at first. It also does not give it that snowy feeling when pressed. Shall be pleased to know the right process.—Student.

[52390.]—**Dynamo.**—Connect your F.M. with cells, and test with compass needle to see if poles are right. Two bichromates ought to make them strongly magnetic. Test A. in the same manner, to see if it produces N. and S. poles in a line with the brushes.—W. H. E., Coventry.

[52392.]—**Gravitation.**—The way to reconcile the two workings is to do them correctly. The first result should be 222·4ft., the second 3·73sec. nearly, and the third 223·6ft. nearly. Then it will be found that after rising 223·6ft. in 3·73sec. the ball will fall nearly 1·2ft. in ·27sec.—J. S. C.

[52393.] — **Water Consumption in an Engine.**—You cannot tell with certainty, from the diagram, how much water in the state of steam an engine uses. A considerable portion of steam is condensed in the cylinder at each stroke of the piston, because at each opening of the exhaust the temperature of the cyl., piston, and passage is reduced, and the incoming steam has to reheat these parts, and so more steam enters the cyl. than is theoretically necessary to do the work. Part of the steam that is condensed is re-evaporated during the stroke, and this re-evaporation is shown by the expansion line on diagram being higher than the adiabatic curve. To calculate from the diagram how much water the engine uses per hour, the rule is, multiply the volume of cyl. to point of cut-off, by the No. of revs. per min. and by 60. Divide the product by the density of the steam in the cyl., and the quotient will give the No. of cubic feet of water expended in the state of steam. But by far the best plan is to fix a water meter on the feed-pipe to the boiler, that will show the amount of water actually used, and you can calculate from that the evaporative power of the coal, and so, if necessary, check the coal merchant.—Labor Omnia Vincit.

[52400.]—**Reading Lamps.**—A query similar to yours was inserted in this paper last September, and was answered by "Nun. Dor." in the issue of Sept. 21st on p. 71, who stated that there was no remedy for the unpleasant smell, that the rubber was being attacked, and that destruction would go on until the pipe, as a pipe, was spoilt.—Machina.

[52401.]—**Pianoforte Tuning.**—To Mr. W. H. Davies.—"A. D." has probably overlooked the explanation preceding the directions given in No. 830, that "The position of the bearings lies between the F, a fifth below the 2ft. C, and the E a major third above (both inclusive)." That is, twelve notes in all. Within these limits it would, of course, be impossible to tune a fifth downwards from G. It is also correct to say, as in No. 918, that each ascending fifth should be one beat flat. If they were tuned sharp it would undo the effect of flattening the fourths, and would come to the same thing as perfect intervals throughout.—W. H. Davies.

[52402.]—**Pulley.**—Such a belt is termed a quarter twist, and needs no "carrier" pulley. The rule is, "the central planes of the two pulleys must intersect the straight line which joins their points of delivery." Now, get two pennies and a knitting-needle, and place them on the table so as to comply with the above conditions, and depend upon it, if you fail to do so, you have no business to meddle with machinery.—W. J.

[52403.] — **Repairing Dies.** — Double shear steel is not the right steel for dies. You should have mild cast steel. No shear steel will carry a good cutting edge for long. Leadbeater and Scott's special die steel would suit your purpose. I know from experience.—E. T.

[52404.]—**Strains.**—If "span" should be spar, and if I understand the question, then the vertical strain on each end is 5 tons, and it is not altered by the spar not being level. But there will be horizontal strains on the masts, depending on how much the spar is out of level.—J. S. C.

[52406.]—**Cylinder Electric Machine.**—What is the use of the pieces of tinfoil gummed on to the cylinder? I never saw them recommended in any book, and I'm inclined to regard them as the cause of all your woes. Try the machine without them, and see if it works better. I suppose the cylinder is dry inside, and the rubber, &c., was hot when used? There must be sparks somewhere, one would think, or you would not feel a pricking.—R. A. R. Bennett.

[52406.]—**Cylinder Electric Machine.**—My first machine was a very similar one, and gave plenty of sparks, but I never heard of strips of tinfoil being pasted on the cylinder. If the machine does no better when they are removed, and the cylinder has been well cleaned, probably the insulation is at fault. The prime conductor should have no sharp angles or roughnesses on its surface, and its ends should be round and smooth. The tube on which it stands will insulate much better if warmed and varnished with shellac dissolved in methylated spirit. To obviate condensation of a conducting film of moisture on its surface, of course the machine should be warmed before using.—J. Brown, Belfast.

[52407.]—**Oxy-Hydrogen Light.**—In reply to W. Hobbs I must say that I have worked the lime-light for about 20 years in almost all the west-end theatres in London and elsewhere. I should advise my friend to be very particular in the following hints: 1. See that the bags are free from air before filling them, as this, when mixed with other gases, is liable to cause an explosion. 2. If you use single boards, have an equal pressure on each bag from beginning of lighting till done. I always use a 75lb. weight for each bag (ordinary size). You can put as much weight on the bags as you like in using the double boards. In lighting, the hydrogen should be ignited first, and the oxygen turned off first when you have done with the light. There would be no fear of an accident if the greatest care is taken. Pure hydrogen gives a more intense light than the carburetted: it would not be noticed if the oxygen gas is made from the purest chemicals that can be got. I should be glad to give any further information whatever. Do you make your own gas or buy it, and where do you purchase your limes, and what kind do you use?—as this depends entirely upon the kind of light you will get from these two things.—Lime-light, 228, Hill-street, Walworth.

[52409.]—**Legal.** — Here B. has only a life interest in the property, and therefore she cannot will it away to whom she likes, as after her death the property was left to her eldest son, C., who dies during her lifetime, leaving two sons, who are entitled to succeed to the property after B.'s death in preference to B.'s other children.—A Liverpool Subscriber.

[52410.]—**Dynamo Machines.**—The relation is variable, because, with a coil of given resistance, area, and number of turns, the E.M.F., and consequently the current, will depend on the strength of the magnetic field, and on the speed of rotation. It would not matter if the coil were a flat strip or a round wire so long as their resistances for a given length were the same.—W. H. E., Coventry.

[52417.]—**Siemens Dynamo.**—This is the most tiresome and tedious A. to wind that "Constructor" could possibly pick. Size of wire, No. 18 double c.c. I cannot very well explain winding and connections to commutator without diagram, which I will send if you feel equal to the job.—W. H. E., Coventry.

[52422.]—**Legal.**—"Tom" can certainly take away the fittings if they can be removed without substantial damage, and provided they were not the landlord's property, which the outgoing tenant sold to "Tom" as his, which is of frequent occurrence. "Tom" must also remove or sell them during his term; but should "Tom," at the close of his tenancy, take a lease of the premises, he must take care to reserve his right to remove his fixtures, which he is entitled to sever under his first tenancy, otherwise, being on the premises previous to the commencement of the second term, they will be irremovable when it expires.—A Liverpool Subscriber.

[52426.]—**Voss Electrical Machine.**—I was troubled with this cracking of the plate of a Winter machine mounted in a similar way, and I attributed it to unequal expansion of the glass when the machine was warmed, the outer part of the plate expanding and straining the centre, which, being shielded from the fire by the mounting, remained cold, and gave way at the hole which is, I presume, the weakest part. If this is the case, the remedy would obviously be to allow the part about the hole to warm also. The brass cheeks might be made in the form of rings with arms not in contact with the plate, or portions of the rings might be cut away so as to leave still less of the plate under cover.—J. Brown, Belfast.

[52432.]—**Railway Time Signals.**—In 1873 the Midland Co. erected a self-acting time indicator at Kegworth, showing the time a train had passed up to 15 minutes. It was set in motion by the passing train depressing a lever attached to the rails, and communicating with the clockwork; at the expiration of the fifteen minutes the pointer returned to its normal position. It has since been abandoned, as not proving sufficiently reliable. At Whiston Bank, on the Liverpool and Manchester line, a train-actuated signal was in use in 1867, but was subject to failure. The same result has also attended the use of similar signals on the Brighton line, and they were both ultimately abandoned.—Nomen, Liverpool.

[52432.]—**Railway Time Signals.**—There is a model of a railway time signal to be seen in the Crystal Palace, called "King's Electric System of Railway Signalling." The arms of the semaphore signals are worked by electricity, which is brought into operation by a plate inside the rails which the train depresses in passing over. Each train, by passing along the line, puts at danger the signal it has just passed, and at the same time takes off the signal behind the one just put on, which till then had been at danger. There is a clock on each signal-post, which, as each train passes, is put back to zero; and so it shows to the driver of each successive train how long it is since the train in front of him has passed the post. This invention has been patented in England and several other European countries.—Machina.

[52435.] — **Extraordinary Phenomenon.** — There is not much doubt that the unusual colours are due to the influence of particles of something in the atmosphere, but whether that something is terrestrial (volcanic) dust, cosmic dust, or the remains of some exploded comet or meteoric shower remains to be proved, if possible. The sun himself has been observed to be green and blue in parts of the world, and as soon as the accounts are "all in," it will be possible to arrive at some conclusion as to the nature of the phenomenon. Personally I suspect that something is due to colour blindness on the part of the observers, for some of the accounts are indeed extraordinary.—NEW. DEN.

[illegible]—**Extraordinary Phenomenon.**—During the past fortnight we have had a series of wonderful and beautiful sunset and sunrise effects in West Lancashire, as though there was some hazy matter suspended in the atmosphere at a greater elevation than the usual vapour planes, which haze appears to catch the light earlier in the morning and later in the evening than the highest cirrus cloud in ordinary circumstances. An idea has been started that these effects result from a wide diffusion of volcanic ash vapour from the Java eruptions and there may be some probability in this suggestion. When I was in the Bay of Naples two years ago, the haze produced over large tracts of South Italy by Vesuvius was very noticeable, and the sunset colours were very similar to those we have lately experienced, particularly a rosy pink glow in the [illegible] part of the sky *after sunset* for some time. This was very noticeable here on the [illegible] [illegible] it changed in a few minutes to a sea-green tint.—HARVEY.

[illegible]—**Ventilation of Rooms.**—It is impossible to give any rule for the ventilation of rooms which is worth having. The force which causes the air to move is constantly changing in amount with every change of temperature, so that if a rule was given it would be of no practical value. I can however give some data from which "H. W. [illegible]" can derive some practical idea of the conditions necessary to effect his object. A room [illegible] provided with three openings [illegible] at the bottom and one opening [illegible] by [illegible] at the top, opening direct through the wall into the chimney, which rises [illegible] above this point, will be sufficiently ventilated when there are 12 persons and five gas-burners alight in the room, each burner consuming [illegible] per hour. The temperature outside is at [illegible], and the temperature inside [illegible]. The room has no fire in it, but is heated with steam pipes. With [illegible] persons, and the same gas burning, the room does not become unpleasant when so used for two hours, but the temperature then rises to over [illegible]. With the same sized room [illegible] with only [illegible] of chimney [illegible] the ventilation is not quite sufficient when there are [illegible] persons in the room, even for two hours, but is quite sufficient for seven persons for an unlimited time. When there is a difference of [illegible] between the inside and out the ventilation under the circumstances mentioned is not quite sufficient. It is a matter of [illegible] that the [illegible] should be placed as [illegible] and that it should [illegible] with no bends if [illegible] In this case it is as well [illegible] and not in [illegible] the chimney. It is also [illegible] will not be affected [illegible] I have only briefly [illegible] important matters to be [illegible] generally. I would [illegible]—A. [illegible]

[illegible]—**Transparencies.**—To remove your [illegible] put a piece of white [illegible] a few days, and shake [illegible] glass well and [illegible] if you like, with [illegible] Your [illegible] with ease. It [illegible] glass globes. [illegible] of expense and [illegible] I have seen [illegible] of time and [illegible] that as my [illegible] either the [illegible] gelatine the [illegible] temperature of the [illegible] varnished with [illegible] make them wash- [illegible] working from one [illegible] This class of [illegible] glass is useless, [illegible] without a [illegible] we had at Mont- [illegible] I saw some very beau- [illegible] done by a [illegible] the address, but I [illegible] he writes. I [illegible] catalogue," and [illegible] might be able [illegible] would be no harm [illegible]

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[52446.]—**Model Boiler.**—I have a horizontal copper boiler 9in. diam., 18in. long, copper 3-16in. thick, brazed seam, ends flanged down ¾in. over body and brazed on, no stays or rivets, externally fired. Will some one kindly tell me what pressure it will stand, and also how to make lever safety-valve to blow off at working pressure or a little above?—C. E. B.

[52447.]—**Boiler for Model Engine.**—I have a model horizontal slide-valve engine 1½in. bore 3in. stroke, for which I wish to make a boiler (iron riveted), capable of burning coal or coke. I should feel greatly obliged if some kind reader would give dimensions of same, also some idea how to proceed in making. I wish to run the engine about 150 revs. per min.—ESMERALDA.

[52448.]—**Peat Litter.**—Could some of your numerous correspondents give me any particulars respecting the manufacture of peat litter? Also the cost of such machinery as may be required, and from whom could the machinery be had?—A. M.

[52449.]—**Greek Inscription.**—In 1813 Sir W. Gell found a bronze tablet in Olympia on which is inscribed an agreement between the Eleans and the Heræans. It is said to present examples of the obsolete digamma among its letters. Where can I find a full account of this tablet, and a translation of its inscription?—STUDENT.

[52450.]—**Fatty Acids.**—Wanted a simple and ready method for the quantitative estimation of neutral fats in mixtures of neutral and acid fats. What is the best handbook on the subject of the commercial testing of fats, and also on the manufacture of oleomargarine?—VICTORIAN.

[52451.]—**Peculiarity in Vision.**—The following experience is not only very interesting to me personally, but will I think be so to many of your readers, and I shall be glad if it can be explained to me. Usually my eyesight is perfect—indeed I think rather above the average, both for long and short distances, and in respect of capacity for much work without a trace of weariness. At times, however, without any warning, and at uncertain intervals of days, months, and even years, objects looked at diminish in size precisely as if I saw them through the wrong end of a powerful telescope; and in the same way, without losing sharpness of definition, they seem removed to a great distance. This is accompanied by a feeling of stress somewhere about the eyes, much the same as when looking at an object so close as to necessitate a slight squint. The longer I look at the objects the smaller and more remote do they become, until the sense of stress grows unbearable. Relief is had by closing the eyes, rubbing the face as if washing it, or by going to the open air where the gaze can be fixed on distant objects, or conversely by looking at something very close to the eye. For example: A newspaper in my hand will suddenly seem no bigger than a shilling, and persons in the room appear of corresponding size; but if I gradually let my eyes travel along the paper and up my arm until I see my coat collar, somewhere on the way I recover my ordinary vision; but probably it will go wrong again in a second or two if I again look at the articles surrounding me, unless I go outside, or wash my face, or move about very quickly. When in bed with my eyes shut, even in the dark, I can at once tell by the feeling that I am so affected, and have repeatedly proved it by experiment. I have described the case to several medical men, including one learned professor who makes a special study of the eye, and I am myself fairly read in physiology and optics; but I have yet failed to discover any solution of my difficulty. I have never yet known any person who had experienced the same thing, except a younger brother of my own, who, not being aware of my gifts, lately described to me, with much surprise, a similar peculiarity in his own vision. The matter causes me no inconvenience even when frequent, and I have only had it once or twice during the last few years; but I should like if any of your correspondents could give me an idea what is its cause optically, what its probable cause pathologically, and whether the ailment is actually a rare one? I hope that only those who know will occupy space with reply.—CORSEA.

[52452.]—**Annuities.**—Required to know the principle upon which the formula

$$A = \frac{P}{n} + \frac{Pr + Pnr}{2n}$$

is based?—M. S.

[52453.]—**C.R. Locos.**—Can "Carstairs" tell me whether the rebuilt single passenger engines, 76, 78, and 114 are a success? Whether Drummond has modified any more of the old 8ft. 2in. singles besides the above, and what size of cylinders they now have?—W. THOMPSON.

[52454.]—**Butcher's Ice Room.**—Will any kind brother with experience of the above room kindly help me? I want constructed or to purchase a wood ice-house, room, or cool meat store, and shall feel much obliged with a little advice on the following points. If hollow sides are compulsory, and if the space is packed with anything? If so, what? and width of space? The best position for ice, and mode of keeping it? Is air ventilation compulsory? If so, does it require much, and if best to pass over the ice on entering or leaving the room? Size of room required, inside, about 6ft. by 4ft., and 6ft. high.—M. SYKES.

[52455.]—**Shaft Journal.**—Would any correspondent oblige me with a rule for determining the length of shaft journals, where the pressure on the journal, the diam., and speed are taken into account? What I really want to know is what length should the shaft journal be when the diam. is 11in., pressure on the journal six tons, and speed 120 revs. per minute.—ANXIOUS.

[52456.]—**Electrophorus.**—I have made an electrophorus in the following manner: The lower part consists of a tin disc 10in. diam., having a disc of ebonite 1-8in. thick glued to its upper surface. The ebonite is hard and polished. The upper or movable part of the instrument consists of a tin disc 8in. diam., having a glass handle, sealing-wax varnished, cemented to its upper surface. On exciting the ebonite with warm flannel, and using the instrument in the usual way, I can get no spark, and only the very feeblest signs of electricity in the disc. What is the cause of the failure? The ebonite disc has a hole 1in. diam. in its centre; the tin disc below the ebonite has a hole 3in. diam. in its centre.—W. P. K.

[52457.]—**Electric Lighting.**—Will Mr. Lancaster or some other friend versed in matters electrical advise me on the following points? I am shortly returning to Tasmania, and am desirous of introducing into part of my factory there the electric light on the incandescent principle. I left behind me a large quantity of No. 14 double-cottoned and paraffined copper wire, and if this could be utilised in the manufacture of a dynamo, so much the better. I have any amount of driving power at command, and the mechanical difficulties of the work are not to me very serious obstacles. What I want to know is (1) the best form of dynamo to work 20 to 25 Swan lamps? (2) Whether this same dynamo could be wound and connected to work two large Brush arc lamps (*a*) by themselves (*b*) simultaneously with the incandescent lamps? (3) The proper mode of connecting the systems, either separately or working together? If the reply will trespass too greatly on the space of our journal, I should feel grateful for a reference to some work upon the subject from which I may gather what I need. I have all the vols. of "ours" to 1870.—MISANKERR.

[52458.]—**To "Sigma."**—I can transmit signals at the rate of 30 words a minute through a rheostat resistance exceeding that of the Atlantic cable by about a thousand ohms. Could I send the same signals through the cable itself? If not, please say why?—HIGHLANDER.

[52459.]—**Watch Winding.**—Would any of your contributors show me how to place the mainspring winder to the barrel to wind up the spring, as I am at a loss? I have bought one, and tried to place, and cannot.—AMATEUR.

[52460.]—**Casting Lead.**—Would one of our readers kindly inform me what is best to cast thin lead in, plain and ornamental? If in sand, what kind? If in moulds, what sort will stand best with frequent use, and if anything is used to make them leave the same clean?—A. B. C.

[52461.]—**Boiler Templates.**—Can any reader kindly inform me the best mode of making templates for large heavy circular boilers double landing, or how to pitch off the holes for double riveting?—J. B.

[52462.]—**Bourdons.**—In adding bourdons to an organ with 1½in. wind, would there be any difficulty, with skilful voicing, in obtaining a good round full tone? Pressure of wind cannot be increased (for reasons too long to go into); but the bourdons can have plenty of wind and be of good scale. Early information will oblige—S. O.

[52463.]—**Famsbottom Scoop for Locomotives.**—Will any reader kindly give sketches, showing the general construction of the Ramsbottom scoop. Also a formula for calculating the height to which the water can be raised relative to the speed.—FEED-PUMP.

[52464.]—**Transmission of Power by Electricity.**—(1) What machines or apparatus would be required to transmit 100 h.p. two miles for pumping purposes? (2) Suppose the engines are at one end of line and pumps at the other, what loss would there be of power if engine was doing, for instance, 100 indicated h.p. Would there be 100 at pumps, or how much less? (3) What would be the probable cost of electrical machines and apparatus to transmit 100 h.p. nominal? The pumps must be at a certain place, and if engines and boilers are there also, we have to pay for coal 5s. per ton; whereas by having engines about two miles from pumps, fuel can be had for nothing, and not even the expense of carting.—F. W. B.

[52465.]—**Belt Working off Pulley.**—I have a flywheel 8ft. and a pulley 22in. diam., distance between centres 12ft. 9in. They are connected by a belt of Helvetian leather 7in. wide. Speed of pulley from 290 to [illegible] revs. per min. The belt is always working off one side of pulley. I have had 2½in. wooden flanges fixed on it; the belt, which is quite tight, works up the flange turns completely over. I should add, the pulley is 10in. wide, and though it may be 1-16in. convex towards the edges, the middle 7in. are quite flat. Will anyone kindly suggest a remedy?—A. B. C.

[52466.]—**Cross Belts.**—I have two pulleys, one 3½ft. and the other 1ft. diam., distance between centres 16½ft., connected by a cross belt 6in. wide. The speed of the small pulley is from 1,000 to 1,200 revs. per minute. The belt, which is a stout patent cotton one: has only been in use a short time, and chafes so much that it is reduced to 4in. in width, and will soon be useless. Can anyone kindly recommend me how to prevent it, or would a 4½in. leather one do better?—A. B. C.

[52467.]—**Paper Making.**—Will some one practically acquainted with paper-making kindly inform me of the various requisites, as local position, supply of water or other power, and other matters, to the successful establishment of such a business where there is nothing of the kind for many miles round? Is it a lucrative trade? Please add any other particulars calculated to assist. What is the best work on the subject?—Semper Quærens.

[52468.]—**Colouring Lantern Photos.**—Will any correspondent kindly tell me how the best lantern photos are coloured? I inquired at an optician's, and was informed that the best moist water-colours are employed, and subsequently varnished. I procured some of those recommended, and carefully coloured one of my slides, dabbing out the skies as directed, and then varnishing; but, as I anticipated, the result was not satisfactory, the colours appearing muddy, and very different from the pure translucent colouring on those I buy. I feel confident, therefore, that some other medium than water must be used, and if any correspondent would be so obliging as to enlighten me I should be very grateful, as I have a large number of photo. slides which I bought at the Polytechnic effects, and should much like to colour well.—Beta.

[52469.]—**Fire and Marine Insurance.**—Can any reader say where I can find answers to the following questions, or any one of them?—Has the proportion of houses destroyed by fire increased since insurance become common, and if so, by how much? Have insurance premiums tended to rise or fall (indicating a variation in the risk), and in what proportion? What proportion of fires is considered to be incendiary in order to obtain insurance money? Has the proportionate amount of wrecks increased since marine insurance became common, and have premiums increased, and in what proportion? Reliable statistics are required.—J. Brown, Belfast.

[52470.]—**Malting and Malt Kilns.**—Would any reader kindly give me full particulars how to malt a small quantity of barley, say eight bushels? Also sketch of small kiln for drying same.—Córdobese, Rio Segundo, Argentine Republic, South America.

[52471.]—**Disinfecting.**—I still want a sketch of a gas-heated baking oven for clothes, to destroy "germs."—Bow.

[52472.]—**Sailing.**—If the rough surface of the canvas sails of a ship could be smoothed and glazed like a shirtfront, would the vessel sail faster or slower?—Wave.

[52473.]—**Millstone.**—I shall be glad if any practical miller or millwright can tell me the effect of great heat on French burr stones. There are a number in a mill that has been on fire. They must have been exposed to great heat, as the shafting overhead had fallen on to them, and was bent double with the heat. The top or running stones were on, so that the stone faces were not exposed to the direct action of the fire. What I wish to know is, will the stones be again fit for work? I have not an opportunity to see them, and think it very probable that some of your numerous readers may have had experience in corn mills that have been on fire, and whether the stones were again fit for work.—Tyke.

[52474.]—**Strains on Jib Chain of Derrick Crane.**—Would any readers inform me how to ascertain the strain on the jib chain of a Derrick crane at any position in which the jib may be placed, and carrying a given load, say 10 tons, on the burden chain?—Radnor.

[52475.]—**Weakened Beam.**—There is a beam in the belfry of Maiden Newton Church supporting the bellcage, Memel timber, 13in. by 12in., the 12in. being the height. It has had a piece cut out of the side, 17in. from one end, 10in. long by 3½in. deep. I calculate that the beam when whole was equal to a safe load of 184 cwt. equally distributed between the bearings 18ft. apart. What is the loss by the piece being cut out?—M. H.

[52476.]—**Ferromanganese.**—Is this substance an alloy of the two metals, and is the carbon it contains combined or not? If combined, what chemical formula would represent its composition? In what way does it act on the iron in the Bessemer and the Siemens' processes for the production of steel?—Salvo Jure.

[52477.]—**Sheep's Teeth.**—What is that bronze-coloured metal-like deposit found on the teeth of sheep, and from what source is it obtained?—Salvo Jure.

[52478.]—**Whitewashing.**—What is the size mixed [illegible]ith white and colour-wash to prevent it from rubbing [illegible] easily, and in what proportion is it used?—Salvo Jure.

[52479.]—**Electric Clock.**—I wish to connect an [illegible]ectric single-stroke bell with the hammer of an ordinary [illegible]ock (in another part of the house) which strikes the [illegible]ours. How can I make the contact so that the bell [illegible]ll be struck the same number of times, &c., as the [illegible]ock strikes? Which is the best battery?—Nomen, [illegible]verpool.

[52480.]—**Barrel Organ.**—I am about to make an [illegible]gan with Munro reeds. I have the levers (32) ready. [illegible]ant two reeds to each lever. Can any friend kindly [illegible]e me a sketch how to put my reeds, showing palate [illegible]d plunger? What size bellows will be required? It [illegible]l be in a case with lid to open.—A. B. C.

[52481.]—**Battery.**—What is the "Powell," recom[illegible]nded (p. 3 8), but not described, by "Current" (No. [illegible]60)?—Antares.

[52482.]—**Electric Bell.**—A 4in. bell, at times only, refuses to work, even when the battery is in good order, and connections good and clean. It seems as if the contact spring stuck to the pillar screw. The bell is hung upside down; consequently, the contact at screw is always good, and the armature is only distant from the cores about ⅛in. Can any fellow-worker assist me to discover the fault? The bell is sent out by a good London firm.—R. Hannen.

[52483.]—**Neuralgia.**—For the last eight or nine months I have been suffering from severe pains in the head, which I have attributed to rheumatism, but have been told that my symptoms are those of neuralgia. These attacks, for the last 12 or 14 weeks, have come on every eighth day—viz., Sunday, at almost the same hour (3 p.m.), and continue, with more or less severity, until Tuesday morning. The first symptom is that of a band being tightly pressed across the bridge of the nose, then that of a heavy weight on the top of the head, and acute pains at the back of the ears, with a bursting sensation; in fact, the whole head is in pain, and once or twice it has extended to the throat—as if I should be choked. The effect on the spirits is most distressing. My occupation on Sunday is the same as any other day. My age is 40. I have for many years suffered from rheumatism in the limbs, but now am quite free. The doctor has ordered tonics; but nothing that I have yet tried has done me any good. I am a butler, but have had to be "nursing valet" to my aged master for the last year. If any of your readers could suggest a remedy, I should feel most grateful.—C. J.

[52484.]—**Dark Slides.**—Seeing that Mr. Lancaster has failed in his promise to give us his paper on the above, will some of "ours" not take up their pen and finish what he has left undone? I would like to get mine made during the winter to be ready for next summer.—Working Man.

[52485.]—**Income-tax.**—Will a legal correspondent kindly inform me whether a shareholder in an English Railway Co., whose annual income amounts to less than £150, can be called upon to have the sum due to the tax deducted from interest, dividends, &c.? In other words, is the tax charged upon the income of the company or that of the shareholder?—P.

[52486.]—**Cracked Fireclay Furnace.**—I have one of Morgan's portable furnaces, the fireclay casing of which has cracked in several places, more especially round the opening, and as these appear to get larger after every using, I should be greatly obliged if Mr. Fletcher would tell me what to stop them up with.—A Two Years' Subscriber.

[52487.]—**Telephone.**—Would "Sigma," or some other reader, give me a diagram of the usual method of connecting the telephone, transmitter, push, bell, battery and commutator at each end of a telephone line? I am using an ordinary microphone as a transmitter. Also, what is the most convenient form of commutator to use?—J. C.

[52488.]—**Silver Solution.**—Will some reader tell me what is the matter with my silver solution? I made it by the battery process by dissolving 1¼oz. of cyanide of potassium in 1 gal. of pump-water. I connected a piece of silver to the positive pole of a Bunsen battery, and filled a porous cell the same size as that in the battery with some of the solution, and placed it in the hole, with a piece of copper connected to the zinc of the battery. I let the batteries work for 12 hours, and then weighed the silver plate, and found only ¼oz. of silver had dissolved in the solution. The articles coat bright in a few seconds; but when I take them out of the vat and rub them, the silver comes off.—H. C.

[52489.]—**Rain-Gauge.**—Will some friends kindly give designs for a good self-registering rain-gauge—one that will give strictly accurate results, and yet not be costly? I want a standard instrument that occupies but little space, and yet the rainfall can be seen at a glance—the rain-gauge being in an open space some distance from the house; so supposing one has not time to empty it, yet by taking its reading the amount can be deducted from the following day's rain, and the record will still be perfect.—M.M.I.Sc.S.

[52490.]—**Weight of Pump Valves.**—Will any brother reader of "ours" kindly inform me what weight the valves should be of a 6in. plunger pump for supplying an accumulator working under a pressure of 260lb. per sq. in.—valves 4in. diam.? I have found that they will not act with certainty unless weighted, or kept down by a spring, although only rising about ⅜in. from their seat. I should be glad to know how to calculate the above, and to understand the necessity for a spring, as it does not seem necessary when working under light pressures only. I should also be glad to know what would be the difference in time of descent of a metal body falling through air and water.—J. Thorpe.

[52491.]—**Legal.**—During the summer of this year I made and sold several bicycles, for which I sought orders. Amongst the number was one for a man, and had to be £5 15s., and to have the use of an old one to learn on, to save the new one until he was able to ride. After using the old one and getting nearly learnt, he tried the new one on three occasions, and then never looked near hand any more. Some few weeks ago I wrote him, asking payment and to have the machine taken away, and his reply was, He never ordered it. I can produce witnesses to prove he pointed out a certain machine in stock was his own and the one he tried. He also let other men learn and use the old machine without my consent. Ought I to give him notice, and sell it by auction, and sue him for any deficiency and expenses, or what lawful course should I take?—Evens, Oakland.

[52492.]—**Legal.**—My wife has 2-5ths, and her sister 3-5ths, of rents of property under their father's will. On their death the property reverts to my children. The trustees are dead, and none reappointed. The sister has possession of the title deeds, and says she has given them to a friend of hers for safekeeping, but won't name the party. In whose hands should the deeds be placed? as they might be difficult to get on her death.—A. Slater.

[52493.]—**Nickel Castings.**—In casting above I am continually having my work spongy. I have tried different kinds of nickel, copper, and spelter, also various fluxes, but have failed to obtain satisfactory results. Will some of "ours" kindly help me?—Aberystwith.

[52494.]—**Violoncello Making.**—I am obliged to "Fiddler" for his reply to my queries as far as he has answered them. I am also obliged to Mr. Leslie for giving a few dimensions, and may take advantage of his generous offer to correspond privately by advertising my address on an early day. Meantime, I should like to know what thickness the ribs ought to be.—Edinburgh.

[52495.]—**To "Jack of All Trades."**—On p. 48, Vol. XIV., you give cut and description of small furnace. Will you kindly give dimensions of one suitable for melting 15 to 20lb. of iron, particularly height and diameter (inside) of chimney? Also what kind of fuel should be used? Do you think a little fireclay mixed with compo. would be any improvement to it, or would it be better to apply a lining of the former? If so, how should it be applied so that it will not crack and strip off, as this has been the result in former dealings with this material.—C.

[52496.]—**To Find the Magnifying Power of a Telescope.**—Sir D. Brewster gives the following method of finding the magnifying power of any telescope: "Having put up a circle of paper an inch or two in diam. at the distance of about 100 yards, draw upon a card two black parallel lines whose diam. from each other is equal to the paper circle; then through the telescope view the circle with one eye, and the parallel lines with the other, and at the same time let the parallel lines be moved nearer to, or farther from, the eye till they seem exactly to cover the circle. The quotient obtained by dividing the distance of the paper circle by the distance of the parallel lines from the eye will be the magnifying power of the telescope." Has the above method been proved to be an accurate one? Would the results be equally correct if the distance of the circle was reduced to half the amount? and if so, must the size of the circle be reduced proportionately?—A. A.

[52497.]—**Chromate of Lime Battery.**—Will "Sigma" kindly tell me the best proportions to use for a double cell battery of this kind? I purpose using the porous cell to hold the zinc plate, immersed in salt and water or sulphate of zinc, so that the zinc may always be left in.—Gulliver.

[52498.]—**Thermo-Electric Battery.**—I want to make one sufficiently powerful to decompose water, but cannot find out the two best metals to use. I have tried antimony and bismuth, but the latter is both too expensive and bad to make castings of. I believe "Noe" make his with German silver and some other metal; but what is this other metal?—I will be glad of any hint whatever.—Gulliver.

[52499.]—**The Westinghouse Engine.**—To Mr. A. Jamieson.—I am much interested with the engraving on p. 284. Will Mr. Jamieson kindly furnish a section of the Westinghouse engine, and details of parts?—Historian, M.I.M.E.

[52500.]—**Leather for Camera Bellows.**—What would be the best kind of leather, not considering cost, and what kind the cheapest? Should it be stout or light? What name as sold by leatherseller? Would black velvet be the best material for lining it?—C. W. Clifford.

[52501.]—**Match Making.**—A mechanic is going to America, and wishes to start in the match trade. Would any fellow-reader give him any information about the machinery and chemicals he requires, and how to mix the chemicals?—Progress.

[52502.]—**Telescopic.**—Can Jas. Dunlop (letter 22102, p. 304) give process for reducing platinum on glass instead of silver?—H. E. S.

[52503.]—**Gas Black.**—Would some of your readers inform me how to prepare gas black for polishing, and the best means of using it?—An Old Subscriber.

[52504.]—**Legal.**—To Mr. Wetherfield.—The local authorities have put into force their powers under the Public Health Act, 1875, in respect of making up paving, channeling, and lighting a private road in which I hold a leasehold house. I am anxious to know who is the proper party to pay for this improvement, the ground landlord or myself.—R. M. G.

[52505.]—**Lacquering Burners.**—I bought a quantity of lamps last season, and not selling them all, I packed them away till this season, when, on opening the case, I found that the burners were black and tarnished. Would any kind reader inform me how I could lacquer them to make them resemble new ones?—H. W. D.

[52506.]—**Windmill.**—Could any of "ours" kindly inform me the size a windmill ought to be to drive a two horse-power in a good breeze, the size of each sail, and how many there ought to be? Also, how to arrange the machinery so as not to interfere with the windmill standing straight with the wind as it turns to face the wind? Also, the best form to make it?—A. J. P.

[52507.]—**Photometer Dark Room, &c.**—The gas company with whom I am connected having resolved to purchase and to fix one of "Sugg's Dr. Letheby's" 60in. photometers at their gasworks, in order to meet the requirements of the Gasworks Clauses Act, &c., I should feel much obliged to any friend who would kindly give sketch and plan of small building to be erected at the entrance to gasworks suitable for the above, the said building to be so arranged internally as to be utilised as office, and to contain the "bar" of weighing machine. Also best mode and material for giving the interior walls a dead black colour.—Trydanydd.

At the Court Opera at Vienna tiny incandescent lamps, suspended by fine swinging wires, give the effect of swarms of fire-flies flitting about a tropical forest. By switches the current is turned off and on at the pleasure of the operator, and the effect, as the artificial fireflies flash and dance in mid-air, is said to have been electrical in other than a literal sense.

ANSWERS TO CORRESPONDENTS.

*** All communications should be addressed to the Editor of the English Mechanic, 31, Tavistock-street, Covent Garden, W.C.

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

CHRISTMAS.

The next number but one of the English Mechanic will have to go to press on Monday, Dec. 24, in consequence of the Christmas holidays. All advertisements, therefore, for the issue dated Dec. 28, must reach the office by 1 o'clock on Dec. 24, and advertisers will oblige by sending, if possible, by the previous Saturday.

The following are the initials, &c., of letters to hand up to Wednesday evening, Dec. 12, and unacknowledged elsewhere:—

Harold Messer.—C. S. Stock.—T. Dockray.—R. G. Jackson.—J. Pickard.—W. H. Bailey and Co.—J. Birchall.—J. Barrett.—H. [illegible]—W. G. Penny.—Major Galloway.—A. [illegible]—[illegible] Brown and Son.—J. A. Schlaeft.—Col. Pendall.—T. L. Stock.—Questor.—A Young Beginner.—[illegible] Floyd.—[illegible]—A Fellow of the Royal Astronomical Society.—Geo. Parke.—Francis Horne.—X. Y.—Wm. [illegible] Grey.—G. B.—Cambrian.—W. E. C.—[illegible] Templeton.—W. E. Dawson.—An Amateur [illegible]—W. W.—[illegible] B. Allen.—Frank Mason.—Heraman.—M.I.M.E.—Weston.—Edwin Haines.

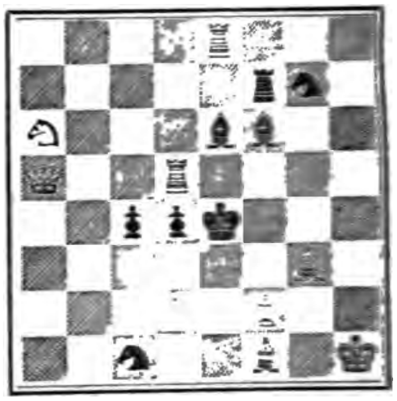
Alfred. Hydrofluoric; but the parts to have the frosted appearance are exposed to the vapour of the acid. See p. [illegible], Vol. XXXV.—A Young Engineer. It depends on what you wish to learn. "Goodeve on the Steam Engine," Lockwood and Co., is a good book, and there are several others. See the catalogue issued by Mr. Calvert, [illegible] Jackson-street, Manchester.—An Old Subscriber. [illegible] suitable, of course, if you have a suitable water supply. We do not know who makes the special turbine referred to, but you can get them from many firms.—[illegible] [illegible] in adding lime cream to the water and in passing it through filter presses to save time. The simpler process is to allow the water time to deposit the lime.—[illegible] The query has too much of the nature of an advertisement. See the list of Back Numbers under Copying Processes.—W. [illegible] The remedy is a purgative, followed by a salt-water enema. See the indices.—B. Buckland. A piece of [illegible] end of spring, and a bit of sheet platinum soldered on to touch against the point. See many papers in back volumes.—A. [illegible] Described many times; simply equal parts of sulphur and peroxide of manganese. As to the rods, you have simply to make suitable moulds and pour in the metal.—W. Corry. See the indices of the last three volumes, and read a reply on p. [illegible], Vol. XXXV. There are some directions on p. [illegible], Vol. XXX.—H. [illegible] You may get an idea from p. [illegible], Vol. XXXVI. There are several in back volumes; but for only six eggs at a time, the expense would be out of all proportion.—Climax. Anything that would stop the carbon would require such frequent cleaning as to become a nuisance; but the gas ought to be burnt without making smoke, which is quite an easy matter if the burner and the pressure are properly adapted.—An Amateur [illegible] A simple furnace will be found illustrated on p. [illegible], Vol. XXXIV. Buy the crucible is best, plumbago for preference.—An [illegible] You will find a recipe for koumiss in No. [illegible], p. [illegible], and a great deal about it in back volumes. [illegible] quart of good milk add a tablespoonful of sugar [illegible] of brewers' yeast dissolved in a cupful of boiling water. Mix in a [illegible] warm water a drachm of [illegible] and put all into a champagne bottle; shake, cork, and wire; lay the bottle on its side in a warm [illegible] place. After ten hours shake well, and repeat the process twice a day for, say, 10 days, when the liquid may be withdrawn by means of a champagne tap.—[illegible] You must do it by dipping. Alongside the bath of melted tin have a pot of oil or grease [illegible] Put the cleaned articles in that [illegible] and then pass them through the tin bath, [illegible] with a layer of grease to prevent waste [illegible] with a wisp of hemp, and polish with [illegible] [illegible] slowly. [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]—[illegible] [illegible] [illegible] [illegible] [illegible] [illegible] it is not necessary to make two [illegible] [illegible] [illegible] ready [illegible] [illegible] [illegible]—S. H. [illegible] [illegible] [illegible] of the water in the well the syphon will answer if properly constructed; but as the difference is so small it would be advisable to depend on a pump.—J. W. See the indices, or list of Back Numbers last week. You are apparently confusing an induction coil and a medical [illegible] if the wire is really as thick as you say, it is very much too thick. Use about three-quarters of a pound of No. 22, and don't trouble yourself with a primary.—D. Brown and Son. Iron is cheapest for such work; but as the quantity is small only, it would be advisable to use copper. Leads suitable for electric lighting would be much larger than is necessary for bells; but the size would depend on the work to be done. No. 20 B. W. G. is a good size for bells, alarms, &c.—A Fellow Workman. See pp. 102, 174, Vol. XXXV., and the indices of recent volumes. 2. The materials must be given before the "best cement" can be specified. See p. 10, Vol. XXIX., for a useful list, and almost any back volume for something suitable.—Tavistock. You will find a good deal as to the experiments and coils in back numbers. Two coils of about the size named in No. 865.—Wm. Hosken. Will 25d. 7h. 46m. be near enough for your purpose? 2. 13·3 cubic feet per pound. There is only one sort of hydrogen; carburetted hydrogen is a different thing, and is usually called coal-gas.—J. H. D. There is no secret about it, as it was used years ago for making stereotype plates. The moulds must be well baked, and it is better to immerse the mould face down in a pot of metal, tilting it so that the air can escape. See article "Stereotyping" in almost any cyclopædia.—Charles J. Wood. Dutch liquid is a heavy oily liquid, produced by mixing equal volumes of olefiant gas and chlorine, and leaving them to condense over water. The others are purely technical terms, the exact meaning of which can be ascertained only from the firms using them. The term "pressed" no doubt means drawn or hardened, and "annealed" would mean that the brittleness had been taken out after the drawing or hardening process. If you had given us the context of the terms, we might have been able to answer in a more definite manner.—Amateur Photo. Your apparatus is at fault. The simplest way is to take the photo. off the mount, use that to produce a negative by printing in the usual way, and then use negative to make copies. For other methods, and also for enlarging, see indices.—J. C., Whitehaven. We stated on p. 25 that the price of the new Patents Act was 1s. 1½d., 1s. 3d. post free, and it can be obtained from the Queen's Printers, East Harding-street, E.C.—Bernard. De la Rue and Co., Bunhill-row, E.C., publish it, but we forget the price. You should try Clerk-Maxwell's treatise, published by the Clarendon Press, 7, Paternoster-row.—Electric. No book of the kind, at that or any other price. See the indices of back volumes.—A. Bentley. Yes, certainly; because it is a hydrocarbon $C_{10}H_{16}O$. It is very generally used for brightening the flame in magic-lantern lamps. To obtain the best results, the camphor should be previously pounded with a little alcohol in a mortar, and added in the proportion of about two ounces to the pint of colza or sperm; but less for paraffin or crystal oil.—[illegible] We do not know such a cell. The chloride of silver cell has been frequently described.—A. B. C. Yes; by covering the hole from which the wind issues with a valve hinged at one end, and with a wire and a weight at the other. But to do this properly a valve-board is required, which is certainly not in the instrument, or the stops would have been added. For sketch, see p. 33, Vol. XXI.—Whitesmith Man. It is Dutch metal; but see reply 52268, p. 312, last week.—Harry Davis. Several methods have been described in recent volumes; but you might find something suitable in Mr. Fletcher's catalogue, Museum-street, Warrington. How would that on p. 44, this volume, suit?—Amateur Gilder. You must have a strong cyanide solution, and a powerful current. We suppose those in the trade use a bath which has been employed for gilding copper articles. See [illegible] "Goldsmith's Handbook," Lockwood and Co.—G. T. There is no such book. The information required must be sought out from articles and papers such as have appeared in back numbers.—Zat. We have already given it. The larger the motor the better the return. We suspect the 80 per cent. is the useful return of the energy put into a dynamo by a steam-engine. Although some elaborate experiments carried out in America gave 90 per cent. in a motor, there is not much hope of such a return from small machines.—E. P. Asphaltum or lampblack in oil of lavender, or ivory black, wax, and turpentine. Or some use a black enamel, which fuses at a lower temperature than the white.—[illegible] Reader. No. [illegible] [illegible] [illegible] Answered many times; see pp. [illegible], Vol. XXXV.—A New Reader. Ure's book on coins may give you some hints, but you would find a number of suggestions in back volumes.—Iris. You want a perpetual almanac. See pp. [illegible], Vol. XXXVI. There is also a table in [illegible] [illegible] September [illegible] [illegible] was Monday.—Dearness. Is there anything [illegible] in recent numbers? What about [illegible]—W. [illegible] We do not know of any other work on the subject. 2. We doubt if they have "adopted" any brake definitely—[illegible] wants timing and regulating, and compensating. See a number of articles and papers in back volumes.—[illegible] We must decline to insert either. You say nothing about previous statements which other correspondents—and it appears in one instance, at any rate, correctly—have accused you of making, which are not to be reconciled with those you now make. We have very little space to spare just now, and we think our readers have almost had enough of the brake question.—British [illegible] [illegible] foreign [illegible] offers, and you would only get [illegible] which we have no room, neither have we [illegible]—except in rare cases—for problems.—[illegible] You and your friend are disputing a question which has puzzled philosophers in all ages, and is likely to do so. Greater poets than Dr. Young have taken your side—naturally; but it has its difficulties when you think over the matter carefully. Probably in this world we never shall know which opinion is correct.—C. [illegible] Torquay. We gave an account of it on p. [illegible], Vol. XXXVI. We fear you will not abandon the steam-engine just yet—at any rate, in favour of this motor. The daily paper mentioned has shown a curious capacity for publishing details of new and marvellous inventions.—[illegible] All raffles are illegal.—J. D. M[illegible] You are very kind indeed—not that you are alone; another correspondent, to whom we replied on p. 232, made a similar flattering proposal to inaugurate a testimonial for our benefit; but we really feel the obligation rests the other way. We are so entirely indebted to our correspondents for the position to which "ours" has attained, and so conscious how inadequately we use the resources placed at our disposal for the common good, that we wonder sometimes we do not get reproaches instead of congratulations. All we can say is, the most grateful return that we can receive from any reader is help in making "ours" more widely known. If every subscriber brought us another within the next month, we should commence the year with twice our present opportunities of being useful.—Samuel Kershaw. [illegible] a solicitor; as far as we can gather from your statement, you are not entitled to inherit.—[illegible]—Full particulars in Vol. XXVII. Cannot help you unless we know what is the difficulty.—[illegible] F. Wilkinson. In type.

CHESS.

All Communications for this department must be addressed to J. Pierce, Bryn Eithyn, Llandwrog, Carnarvon.

PROBLEM DCCCLXV.—By J. Pierce.

Black.



White. [8—5]

White to play and mate in two moves.

Solution to 862.

White.	Black.
1. Q-Q B 7	1. Kt [illegible] B [illegible]—Q 5 (a) or K takes Kt
2. Q takes P at Q 5	2. Anything
3. Mates	
	(a) 1. Kt takes Q
2. Kt (K B 5)-K 7	2. Anything
3. R or B mates	

NOTICES TO CORRESPONDENTS.

Correct Solutions to 861 by F. F. Indiake; to 862 by Rev. W. Anderson.

E. Stanley Fairbairn.—There is no mate in your solution if after 1. $\frac{\text{[illegible]}}{\text{Q Kt 4}}$ 2. $\frac{\text{Q-Q B 5}}{\text{Kt-K B 4}}$

M. Graham.—The omission was set right in the last number.

Problems and games received with thanks from F. O'N. Hopkins, J. Russell, and W. T. Pierce.

Mr. J. [illegible], Glasgow, has won the first prize (£2) in English Mechanic [illegible] Correspondence Tourney, having won ten games out of eleven. The sole game which he lost was won by Mr. A. E. Studd. We hope shortly to be able to publish the names of the winners of the second and third prizes.

Secretaries of Chess Clubs who are interested in playing matches with others at some distance are requested to communicate with Mr. W. R. Bland, Duffield, Derby, as it appears that if united action is not speedily taken, the Railway Companies are likely to withdraw the privilege hitherto accorded to members of Chess Clubs of travelling at pleasure-party rates. Secretaries are requested, when they write, to inclose sixpence in stamps towards defraying expenses.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India via Brindisi, 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 6d. each to cover extra postage.

Messrs. Jones & Willis and Co., of 734, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 6d. each copy to cover extra postage.

Vols. XXV., XXVII., XXVIII., XXX., XXXI., XXXII., XXXIII., XXXIV., XXXV., XXXVI., and XXXVII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post-free from the office, except index numbers, which are 3d. each, or post-free, 3½d.

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI. and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, DECEMBER 21, 1883.

ILLUMINATING GAS FROM MINERAL OILS.

THE announcement that the Commissioners of Northern Lights have given instructions for the erection of mineral-oil gasworks on Ailsa Craig to supply gas for working the fog-signal engines, and also for burning in the "lantern" which is being erected on the rock, is an indication that they, at least, are not satisfied with the electric light as a guide to mariners. There is much diversity of opinion on the matter, and little difficulty in finding a host of experienced navigators who are ready to declare that they prefer the old-fashioned oil-lamps to the electric lights which have been erected on certain parts of the coast. The Trinity House have advisedly moved rather slowly in the matter, and although they have had at least one lighthouse in which electricity has been used for what we may now term many years, and a few others in which it has been tried for longer or shorter periods, they do not exhibit any very ardent desire to forsake the old style. Recent experiments in Ireland have demonstrated the great value of gas for lighthouse purposes; but, unfortunately, lighthouses are not always located in spots where an unlimited supply of coal-gas can be obtained, and it is not, therefore, surprising that the commissioners of Northern Lights, having determined to try gas at Ailsa Craig, should have adopted the system which prepares the gas from one of the paraffin oils, especially as in the circumstances the gas can be manufactured more cheaply than from coal. Dr. Stevenson Macadam, of Edinburgh, has made a large number of experiments with paraffin oils, in order to discover the best means of obtaining a permanent gas from them, and has satisfactorily demonstrated that, properly treated, the shale oils will yield an excellent illuminating gas at a comparatively low cost. In the earlier trials with the paraffin oils, no difficulty was experienced in obtaining a permanent gas; but it was found that if large quantities of gas of high illuminating power and uniform quality were required, much skill in manipulation and great attention to details were necessary. Not only did the results vary with the chemical composition of the paraffin oils, but they also varied with the heat employed in gasifying the oil. At low heats, it was found that the tendency was to distil oil rather than permanent gas, whilst at high heats there was much risk of decarburising the oil and gas, and obtaining a product of weak illuminating power. At last, however, suitable heats were discovered, and when the proper quality of oil to give the best results was found, a permanent gas of high illuminating power was obtained with only a small quantity of tarry matter and a slight amount of deposited soot. The paraffin oils employed in Dr. Macadam's experiments are technically known as crude, green, and blue, the first-named being the oil which is obtained direct from the destructive distillation of shale, and which necessarily varies in quality. The green oil is obtained by re-distilling the crude oil, and removing the lighter constituents by fractional distillation; the blue oil is the product of a rectifying and freezing process, in which the green oil is treated with sulphuric acid and soda, the spirit, burning, and intermediate oil being distilled off, and the solid paraffin or wax removed by freezing. By this means three fairly definite paraffin oils were obtained, and after a number of experiments, Dr. Macadam found the best results by running the oil in a thin stream into a retort kept at a bright cherry-red heat. The crude oil has a specific gravity of 850, a flashing point in the close tester of 92° Fahr., and a permanent firing point of 106° Fahr. Its cost is, or was at the time of the experiments, 4½d. per gallon; but its low flashing point rendered it a dangerous oil to store for the production of gas. The green oil has a specific gravity of 884, a flashing point of 165° Fahr., and a permanent firing point of 193° Fahr. This oil is practically safe under any ordinary conditions of working, and yields about 3·80 per cent. more gas per gallon of oil than is obtained from the crude product, but slightly less when the oils are measured by weight. Its price is 5d. per gallon; but as it gives about 5½ per cent. more light value when measured by weight, the figures come out as 3·79 and 3·74 respectively for crude and green oil, when reduced to the light-value unit of a pennyworth of oil. Taking into consideration the safety of the green oil, it is clear that it is much superior to the crude oil. The blue oil has a specific gravity of 878, a flashing point of 163° Fahr., and a permanent firing point of 268° Fahr. Its cost, however, is 7d. a gallon, and its value reduced to the penny unit, only 3·38. Still, it yields the largest quantity of gas from a gallon—a consideration in storage calculation—and is practically free from any risk which attends the use of oils containing the lighter components of the crude material. Tested by a Bunsen photometer the gas yielded by the blue oil gives 54·28 standard sperm candles on a consumption of five cubic feet of gas, and a gallon of the oil yields 127·42 cubic feet. One gallon of the crude oil yields 98·76 cubic feet of gas of 50·36 candles, and a gallon of green oil yields 102·52 cubic feet of 53·24 candles. The cost of the gas from the blue paraffin oil is about 10 per cent. more than that from the crude oil, but against that has to be set perfect safety as compared with considerable risk, and smaller storage space required for a given quantity of gas-making material. A special blue oil sold at the same price as the other—viz., 7d. a gallon, gave still higher figures for illuminating power and quantity of gas per gallon of oil, with the special advantages of remaining liquid at any ordinary temperature, and of being capable of safe storage under any natural conditions, for the flashing point is 270° and the permanent firing point as high as 335° Fahr. Some experiments were made by Dr. Macadam with other illuminants, including a rectified coal oil, which, however, gave the lowest results of any, and demonstrated the fact that the coal naphthas cannot compete with the paraffin oils in yielding large quantities of rich illuminating gas.

It will have been noticed, from the figures given above, that the gas obtained from the paraffin oils has a very much higher illuminating power than that of gas obtained from Boghead cannel (40 candles), and about from three to four times that of the coal gas supplied in London and many places in the provinces; hence, so to speak, a given number of "candles" can be stored in a comparatively small space—as, in fact, has been done with the oil gas used for lighting railway carriages, which appears quite able to hold its own against the electric systems. Obviously, however, if the paraffin oils give so much light in the shape of gas, they will give more if consumed in the liquid state and to ascertain the exact proportion as near as possible, Dr. Macadam made some of his most interesting experiments with common lamps, a gallon of the ordinary paraffin oil (burning oil) yielded a light equal to 22lb. of sperm in standard candles (a standard candle burns 120 grains per hour); and in a Doty lamp it gave a light equal to fully 27lb. of sperm. Since those experiments were made lamps have been improved, and there is now no difficulty in obtaining a lamp—one with an inch and a quarter flat wick—which will give a light equal to the 27lb. of sperm from one gallon of refined oil. Dr. Macadam estimates the crude paraffin oil to be worth three-fourths of the value of the refined oil, and the green oil as equal to four-fifths, which give, when compared with the light-value of the gas produced by both, 80 per cent. of the light-value of the oils. The loss is a trifle less in the case of the blue oil; but taking it at 20 per cent. all round, the question arises whether it is worth while to lose 20 per cent. of the light-giving capacity of the oil in order to grasp the advantages offered by the gas. It must be remembered that the loss of light power is only on the total quantity of oil consumed—that is, more oil is needed to give the same number of candle-hours when it is used in the form of gas than when burnt as oil in lamps provided with wicks. The actual photometric value of the gas is higher than can be obtained from the oil in practice, unless very great attention is paid to the wicks, which would require frequent renewal. There is, too, a limit to the wick area which can be used in any given lamp, and certainly a considerable expenditure of labour in trimming, cleaning, &c., besides loss from breakage of chimneys. Taking all these points into consideration, it seems to follow that there are many places where it would be advisable to convert the oil into gas, especially as it can then be used as required for obtaining motive-power by means of gas-engines, and also for illuminating purposes. Where coal-gas can be obtained at any reasonable price, say, 4s. per 1,000 cubic feet, the oil-gas has no standing; but considering how easily it is made (the retort can be kept at work for days together with the minimum of attention, for the oil is simply allowed to trickle in continuously), its high photometric power (at least 50 candles), and the small space occupied by the required plant, oil-gas is especially adapted for lighthouse work and for use at country mansions. Where the gas is required for motive power (it is used at some lighthouses in the engines employed to work the foghorns), it would be advisable to add to the plant an arrangement for producing water-gas by driving steam over red-hot coke. The carbonic oxide and hydrogen thus obtained might be mixed with the oil-gas to reduce its illuminating power (it is too rich for burning at ordinary gas jets, except No. 1), and to increase the explosive power when used in engines. In districts where coal is found on the spot, or can be had at a cheap rate, oil-gas is economical only for lighting; but in that direction it seems likely to hold its own against the electric light, especially in railway carriages, lighthouses, and other places which cannot be directly connected to large gasworks by fixed piping. If a simple portable apparatus were devised, in which the gas could be made and used at once, it would, we think, find a ready sale: but to be complete, it would be necessary to use oil for heating the retort, and it must, above all things, be free from any risk of explosion. Something of the kind is available for use with gasoline and benzoline; but there can be no doubt that the green or blue paraffin oils would be preferred to the more volatile hydrocarbons.

PATTERN MAKING.—XIX.

Columns and Pipes.

TAKE it a rule to joint all columns and pipes, whether they be small or large. It prevents the tearing away of the upper half of the mould, and the joint forms a convenient basis for the marking of centre and parallel lines, the setting square of blocks, facings, flanges, bosses, &c. Pipes and pillars up to seven or eight inches in diameter will be made of solid stuff; if over those sizes they should be "lagged up." Fig. 1, Vol. XXXVII. p. 449. The transverse blocks or bars upon which the lagging is to be laid may be about 12in. or 15in. apart, and each bar should have a dowel in the centre. The number of pieces of lagging to the circle will vary with the diameter of the pipe or column. An 8in. pipe may have eight strips to the circle, while a column of 16in. or 18in. diameter may have a dozen. Fit the strips and glue successively in the manner described when treating of engine cylinders, the only difference being that a long joint is not made to fit close so readily as a short one. When built up, secure the two halves of the pattern with centre-plates, and put into the lathe. If the pipe be long, staple the joint at intervals before attempting to turn. Do not turn any one portion to finished sizes immediately, but rough the whole pipe down from end to end first. If other work can be prepared in the interval, it is even better to let it remain thus roughed down for a few hours before finishing, than to finish at once. The reason is, that all timber, whether well seasoned or not, has a tendency to spring, and will in most cases buckle more or less out of its original shape when newly-cut grain is exposed to the air. For this reason a careful workman, when beginning a lengthy job, always "gets out" as much stuff as he can see his way clear to get out, and "jacks" it all over before planing or turning any one portion to its finished dimensions.

If the column or pipe be of small diameter in proportion to its length, it will vibrate or "wobble," to use a workman's term, in the lathe, so that to turn it true will be impossible. Make a steady, shaped roughly to fit the bed of the lathe, and to take the diameter of the pipe. The sketch, Fig. 101, shows the best way to make a steady. By means of the sliding blocks A A, replaceable at pleasure with blocks of any other dimensions within the limits of the Vee'd portion of the steady, we can make it a standard tool for pipes of various dimensions. Wedge-shaped cottars, B B, will hold it firmly in position. A lubricant must be applied where the pipe runs in the steady, else much heat will be developed, and an excessive amount of friction be set up. Soft soap, or soft soap mixed with blacklead, are good lubricants.

It will facilitate the turning operation if, in a long pipe, after having reduced the two ends to the required diameter, we plane a straight flat along the pipe from one of the finished ends to the other. We can then see at a glance, when working at any portion of the pipe, whether we are nearly or quite down to the size, without having recourse to callipers and straightedge continually.

Flanges round, square, or of other shapes, socketed or spigoted ends, belts, mouldings, &c., will be required for pipes and columns. If the pipe is to be flanged, the flanges will be made distinct from the body of the pattern. A flange will be made in halves, dowelled together; and where it is put on at the end of a pipe, the hole must be made of such a size that it shall drop into a groove somewhat smaller than the print, to keep it steady. If the print at the end of the pipe is, say, 4in., the groove may be 3½in. in diameter, Fig. 102. The stuff should be got out thicker than the actual thickness of the flange, to allow of a small radius or hollow being turned out at the back. If the casting is to be faced, ⅛in. must be added to the thickness on the front side of the flange on that account. If the flange is to go on some part of the pipe intermediate from the ends, it is usual to turn it as a "body flange"—viz., a flange having a hole of the same diameter as the *outside* of the pipe, Fig. 103. The flange can then be slid along and screwed to any desired position, and the casting can be "stopped off" to the corresponding length. In body flanges the hollow on the back is omitted, being left for the moulder to rub in sand.

For socket and spigot pipes, or faucet and spigot, as they are called also, the pattern may have blocks glued upon it just where the socket is required, large enough to bring it up to the proper size, and long enough to include the socket print which, of course, will be larger than the outside of the pipe by the allowance for "caulking." This method of blocking up the pattern with a permanent socket, though right *enough for standard work,* would be absurd in a jobbing shop where pipes of all lengths and of both kinds are made from a single 9ft. length of pattern. We must have the socket, like the body flange, a thing quite distinct from the pattern, to be screwed on anywhere or removed at pleasure. The most convenient form is an iron pattern socket in halves fitting over the body of the pipe, and cast very thin to reduce its weight. A single screw run in from the top holds it in position (Fig. 104); dotted lines indicate how the socket is lightened out. For the spigot a bead of lead may be cast, bent round, and tacked to the pattern, or, if for permanent use, it may be turned out of the solid.

If round or square holes are wanted in flanges they should be put in by templet—in this case a piece of thin wood cut to the shape of a half flange and having slot holes cut out,—the termination of which gives size and position of cores. The cores rubbed to the thickness of flanges are thrust into position by the templet, and the slight friction of their faces against the faces of the mould is sufficient to retain them in place during the inflow of the metal (Figs. 105—106.

Pipe patterns from which a large number of castings are required are always made in wood or (where the quantity is very large) in iron. Yet we sometimes have pipes of a large size to make where the number of castings is not sufficient to pay for the cost of a pattern. In that case, we make a loam pattern. That is a different thing from a loam mould. In the latter case our boards are made to strike the actual *mould* (Art XI. p. 497 Vol. XXXVII.) In the former, the boards strike up the *pattern* from which the mould is to be made. The flanges will not be struck up but made in wood; unless, indeed, they happen to project only a little distance from the pipe body. Mouldings and sockets, however, will be struck as part of the loam pattern. The annexed figures, 107, wil sufficiently illustrate the way in which a loan pattern and its core are struck up, without verba explanation. We shall return to the subject o loam patterns again in connection with some mor elaborate forms of work.

Branch pipes, fitted to a main piece of pipe might have their ends struck out geometrically but we can always, or almost always, chalk th main pipe and cut the branch to a fit in less tim than would be occupied in striking the neces sary lines. Where branch and pipe, however are of the same diameter, there is a ready and simple method of insuring a fit at once Having marked in the joint of the branc the line where it abuts the edge of the pipe, Fig 107; on this, as a base line, construct a triangle whose sides shall be inclined towards it at a angle of 45°, meeting consequently and formin the apex at the centre line of the pipe, Fig. 108 Cut to these lines at right angles with th joint.

Where the cut faces intersect the circumferenc of the branch a curve will result, which if worke to will insure the required fit without furthe trouble (Fig 109).

Fig. 110 shows a tee pipe, or tee piece, mad in the usual way, with a wide throat at the poin of junction, for the purpose of allowing freedo of water way and diminishing friction. Here special core box (Fig. 111) is advisable, to get th throat of the correct shape corresponding wit the pipe. The core for the pipe, being plain an circular, can be struck up separately, and th branch core butted against it in the moul These throat core boxes are made for vario sized pipes, and kept in the pattern stores read for use.

PRACTICAL NOTES ON PLUMBING.—LXXXVII.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from p.* 298.)

Measuring for Lead Gutters (*continued*).

SO far let us suppose all to be done, and ready for bossing, or working up the corners, which is done as follows:—"Take the mallet M (or some plumbers use the dummy; I use the first to hand) and bossing stick R, and having the lead with its corners cut off, as illustrated at Fig. 408, and trued up shipshape, proceed as follows: First let the mate hold the lead nice and firm, to prevent it swaying about. The best plan to do this is for him to kneel at about the figures 1882, then place the other knee at 18, and with his fingers put round the edge of the lead, let him pull it towards his knee; this will hold it as firm as a rock, and the plumber can work with ease as follows: Place the mallet as shown, and with the bossing stick work the lead from the corner steadily and regularly upwards. The mallet is to keep the lead to its shape *regularly round*. When learning, you must proceed in this work very steadily, and not want to do it all at once. Keep working it upwards, but not too much so as to weaken it (or to cause the end *a* to become rounded or out of the square); but if anything rather let it thicken. Keep at it, and do not forget to keep it well round until it is near about high enough; then you may work it nearly square, and as shown at B 4, R, and at Q, diagram 407. Having bossed up the corners, next let the mate "bash down" the gutter as follows: You take hold of the buckled or puckered up side, as at T, diagram 415, and let your mate throw it down straight, and let him follow it up with his hands to prevent it springing back or from "rounding itself"—that is, by springing up about 1½in. after it was thrown down. If this is allowed to take place, the straightness of the edges cannot be maintained, and will give you extra work when laying it. Now having got so far, next turn the lead on its side, as shown at diagram 416,

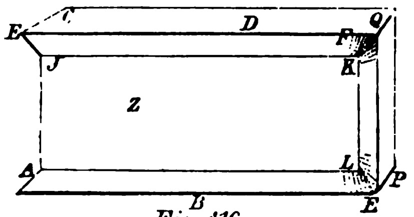

Fig. 416.

and with your dresser and mallet put in the two stiffening lines A L and J K, and with the dresser hollow the centre of the gutter up as shown; then dress up the arris E F to a true line. After this, lay the gutter gently down as at diagrams 417 and 418, and it is now ready for "putting in," excepting the putting in of the four hand holes on the turn-up edges, which is done by bending the turn edge of the lead over on the *inside* of the gutter, as illustrated at two drip end hand holes K and F, diagram 419. This allows you to grip the gutter firmly when lifting it into its place. The hand holes will be best placed, say, for a 10ft. gutter, 2ft. from each end. Now see that the joint in brickwork, as shown at A R, Fig. 410, is properly raked out to a depth of at least 1¼in., 1½in. would be better. Now sweep the gutter thoroughly clean out, so as to have no small pieces of stone or other hard substances in the gutter; also see that the nail heads are thoroughly punched home, and proceed to put in your first gutter, which, if a wide one, should have a piece of quartering Q (Figs. 417 and 418) laid in the centre, so that the middle of the gutter will be kept up, and thus better allow the arrises of the gutter to take a bearing on the gutter-board. Now, having the gutter properly prepared and lifted into its place, let the mate now with his holding-down stick hold down the corner of the gutter at S, Fig. 418, and as at S, Fig. 412. Put the end of your dresser on this corner, part on the end and part on the side, turn up lead at S (your mate still holding down). With your hammer strike the dresser a heavy blow, which will cause the lead to go well down; if it be the first gutter with a drip, as at Y, Fig. 409, work the drip down as to be hereafter spoken of; but for our purpose let it be the head gutter, as at Fig. 420. If so, then put a nail into the stand-up side at *a*, Fig. 420 (which is an end or overcloak gutter), so as to keep it down. Now with your dresser flatten your stiffening line, and smooth the bottom. Proceed to do the other corner, then go and "work down the drip," which at first will require your particular attention. Proceed as follows:

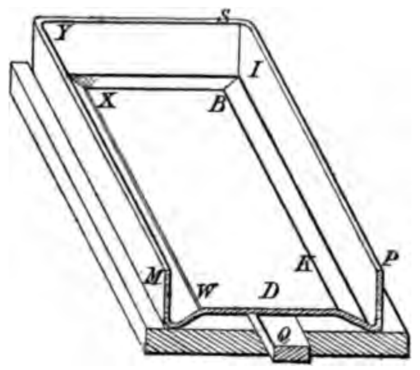

Fig. 417.

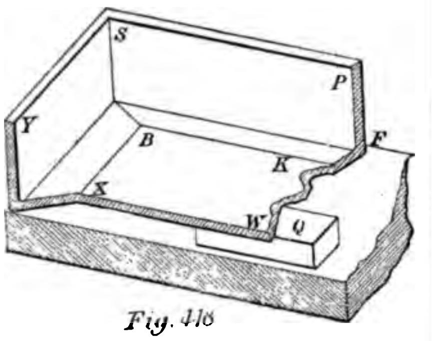

Fig. 418

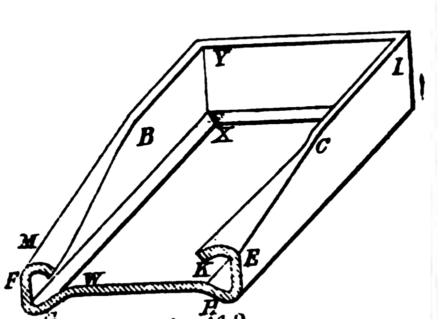

Fig. 419.

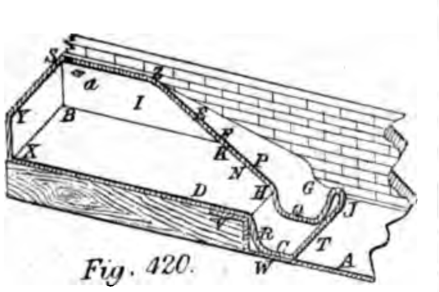

Fig. 420.

First see that no grit is between the under and over cloaks of the lead. Now, with the side of your mallet, or a short piece of roll, knock the lead a little down into the angle towards the drip, as shown at R, diagram 420. Next, from about 3ft. from the drip, bend the stand-up side of the lead down, as shown at Z E F P Q G, and give this a "smack down" also with the side of the mallet, as shown at Q G, but not right back on the arris of the side lead so as to cripple it. Now let the mate, with the holding-down stick placed at Q, hold this lead firmly down, and you with the dummy work the side of the lead up again, beginning at E, and working it regularly along from E to H. This will lengthen the top edge of the lead, and cause it to become rounded (similar to that shown at P G J, diagram 420 *a*). This beating up will allow the corner of the lead to be easily bent down over the end of the drip without too much work afterwards. Having this worked nearly upright, bend it down again, and work it until the top edge is quite rounded, and like that shown at K L, diagram 413. Now proceed to work the lead into the corner of the drip, which is done as follows: Let the mate with his holding-down stick hold the lead firmly down from springing, as shown at W, diagram 421, and you take the hornbeam dresser and mallet at about 5in. from the corner as at N. Knock the lead well back into the angle of the drip, then take a *dull* chasewedge, whose edge is ½in. thick (I like a piece of soft wood instead of boxwood) as at M, diagram 407, and with it work the lead into a kind of bulged bag, so as to get surplus lead in order that it may be worked into the corner G (Fig. 413) without straining it. The beforementioned bulged bag is well shown at P Q in diagram 427. It is formed by carefully and regularly working all the outer parts equally towards the centre, and without straining the lead more in one part than another. Do it regularly, and in such a manner that the lead shall be as thick in the angle as in the other parts. Keep at this until it is properly down, as at C G diagram 413. It will be then well to tack it down as shown at F E, or by sticking a 4in. nail, or better, a wall hook, through the two leads and into the joint of the brickwork. After you have hooked, nailed, tacked, or otherwise fastened the corner down to prevent it from rising, proceed to work the other side, and having this done, trim the lead so that there may be a 1½in. splash lap left, and as shown in diagram 413. In order that the overcloak shall not rise, put a wall hook, nail, or tack, into the lead, as shown at E F 1 diagram 413; and the drip and gutter may be finished, and ready for putting some boards into, to prevent it being destroyed. I may here mention that most of our lead gutters often get half worn out long before the roof or building is completed, which is due to the fact that the plumber will not look after a few boards to lay in them whilst the slaters, bricklayers, &c., are doing their work. I consider that when gutters are laid, it is the duty of the plumber to see that they are properly protected, more especially as it oftentimes will not cost him a penny to do it.

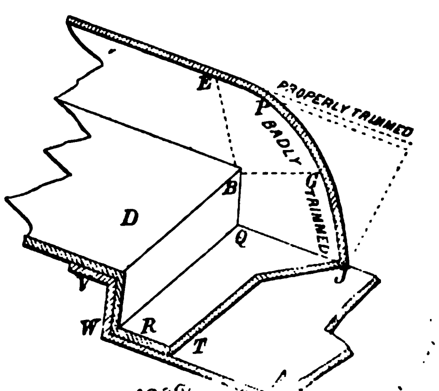

Fig. 420a

(*To be continued.*)

A CHEAP MEAL.

A SUPPER to about 150 people has been given in the Grove-walk Schoolroom, Hoxton-street, Shoreditch, by Dr. T. R. Allinson, under the auspices of the National Food Reform Society, with the object, in the words of the invitation, of proving the tastiness, healthiness, and economy of a non-flesh diet. Those invited were for the most part women attending the mothers' meetings and other religious parish organisations of St. Leonard's, Shoreditch—the society seeking, by the demonstrations they have undertaken, and of which they have already given several in different parts of the metropolis, to appeal through the palate and the stomach to the understanding of the poor, especially of all sections of the labouring classes, and to instruct them in that of which the London working population know less than their fellows in any country—the use and wholesome preparation of vegetable food. The bill of fare comprised three course—Scotch broth and a slice of whole meal bread: for a savoury dish, green pea pie with potatoes, the pie crust being made with vegetable oil: and for desert, sweetened semolina and stewed prunes. Mr. F. P. Doremus, hon. secretary of the society, addressing those present after the cloth had been drawn, said that as they had all apparently enjoyed their supper they might, as mothers of families, like to know something about its ingredients and preparation. The cook told him that in making the soup there were used, for every gallon of water, four ounces of pearl barley, one turnip, one carrot, two ounces of groats, pepper, salt, &c., to taste; in the green pea pie the contents were peas, a hard-boiled egg, tapioca, and mint to flavour; for the dessert, one pound of semolina to the gallon of water, with sugar to sweeten, served with stewed prunes. After exhibiting some coloured diagrams to show graphically the relative quantities of water, muscle-forming, bone-forming, and heat-giving constituents of whole-meal bread, oatmeal, and beef, he remarked that they would see by the difference in the proportions of these substances that in a pound of butcher's meat 12oz. represented the water present, for which they were paying at the rate of 9d. to 1s. a pound; while in the peas they got from the corn-chandler, for instance, the water was a very small part of the whole, and they could from the cistern get for little or nothing the water it was necessary to add. Thus, again, when they bought haricot beans they obtained for 2d. or 3d. 14oz. of solid food instead of the four ounces contained in the pound of flesh meat they had to pay a 1s. for. Pointing to the Scotch gillies and oatmeal-and-brose-fed men who formed the pride of our Highland regiments as specimens of a manhood to which the bone and sinew had been given by a vegetable diet, he instanced his personal experience of four or five years in favour of the sufficiency, wholesomeness, and superiority of a dietary into which flesh, whether of mammal, bird, or fish, never entered. This society did not, like some philanthropists, recommend what the members did not themselves adopt; they practised what they preached. It might surprise some of those present to learn that the whole cost of the food supplied to each person there was 3d. for the supper. Another view of the matter was that the misery of which they had too much in London was not only due to the high price of provisions, but very greatly to the want of work. If people would give up flesh-eating, one effect would be to bring under cultivation nearly all the acres of land in the country, either for the growing of grain or as market gardens; and it should be remembered that every million quarters of wheat raised in these islands gave employment to 16,000 people, while the same land devoted to cattle raising would not find work for one-sixth that number of hands. This calculation took no account of the increased requirements of the milling, baking, and other trades to which a stimulus would be given. Dr. Allinson spoke on the relative values of farinaceous and other vegetable foods compared with meat. The company being invited to declare, by show of hands, if they felt satisfied with the supper, the response was unanimously in the affirmative.

COUGHS.

It is sometimes forgotten that *coughs*—properly so-called and in their integrity—are convulsive, expiratory efforts intended to eject from the air-cells or passages of the lungs, or from the windpipe or larynx, either secretions or exudations, or occasionally foreign substances, which impede the act of respiration. Unfortunately there is seldom any constant relation between the frequency and force of a cough and the physical need for it. This is because, the act being, of course, performed by virtue of a special excitation of the nervous system, the degree of excitability of the nerves concerned in the production of the muscular contractions producing cough determines its force and frequency, instead of their being governed, as they ought to be, solely by the exigencies of expulsion. Moreover, owing to the sympathetic connection of nerves energising different groups of muscles and in relation with different centres, cough may be produced by excitations which are not local to the breathing organs. Therefore we find that *cough*, which ought to be a very simple process or function of a remedial, or, at least, physically helpful kind, is, in fact, itself a cause of disturbance and disease by reason of its excessive and disorderly character. Very grave mistakes are made in practice by treating cough as a pulmonary affection and in itself morbid. It is in a very large proportion extra-pulmonary in its cause, and it is only morbid in itself when there is no disease or disturbance in the lung which can create a need for expulsive efforts. Cough is always a nervously induced phenomenon, and as such it ought to be treated with the utmost carefulness, so as to ascertain its cause, its *raison d'être*, and the proportional relation which subsists between need and effort where need really exists. Without clear views on these various aspects of the question of cough in each particular case, it cannot be intelligently treated.—*Lancet*.

THE LATE ROBERT B. TOLLES.

The death is announced of Mr. Robert B. Tolles, optician, of Boston, U.S.A. During several years past he devoted himself to the improvement of the microscope, and to the production of telescopes of unusually short focus, and his work was characterised by great originality and excellence. He was one of the first opticians in America to construct object-glasses for the microscope on Amici's immersion system, and he succeeded in developing several original formulæ by which he extended the apertures far beyond the limit previously attained in either Europe or America. One of the earliest examples of his work seen in this country was a one-sixth water-immersion object-glass, now in the possession of Mr. Frank Crisp, Secretary of the Royal Microscopical Society, and which was the subject of much discussion in journals devoted to microscopy. Mr. Tolles claimed for this object-glass an aperture which was generally regarded as impossibly large. After much controversy, he had the satisfaction of receiving the support of Prof. G. G. Stokes, Secretary of the Royal Society, Prof. S. Newcomb, Director of the Washington Observatory, and Prof. E. Abbe, of Jena University, for the general accuracy of his views. He was an enthusiast in his work, and was almost incessantly engaged in making experimental object-glasses both for the microscope and telescope, many of which exhibited rare qualities, and were eagerly sought for by amateurs of fine work. He made the highest power microscope object-glass produced in America, a water-immersion of 1/75in. in focal length. One of his latest and most successful telescopes was a 5½in. portable equatorial of very short focus for Prof. Hamilton L. Smith, of Harvard University, who has published his trials of the instrument, proving it to be of exceptionally fine quality. The numerous improvements devised by Mr. Tolles in the construction of the microscope have done much to place American optical workmanship on a par with the best in Europe.

Critical Point of Liquefiable Gases.—A Paper appears in the *Journal de Physique*, by M. J. Jamin, on the "Critical Point of Liquefiable Gases," in which he discusses a new theory. He says:—"I believe that gases are liquefiable at all temperatures when the pressure is sufficient." Describing Cagniard de la Tour's experiment, he says: "According to known laws, the quantity of vapour above the liquid increases very rapidly, its density increasing at the same rate as its weight without known limit. Again, the remaining portion of the liquid expands at an increasing rate until it passes that of the gas (Thilorier): it is clear, then, by the effect of these inverse variations, that at last a limiting temperature must be reached when the liquid and the vapour must have the same weight for the same volume. At this point they are inseparable: the vapour does not rise nor the liquid fall, and the surface of the liquid disappears." Thus, the critical point is the temperature when a liquid and its saturated vapour have the same density. From the experiments of Cagniard de la Tour he deduces that at the critical point a liquid has no latent heat, and in summing up he says: "At the critical point there is no difference between a liquid and its vapour, neither in tension, nor density, nor thermal constitution, nor appearance, nor any property by which they can be distinguished."

Luminous Jewels.—M. Gaston Trouvé, the well-known electrician, of Paris, has lately designed a series of ornaments for ladies' wear, which consist of glass, coloured and cut to imitate rubies, diamonds, &c., fitted in an envelope, surrounding a small incandescent lamp of low resistance. The light shines through the pieces of glass only, and gives them all the appearance of the stone they are intended to imitate. The lamp is fed from a small battery, which is carried about the person. It is composed of three pairs of zinc-carbon plates (two carbons to each zinc), or a larger number according to the current required. These plates dip in a saturated solution of bichromate of potash, which is contained by an ebonite cell with three compartments. The plates are fitted into a cover, which is kept securely down on the top of the cell by two bands of indiarubber passed round the whole. Finally the battery is encased in two sheets of gutta-percha, so as to entirely prevent any leakage. A miniature switch is carried in the pocket or elsewhere within reach, to which the battery and lamp wires are connected. The pressure of a finger on the arm of this switch makes or breaks communication with the lamp. The battery weighs (with six plates) 300 grammes, and will work about 30 minutes with a two to three volt-lamp. A larger battery to work a four or eight-volt lamp weighs 800 grammes.—*Electricien*.

SCIENTIFIC SOCIETIES.

◆

ROYAL ASTRONOMICAL SOCIETY.

The second meeting after the long vacation was held at the Society's rooms, Burlington House, on the evening of Friday, Dec. 14th. Mr. E. J. Stone, president, in the chair.

Mr. Ranyard read a note on a narrow belt which he had seen on the planet Saturn. He said that he believed narrow belts similar to those seen upon Jupiter were very rare. There were many observations of broad belts of a bluish-brown colour upon the ball of the planet; but he was not aware of any other observation of a sharply defined narrow belt. While observing the planet on the evening of the 4th Nov., with an 15in. silver-on-glass reflector, he noticed a narrow dark belt which stretched across the disc, and at moments of good definition could be seen to fade away towards either limb: but he thought that the decrease in intensity was not as marked as in the case of similar belts upon Jupiter. The colour of the belt was a dark blue-grey, strikingly different from the reddish-brown of the belts upon Jupiter. On the 4th Nov. it was a striking object, nearly as easily seen as the Cassini division on the ring, though not so dark. He estimated its breadth as not double the breadth of the Cassini division, where it is seen broadest in the ansæ. The belt was again seen on the 13th Nov., but it was not then so conspicuous, and the definition was not as good as on the 4th. On the 21st he saw it again, and it was also seen by Mr. Hopkins, who observed it with him. He had tried to find whether any other persons had seen it, and had found that Dr. Copeland had on the 6th Nov. seen a dark belt, which he described as in about 20° south latitude, sharp towards the Equator, and shading off towards the Pole. He estimated its breadth at about twice that of the great division in the ring. It should be remarked that taking ten and a quarter hours as the rotation period of the planet, the opposite side of the ball would have been turned towards the earth at the time of Dr. Copeland's observation as compared with Mr. Ranyard's observations of the 4th and 13th.

Mr. Knobel remarked that the curvature of the belt as shown in Mr. Ranyard's drawing did not appear to correspond with the position of the axis of the planet.

Mr. Ranyard said that he had not given particular attention to the curvature of the belt. His attention had been more particularly directed to the breadth of the belt, the fading off towards the limb, its colour, and the position of the belt upon the planet. Dr. Copeland and Mr. Hopkins gave the position of the belt as a little higher up towards the South Pole than according to his estimate of its position.

Mr. E. J. Stone explained a paper on the supposed possible independence of Bessel's and Le Verrier's expressions for the mean longitude of the sun, subject to the conditions imposed upon them by their use in practical astronomy in the determination of mean solar time. The paper was chiefly in answer to criticisms made by Prof. Adams and Prof. Cayley. He said that Prof. Adams assumes that we have what he calls a mean solar day, just as we have a standard yard kept at Greenwich, which can always be referred to. But this is evidently not the case; the length of the day depends upon the angular velocities of the sun and when a change is made in the theory of the sun's motion, it will necessitate a corresponding change in the length of the mean day.

Prof. Adams said: I am sorry to differ so completely from the President. He has said that the mean sun is an imaginary body. I reply that it is simply the place of the real sun cleared of all periodic inequalities to which the sun's motion is subject. Mean time is simply determined by the transit of that body, supposing it to move in the equator instead of in the ecliptic, and it does not depend on the motion of the sun in longitude. The rate of revolution, by which we count time, is therefore 365 times as rapid as the motion in the longitude which Mr. Stone's reasoning refers to.

The Astronomer Royal read a note entitled "Observations of Comet *b* (1882)" (Pons-Brooks), made at the Royal Observatory, Greenwich. He said that the spectrum of the comet consisted of three bands agreeing with the ordinary spectrum of the Bunsen flame. The bright lines had been traced for a distance of 4′, that is 2′ on either side of the nucleus. There does not appear to be any very decided continuous spectrum except from the nucleus and the parts immediately adjacent to it. The spectroscopic observations have been made by Mr. Maunder.

Mr. Knobel read a paper on the "Rotation Period of Jupiter," in which he showed that there was a difference in the rotation period of the great red spot and the white spot which has been conspicuous for the past year.

Mr. Mattieu Williams read a paper on the recent twilight glows. He said: The idea had occurred to me that the remarkable sunset tints were due to a cloud of meteoric dust, and I was making experiments on that assumption when Mr. Ranyard's article on the subject appeared. I commenced operations by exposing slips of glass, covered with glycerine, in suitable positions to catch the dust. On testing these slips after exposure with acid and ferrocyanide of potassium, I got indications of the presence of iron; but just at that time the snowstorm of the 5th December gave the opportunity of collecting the matter brought down from the air by the snow in greater quantities. The experiments were made at Stonebridge, the wind blowing at the time across the Weald of Harrow, one of the most thinly-populated districts in the neighbourhood of London. In the first instance, an ounce and a half of snow was collected by means of a clean plate of glass. On melting the snow there was a black residue at the bottom of the water; this was collected and found to contain a great quantity of magnetic particles of iron. Mr. Williams showed to the meeting a filter paper covered by a dense blue precipitate, obtained by adding ferro-cyanide of potassium to the sediment from the water derived from the ounce and a half of snow. He had since collected 75oz. of snow, and he showed to the meeting a little bottle containing black sediment derived from the 75oz. It was full of particles which were acted upon by the magnet, and the chemical reactions also showed that the dust was chiefly composed of magnetic oxide of iron. One interesting feature about the ferro-cyanide precipitate is that it exhibits a striking green colour, very different from the blue precipitate obtained from pure iron. He had not yet been able to properly test the question, but he thought that the green colour indicated the presence of nickel. Mr. Williams suggested that similar observations should be made on Ben Nevis. It was important to determine what was the matter ordinarily brought down in snow, and whether there was any great change at the present time: such an examination of the materials brought down by snow ought to be part of the routine work of mountain observatories.

Mr. Knobel asked why Mr. Williams attached such importance to the presence of nickel. He had not mentioned what was the additional evidence of its presence besides the green colour of the precipitate.

Mr. Williams said that the importance of determining the presence of nickel turned upon the fact that meteoric iron usually contains nickel, whereas, terrestrial iron does not. There was another indication of the presence of nickel beside the green colour. Cyanide of potassium in excess absorbs cyanide of nickel, and he had found that this held good with the snow precipitate, but he hoped still further to test the matter.

Mr. Ranyard said: Mr. Williams sent me a little of this snow residue, and it seems to be very satisfactorily free from terrestrial dust, for, on adding hydrochloric acid there is no indication of its containing particles of carbonate of lime, and with the wind blowing across the Weald of Harrow there certainly would be such particles, if the snow had contained terrestrial dust. The sediment contains a large number of amorphous grains of black oxide of iron, which, when the dust is placed under the microscope in a drop of glycerine, may be seen to swing as a magnet is moved in the neighbourhood. Such grains of black oxide might be volcanic in their origin—in fact, I have obtained very similar grains from some volcanic dust which fell upon the deck of a man of war out of sight of land in 1812. This dust was sent me by Mr. Symons, who stated that there was an eruption in the Island of St. Vincent about the same time; but the St. Vincent dust does not contain anything like so large a proportion of black oxide, and it does not contain any smaller particles of metallic iron such as I find in Mr. Williams's snow residue, and as I have also found in some snow residue I collected in London. These small particles of metallic iron can be easily recognised by their shape under the microscope, and there is, I think, very strong evidence that they are meteoric in origin. Copper may be thrown down upon them from a solution of sulphate of copper, showing them to be metallic iron. Similar particles have been collected from snow at various times by several observers, and they have been shown to contain nickel-iron, which conclusively points to their meteoric origin. One interesting point in connection with this snow residue is that it is black, or nearly black; whereas the dust which fell in Java after the eruption of Krakatoa made the landscape appear white. I have collected the residue from snow in other years, and have found it to be much lighter than the specimen shown by Mr. Williams. The question of whether the dust brought down by the snow matches with the dust which fell in the Java region is one of considerable interest, with regard to which I hope that there will be further evidence forthcoming. If the dust which caused the blue sun and the sunset phenomena to be seen in the West Indies on the 2nd of September, was derived from Krakatoa, we must believe that it travelled half round the earth at a rate of nearly 200 miles an hour for seven days without producing a cyclone or any exceptional storms at the sea level. One can hardly predict what is possible in nature, but such a state of things seems very improbable at first sight. If the dust which produced the blue-sun phenomena was meteoric, we should expect to find that the phenomena caused by the dust appeared over a whole hemisphere of the earth at about the same time. At present, it has been shown that the phenomena was seen in the West Indies and on the Gold Coast on the 2nd of September, and that the sunsets were seen in Australia on the 10th September, and in Ceylon and India on the 9th September. Light will be thrown on the subject if we can find out when the phenomena began at various stations. I think facts are coming to light which show that the phenomena were not at first equally distributed over a whole hemisphere. I may mention that the dust brought down by the recent snowstorm contains a number of rounded particles of quartz. I have compared them with Egyptian dust and dust blown from the Sahara. The particles in the Egyptian and Sahara dust are, I think, more rounded; but there can be no doubt that there has been some friction going on between the particles that have been brought down to us by the snow. The dust particles carried up from the Sahara are seldom carried as far north as Rome or Naples, and never as far as Paris and London. It seems very difficult to conceive how such large and heavy grains as the black oxide particles contained in the snow residue could have remained in the air for over three months, and be carried as far as from Java to England, which the volcanic theory requires us to suppose.

The Astronomer Royal said: It is a very important point to settle whether this dust has its origin outside the earth, or whether it may be due to local terrestrial causes. I should therefore like to ask Mr. Williams whether there is not any possibility that the iron may have been brought from some furnaces in England. He mentioned that there was a wind blowing from the north-west when the snow fell. Are there any iron furnaces to the north-west of Stonebridge.

Mr. Williams said that no doubt there were such furnaces at a distance of 100 miles away, but it was impossible to believe that such an amount of black oxide could have been derived from them, especially when the specific gravity of the particles was taken into account. They were about four and a half times as heavy as water. He believed that the particles were derived from a great meteoric cloud through which the earth was passing, and through which it had been travelling for the last three months. There is one point to which I should like to draw attention, that is, the fact that there are two distinct sunset glows every evening, one following the other. The first corresponds to the ordinary sunset glow in which the under surfaces of the clouds are lit up by the sun; this dies away, and the clouds are then seen as dark objects floating on a bright background of illuminated matter above them. This shows the great height in the atmosphere at which the dust producing the colours of the second glow is distributed.

Hot Water for Colds.—Dr. George R. Shepherd, Hartford, Conn., says, in respect to the use of hot water as a remedial agent in the treatment of inflammation of the mucous membrances, "I have used hot water as a gargle for the past six or eight years. In acute pharyngitis and tonsillitis, and in coryza, or cold in the head, if properly used in the commencement of the attack, it constitutes one of our most effective remedies, being frequently promptly curative. To be of service it should be used in considerable quantity (a half pint or a pint at a time), and just as hot as the throat will tolerate."

Hudson and Kearns' Diaries.—These diaries are especially designed for engineers, surveyors, architects, and professional men. We always use them ourselves, and are not surprised to hear that the demand yearly increases. The makers are still busy with improvements, especially with regard to the date-indicating diary blotting-pads. No. 8, on which there has been quite a run for the coming year, is made of the finest stout blotting-paper, and the block of plain paper at the right-hand side has been found a most useful addition. No. 4, made in the form of a portfolio, is a pad which seems to be appreciated. Nos. 6 and 7 are the most general pads, being so very cheap. Among the diaries for general use we especially note Nos. 9 and 10 as being very cheap and more complete than in past years. No. 11, especially prepared for builders and those connected with the building trade, contains all the information as in Nos. 9 and 10, and some new tables, &c., at the end. No. 12 and 13, specially prepared for architects, surveyors, and engineers, contain, as heretofore, much information. All the diaries are printed on paper of superior quality, and are strongly bound in cloth gilt.

SCIENTIFIC NEWS.

WE may remind our readers that with the absence of moonlight in the early evening now prevailing, comet Pons-Brooks ought to be picked up with comparative ease. Its approximate position for any day in the month can be found from the table on p. 277; but on Sunday next it will have R.A. 20h. 41m. 54s.; N.P.D. 55° 57′, and be near Epsilon Cygni.

The extraordinary phenomena of the coloured sun and moon have brought forth a number of explanations; but the evidence at present favours the hypothesis that the effects are due to a large quantity of meteoric dust in the atmosphere—at least, several samples of snow which have been gathered yielded considerable amounts of magnetic iron. The dust propelled into the upper regions of the atmosphere by recent volcanic disturbances consists, according to M. Daubree, of colourless crystals of felspar, small black fragments of augite, a large number of transparent crystals of hypersthene, and crystals of magnetite and pyrites. A similar composition of the dust was found by M. Rénard, of Brussels.

In a paper recently read at a meeting of the Physical Society, Professor S. P. Thompson showed that if electricity be considered as a self-repulsive medium, a surplus in one place and a deficit in another would give rise to motion between them, i.e., attraction. Prof. Thompson follows the hypothesis until he infers that electricity is either the ether or other electrified—most probably the former.

In a lecture on "Solar Radiation and Atmospheric Absorption," delivered the other day at Glasgow by Captain W. de W. Abney, the lecturer stated that he had selected that subject because it was not so well understood as it ought to be, and because dark rays had a very marked effect upon the earth's economy, for without those rays the world would be left in perpetual frosts, and would be uninhabitable. He has arrived at the conclusion that the solar temperature is 5,200° C.

At a recent meeting of the London Section of the Society of Chemical Industry, the apparatus invented by Dr. Raydt, of Hanover, for facilitating the utilisation of liquid carbonic acid in breweries and manufactories of aërated beverages, was shown. The pressure required is as much as thirty-six atmospheres, and the liquefied acid is conveyed in strong wrought-iron cylinders fitted with a brass screw valve.

At the Parkes Museum recently, Dr. G. V. Poore lectured on coffee and tea. He expressed the belief that stimulants, both alcoholic and alkaloidal, had their uses, and that we ought to be sure of our ground before we override appetite with dogma. The cup of coffee—genuine, it should be observed—contains more alkaloidal stimulant than a cup of tea, and owing to the absence of tannin, its action is more rapid than that of tea The danger of excessive tea drinking consists mainly in the quantity of astringent matter, which is a prolific source of dyspepsia amongst sedentary workers, especially if they boil the tea. Dr. Poore said that coffee should be fresh roasted and ground, both of which operations ought to be done at home; from one and a half to two ounces is the quantity for a pint of water. When wanted early in the morning, it should be infused in cold water over night and heated to the boiling point, but not to violent ebullition, when required for drinking.

Mr. A. Cowley Malley, of Munslow, Craven Arms, sends us a photograph 8½in. in diameter of a slide of scales of Polyomatus Argus enlarged 750 diameters. The time occupied from the preparation of the slide to the finishing of the print was three hours.

The installation of the electric light amongst some of the shops in the vicinity of Brixton station appears to be one of the most successful, and to give satisfaction all round. The arc lamps used now are those of Clark, Clark, and Bowman, which have a very delicate feed arrangement. The installation extends over a considerable distance, and includes incandescent lamps, and at least one motor, which is used by a grocer for grinding coffee. It is probable that the majority of the tradesmen will adopt the light, as one arc lamp is sufficient to brilliantly illuminate a large shop window, and costs, I believe, a rental of 10s. a week.

At Niblo's Theatre, New York, Edison's incandescent lamps are used in several scenes in "Excelsior": in the last, the dancers are provided with wands having Edison lamps at the ends, while festoons of similar lamps are lowered from the flies. The 400 lamps are rendered incandescent at once, the effect being magical and impressive.

The United States Lighthouse Board intend to erect a tower 250ft. high at Hallet's Point, on which are to be placed six electric lamps of about 4,000 candle-power each. It is expected that the lamps will throw such a flood of light as will render the passage of Hell Gate as safe by night as by day.

The Boston and Albany Railroad is building a compound goods engine, with two large and two small cylinders. The driving wheels will be 54in. in diameter.

Herr Poetsch has invented a method of sinking shafts in watery running ground by first freezing the water, and then working the frozen mass out by hand. The wet ground is frozen by placing pipes in boreholes, and then passing through them a solution of the chlorides of magnesium and calcium, which reduces the temperature to about − 35° C.

The *American Naturalist* says that amongst the discoveries of the U.S. Fish Commission last summer is a deep-sea fish, closely allied to the very strange Eurypharynx dredged last year at the bottom of the Mediterranean. Five specimens were obtained, and a study of the anatomy shows that it presents so many peculiar features as to entitle it to form the type of a new order. Ten new genera and seventeen new species of fishes were collected in addition, besides new molluscs and worms.

USEFUL AND SCIENTIFIC NOTES.

A New Method of Obtaining Pulp.—G. Archbold macerates wood or straw, cut into suitable pieces, in dilute milk of lime, after twelve hours introduces them into a suitable digester, and saturates with sulphurous acid, the pressure amounting to four or five atmospheres. In two hours the material is so loosened up, that after washing with water and further treatment under pressure with 3 per cent. chloride of calcium and half per cent. aluminum sulphate dissolved in a little water, the stuff obtained without any further operation has the appearance of cotton, and can serve for the manufacture of fine qualities of paper.

Coffee and Alcohol in Brazil.—According to the statement of the Vice Director of the Rio Janeiro faculty of medicine, it appears that in Brazil, where great quantities of coffee are used and where all the inhabitants take it many times a day, alcoholism is completely unknown; it is further stated that the immigrants arriving in that country, though beset with the passion for alcohol, contract little by little the habits of the Brazilians, acquiring their fondness for drinking coffee and their aversion for liquors; and as the children of these immigrants brought up with coffee from their early years never contract the fatal habits known to their parents, it would seem that the number of drunkards in the country is in inverse ratio to the amount of coffee consumed. A South American correspondent of the *Medical Times* confirms the above statements, asserting that the number of cafés in the large cities of Brazil—where multitudes of persons from the highest down to the lowest go in to take a cup of that delicious beverage which none but Brazilians know how to make properly—is enormous, while drinking saloons or bars are very few, and their patrons fewer still.

Action of Sunlight on Phosphorous Anhydride.—At a recent meeting of the Chemical Society a paper was read "On the Alleged Decomposition of Phosphorous Anhydride by Sunlight," by Messrs. R. Cowper and V. B. Lewes. In a paper read before the Southport meeting of the British Association by the Rev. A. Irving, the author stated that phosphorous anhydride, prepared by passing a slow stream of dry air over molten phosphorous, decomposed, when exposed to sunlight, into amorphous phosphorus and phosphoric anhydride. The authors have repeated this experiment, and analysed the sublimate obtained in the manner described by Irving—it consisted of 78·2 per cent. of phosphoric anhydride, 4·7 per cent. phosphorous anhydride, and 17 per cent. of phosphorus. On exposing this white mixture to sunlight it became red, the phosphorus being converted into the amorphous variety. In another experiment the air, after passing over the melted phosphorus, bubbled through carbon disulphide. After some time the bisulphide was allowed to evaporate on blotting paper, when enough phosphorus was left behind to give dense fumes.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

REPORT OF THE O'GYALLA OBSERVATORY IN HUNGARY—WHAT IS A "FIELD GLASS?"—SEEING THE STARS IN THE TRAPEZIUM OF ORION—UPSETTING ONE'S GRAVITY—VERTICAL SUN ON DECEMBER 21ST—COMPLEMENTARY COLOURS IN THE POLARISCOPE—THE RECENT SUNSETS—THE USE OF A LIGHTNING CONDUCTOR—SATURN—CHINESE WHITE AND GLYCERINE—LIGHTNESS OF WINTER NIGHTS—RAIN GAUGE—FINDING THE MAGNIFYING POWER OF A TELESCOPE.

[22140.]—I would commend the study of the fifth annual volume of observations made at the Astro-Physical Observatory of Dr. Von Konkoly at O'Gyalla in Hungary, to the study and attention of all those who may feel disposed to listen to the whining of a party of pseudo-scientific mendicants in this country. These gentry (with one word for science and half-a-dozen for themselves) are never weary of assuring the ignorant British public that the one way only in which the physical structure of the heavenly bodies can be adequately and successfully studied in this country is by the establishment of a gorgeous and Palatial Physical Observatory—with a Directorate and Observerships on a corresponding scale—at the national expense, for the private pecuniary benefit (only on this point they are reticent) of certain hangers-on and creatures of the "Department" at Brompton. To anyone who may have been imposed upon by this kind of scientific begging-letter writing, I would, as I began by saying, commend the perusal of Dr. Von Konkoly's record of the mass of admirable work effected at O'Gyalla at his sole cost and charge. During the year 1882 the spectrum of Comet Wells was observed, as was that of the glorious Comet of September in that year, five bright lines in the hydrocarbon spectrum of which were measured. Observations, too, of the spectra of shooting stars were made. Numerous spectra of the fixed stars, also, were observed. Incredible as it may appear, daily observations of an exhaustive character of the Sun's surface, the structure and position of spots, &c., were made, whenever the sky was clear, in this observatory, unsubsidised by one single gulden by the Hungarian Diet. The spots have been specially observed in position with a view to the determination of the period of the Sun's rotation. Meteoric astronomy, also, would seem to have claimed a considerable share of attention; and of course, such phenomena as the partial Solar Eclipse of May 16, 1882, were not neglected. The whole volume affords evidence of the excellence of the work which is being carried on by the noble-minded Hungarian who produces it. Such disinterested labours as those of Dr. Von Konkoly go far to redeem science from the odium brought upon it by the mean and designing hangers-on to its skirts, whose sole idea seems to be to trade on it in the veriest huckstering spirit, and to pose as its votaries solely for the sake of what they can make out of it.

I am a little curious to know what sort of "field glass" it can be of which "Orion" speaks in letter 22098 (p. 301) as "magnifying about 25 diameters." "Field glass" is a word which has acquired a definite technical meaning, and is, in this country, understood to mean a double Galilean telescope, magnifying from 4 to 6 diameters at the outside. I really ask for information.

The dictum of Dr. Klein, concerning the visibility of the two fainter stars in the Trapezium of θ Orionis (quoted by Mr. Dunlop in letter 22102, p. 304) suggests a reminiscence of the Irish pickpocket, who, on being told that two witnesses distinctly saw him take a gentleman's handkerchief, replied that he "would bring six witnesses who didn't see him take it!"

I have often said that I must decline to do sums for anybody; but glancing over query 52392 (p. 313), I would venture to point out to "Beginner" that if he takes 257·6 from 480, he will find that 222·4, and *not* 122·4, remain.

In reply to query 52398 (p. 313), the Sun will be vertical at Greenwich Mean Moon on the 21st (the day when this will appear) over a point in the South Atlantic Ocean to the west of the Great Namaqualand in South Africa. At midnight on the same day, he will be exactly overhead in a part of the South Pacific to the southwest of the Friendly Islands, and not very far from the "Minerva Reef" of the charts. In the first case, the latitude of the point will, of course, be 23° 27′ South, and its longitude 1min. 48sec. West. In the latter, the latitude remaining sensibly the same, the longitude will be 11h. 58m. 27s. East.

It would take up too much space in a mere letter to answer query 52442 (p. 314) adequately; but "Nicol" will find the explanation he seeks in "The Polarisation of Light," by the late lamented President of the Royal Society, in the "Nature" Series, published by MacMillan and Co.

The perfectly glorious sunsets—or, to speak more accurately, exhibitions of the afterglow—to which reference is made by Mr. Ingall in query 52435 (p. 314) are now known to have been observed in Europe, Asia, Africa, and America. Hence, it would seem that we must look for some cosmical cause for these exquisite phenomena. An attempt has been made to trace their origin to the terrible volcanic eruption in Java in August last, it being alleged that the pulverulent ejecta of the Javan volcano Krakatoa have been carried up into the air, and diffused by currents through the entire atmosphere. Apart from a consideration immediately to be referred to, I think that anyone who will study Maury's "Physical Geography of the Sea," or any good text-book on physical geography, will see that the perfectly well-ascertained course of the chief atmospheric currents will suffice to dispose of this hypothesis. The consideration to which I have just referred, moreover, seems further to put its unsoundness and unscientific character beyond a doubt. It is this: A good deal of snow fell in this country during the first week in December; and, naturally, in its descent it would bring down any minute particles which happened to be floating in the air. If these particles were limited in number (as they must be if they consist of the dust from a single volcano), the snow would, as I have said, bring them down, and there would be an end of the phenomena to which they gave rise. Now, as it happens, after the chief fall of snow, it was a matter of common observation that, for a night or two, nothing whatever remarkable was visible after sunset. Since then, though, the western sky has on more than one occasion glowed with tints of the same unearthly beauty as those which had previously set all mankind, civilised and savage, wondering. The second explanation which has been advanced seems to me to meet this difficulty. It is that the earth has encountered a ring or cloud of meteoric matter in space, and that it is to impalpable particles of iron in the upper regions of our atmosphere, that we must look for an explanation of the recent enchantingly beautiful phenomena. For, while as in the former case snow would bring down this meteoric powder, and temporarily clear the atmosphere, as the earth continued her course through the external ring of it, fresh particles would descend towards her surface, and be carried over it by the currents existing in the air. It would be important to ascertain whether anyone collected the snow which fell early this month and examined the sediment deposited when it melted, chemically and microscopically. If so, and such sediment was found to consist mainly, or largely, of iron oxide, it seems to me that the meteoric theory would be placed almost beyond dispute. (Since writing these lines, I see, from one of your contemporaries, that two observers, at least, found the sediment from the snow which fell on the 6th and 7th, to be full of iron dust.)

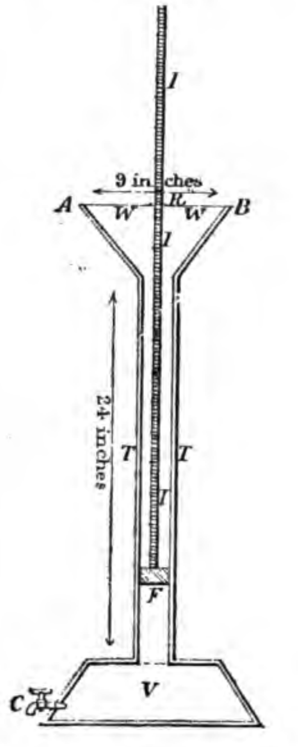
People, speaking generally, place such blind and implicit faith in lightning-conductors erected by competent manufacturers and under proper supervision, that I rather wonder that so little notice has been taken of the extraordinary accident which happened at Chichester Cathedral during the thunderstorm on November 25th. The spire was fitted with a lightning-conductor formed of a kind of woven copper ribbon, which was connected with the spire by iron staples and passed through glass insulators, ultimately descending 6ft. into the ground. Now, the lightning struck this elaborate arrangement, fusing and utterly destroying some 150ft of it (commencing about 40ft. from the top of the spire), and scattering thousands and thousands of fragments to a distance equal to the length of the part destroyed. At the parapet the lightning seems to have quitted the conductor altogether, travelled along the lead gutter, and so down a stack-pipe which it split all to pieces. This seems to me to open a very serious question indeed; because if so elaborate an affair as the Chichester conductor proved so much worse than useless when a thunderstorm came, what security have we that a similar disaster may not befall at, say, the Government magazines at Purfleet or elsewhere? I should like to know what "Sigma" has to say about this. Possessing the profound and intimate acquaintance with electrical science that he does, any utterance of his on a question of such real importance to the public safety could not fail to be valuable.

I do not quite know whether the editorial footnote on p. 321 is meant to convey a gentle hint to myself, or not; but I may begin my replies to those of my brother correspondents who have commented on the reproduction of my sketch of Saturn on p. 263, by saying that my own copy of the English Mechanic contains such a wretchedly bad impression of the wood-cut that it is hard to tell exactly to what extent the engraver is in fault. I can, however, state quite definitely that he has not exactly copied what I drew. Notably is this the case with the shadow of the planet on the rings; the equatorial edge of the dark polar capping (which was parallel to the elliptical curve of the inner edge of the ring, and not cocking up on the following side, as in the picture); in the breadth of Cassini's division, and so on. Moreover, my Saturn was on a black background, which your artist has eliminated altogether. With reference to what Mr. Baird Gemmill says, in letter 22121 (p. 321), about the markings on the ball, though, I may remark that *during the time that I was making my sketch* the polar shading on the planet was practically homogeneous, although I have often seen the ball striped by parallel belts. The darkening of the preceding portion of the edge of the polar capping was evolved from the depths of the moral conciousness of the engraver, as I saw nothing of the kind. I can, however, say definitely, that no "wavy" appearance of the edge of this shading was perceptible while I was drawing the planet. Before concluding my remarks in connection with letter 22121, I should like to express my entire concurrence with Mr. Gemmill as to the importance of watching for the passage of Saturn over stars of any considerable size. I quite agree with Prebendary Webb that very important information as to the constitution of the rings might be obtained from the observation of such a phenomenon. Turning now to Mr. Vivian's letter (22125), on p. 323, I would say that he is quite right about Cassini's division being broader in the ansæ than your engraver has represented—and as I drew—it. The dusky ring was very fairly well seen on the night of the 9th ult., but I could not, as I stated in my letter (22053, p. 263), see its inner edge as absolutely continuous all round. It was sharp enough in the ansæ, and, of course, where it crossed the body of the planet; but I could not quite connect the whole of its visible inner edge as part of a continuous ellipse. The small portion which was seemingly discontinuous, was obviously that nearest the earth. How this was engraved I don't know. In my own copy the interval between the ball and the rings is a hopeless smudge! As an illustration of the variation of Saturnian detail under slight atmospheric changes, &c., I may mention that although while I was sketching the planet on the 9th of November, not a trace of Encke's division in ring A was perceptible, I could hold it quite steadily, for many seconds at a time, on that of the 5th inst. I have not specially noticed that Saturn and Jupiter require different foci, as stated by "Brickwall" (letter 22126, p. 323). Assuming that they do, I think it probable that the greatly superior brilliancy of Jupiter must contract the pupil of the eye, and so produce a slight change in its focal adjustment.

In connection with the concluding paragraph of letter 22126, I should like, as the unfortunate "Someone," who has incurred "Brickwall's" wrath by recommending (p. 36) the addition of glycerine to Chinese white to soften it, to recall to his recollection the anecdote of the old woman who pestered her minister to pray for rain. For some time he, sensibly enough, refused; but, overcome by her importunities, at last yielded to her request. Immediately there came a violent hailstorm and cut up all her cabbages. "Ah!" exclaimed the old lady, "that's just like Mr. Jones—*he always overdoes everything!*" "Brickwall" has been "overdoing" the glycerine—that's all. I should never have dreamed of recommending it, had I not previously employed it myself with perfect success.

I think that it was Arago who suggested that the strange lightness of some moonless nights to which "M. A." calls attention in letter 22127 (p. 323), possibly has its origin in the phosphorescence of the earth itself.

How will this suit "M.M.I.Sc.S." (query 52489, p. 331)? Here A B represents the mouth of a funnel, which should be accurately turned in the lathe to an internal diameter of 9in.; T T is a tube of precisely 2in. in internal diameter and 24in. high, into which the funnel fits; the other end of this tube entering the vessel V, which is furnished with a tap C; F is a wooden float fitting the interior of the tube T, but not so tightly as to prevent its easy motion up and down. From the centre of this float rises the rod I, I, I, which is kept vertical by passing through the thin ring R, supported over the centre of the funnel's mouth by the wires W, W. It only remains to graduate the wooden index rod I, I, and our rain gauge is complete. This may be done by considering that as area × depth = volume, a cylindrical inch of water 9in. in diameter, will fill 20·25 inches of a cylinder only 2in. in diameter, so that all we have to do is to measure off 20¼in. from the bottom of the float F upwards, and divide this into 100 parts (each of them obviously 0·2025in. in length) to get what we require. The ring R forms our index. We commence by filling the vessel V to the level of the bottom of the 2in. tube, and then mark 0 on that part of the rod I, I, cut by the ring R: ·2025in. lower down the mark 1, and so on. Then it is abundantly evident that as the rain enters the funnel and passes down into the tube, for every hundredth of an inch that falls on the 9in. area the float will rise 0·2025in., and the divisions being perfectly legible may be read out of window by the aid of a field-glass or opera-glass. When the index is up to the top, the water must be drawn off by the tap C until it sinks to zero again.



Brewster's method of obtaining the magnifying power of a telescope, to which "A. A." refers in query 52496 (p. 331), is accurate enough in theory, albeit not a very practical one. The results would not be correct if the paper circle were too near, because the focus of the telescope would have to be altered; and it is the magnifying power of a telescope, when adjusted for parallel rays, that is always measured.

A Fellow of the Royal Astronomical Society.

SELENOGRAPHICAL—FRACASTORIUS—ALFONSUS—HORROX.

[22141.]—In connection with my last letter on this formation (22099), allow me to add an observation made on Sept. 2, 1882, 5h. to 6h. a.m., and which was overlooked at the time I wrote last. I transcribe from my observing book:—

"On April 21, 1874, 8h. to 9h. p.m., I discovered the rills *a* and *b* on the floor of Fracastorius. I noticed then that rill *b* was not so easy as rill *a*, but that it was well seen from crater *c* to its junction with *a*. This morning, on the contrary, rill *a* was not seen at all, nor rill *b* for some distance from *a*; but the portion from *b* to 5 was very well seen. This observation, therefore, completes fully that of April 21, 1874, and dispels all doubt about the existence of rill *b* from *c* to mountain 5 on the W.

Alfonsus.—Every selenographer has noticed the three or four dark spots contained in Alfonsus. On May 15, 1883, 8h. p.m., I found a whitish craterlet in the centre of the triangular spot on the E. of the floor, and a darkish one in the centre of the round spot on the S.W. Schmidt, who has closely watched these spots and detected variations, does not mention any of these craters. I shall be glad to hear what other selenographers have seen here.

Horrox.—Dec. 6, 1883, 8h. 30m. p.m., found three very minute craterlets on the N.W. outside slope of Horrox, the middle one and the largest of which is faintly shown in Schmidt's map. At this time the floor of Horrox was nearly full of shadow.

C. Gaudibert.

SATURN.

[22142.]—Mr. Gemmill (letter 22121, p. 321) has done good service in calling attention to the utter absence of systematic observation of this planet. There are plenty of observers and instruments; what we need is hearty co-operation. The Liverpool Society are, I believe, moving in this and other matters: perhaps a few suggestions as to this planet may now be useful. The following points, I conceive, are worthy of attention:—

1.—The Ball.
  a. Number of belts seen at any one time.
  b. Oblique belts, or any deviation from the usual parallelism.
  c. Waviness of outline, especially the boundary between the bright equatorial region and the first dark belt.
  d. Colour of the belts and different parts of ball.
  e. Bright or dark spots on ball.
2.—Ring A (outermost).
  a. Dark lines or bright streaks.
  b. Comparative brightness of inner and outer edge.
3. Ring B (middle).
  a. Streakiness or shading.
  b. Inner edge is suspected of variability in brightness.
4.—Ring C (inner or dusky).
  a. Mottling or streakiness.
  b. Colour.
  c. Comparative breadth where it crosses the ball, and in the ansæ.
  d. Relative brightness in each ansa.
  e. Least aperture with which distinctly seen.
  f. In which ansa there appears the greater extent of dark sky.

Should a star be seen within the ansæ, its behaviour when passing behind the dusky ring, and in Cassini's division, should be carefully noted. The exact time of any observation should be recorded, and it is desirable to make sketches (however rough) illustrating the particular feature under observation. Aperture of telescope (reflector or refractor) and power of eyepiece should always be given.

W. S. Franks.

SATURN'S RINGS—DEFINITION OF JUPITER AND SATURN—LIGHT NIGHTS.

[22143.]—If Mr. S. Maitland Baird Gemmill will *dele* the letters "er" after "great," in the sentence respecting Saturn, to which he refers in letter 22121, p. 321, he will perhaps arrive at the meaning intended. The sentence will then read: "No doubt the rings of this planet monopolise observers to such a degree that they neglect other phenomena which, though less attractive, may be of great significance and interest." The error probably arose in copying, and escaped me in proof.

None of us will dissent from the views of this correspondent when he says that "no astronomical phenomena *can* be *in themselves* of *greater* significance and interest than the rings of Saturn"; but it is rather staggering to find him, immediately afterwards, advocating the publication of drawings in which the rings are to be omitted altogether!

The fact that Saturn appears better defined in a telescope than Jupiter has lately been mentioned in your columns. I have almost invariably had the same experience. In the Autumn of 1880 the fact struck me as especially well marked, and I wrote to the *Popular Science Review* for Jan., 1881 (see p. 12), mentioning the circumstance.

The occasional lightness of winter nights referred to by "M.A." (22127, p. 323) has been noticed here at different times. No doubt the peculiarity is due to a diffused form of aurora or some allied phenomena. On March 2, 1883, I recorded that "The latter part of the night was very light, though the evening was extremely dark. The sky appeared to be suffused with a glow as of faint moonlight." My notebook contains mention of other instances of similar character, though I never made an effort to observe and record the phenomenon systematically.

Bristol, Dec. 15. **W. F. Denning.**

THE WESTINGHOUSE BRAKE.

[22144.]—In the English Mechanic of Nov. 23, "Imprimatur," in drawing attention to failures of the Westinghouse brake, asserts that you are constantly receiving evidence of the unsatisfactory condition of the brake in the United States. He also mentions a disastrous accident on the Long Island Railroad as one of the shortcomings of the brake in question. As a matter of justice, I wish to say that the brake that failed on the Long Island Railroad was the Smith vacuum. I ran a locomotive for five years on an American railroad, and used the Westinghouse brake the most of the [illegible] locomotive. I was in charge [illegible] for upwards of two years, [illegible] no difficulty in keeping the [illegible] when the [illegible] them [illegible] as well as incompetent. [illegible] important road in America, with [illegible] what [illegible] the Westinghouse [illegible] passenger equipment, and the brake [illegible] available as the locomotive. Most [illegible] are operated without any station [illegible] and the brakes relied on entirely [illegible] and the effectual manner [illegible] duty is the best testimony as to its [illegible]

[illegible] prevalence of failures reported by your [illegible] against the Westinghouse brake, [illegible] indicate that it is not taken very [illegible]

[illegible]NCERNING LOCOMOTIVE ENGINES.

[illegible] Mr. W. J. [illegible] (p. 30[illegible]) appears to [illegible] reply, p. [illegible] I pointed out, [illegible] of an express engine [illegible] miles an hour should move at [illegible] Different locomotive super- [illegible] different opinions as to the best [illegible] speed to adopt, in proof of which I refer [illegible] the various speeds of pistons [illegible] Locomotive boilers generally [illegible] per square inch, to give the [illegible] is impossible. The "load," [illegible] of wind, &c., must all be [illegible] and even two drivers will [illegible] in the same way. The rule [illegible] has often been given in your [illegible] is perfectly correct. I have proved [illegible] in practical working. There is not, [illegible] calculation," to tell what speed [illegible] we should not see [illegible] so many engines [illegible] the expectations of [illegible] locomotives is the result [illegible] step by step. [illegible] cylinders and [illegible] strong enough, the designer, [illegible] cylinders to 18in. [illegible] the size of his [illegible] steam enough. [illegible] These are [illegible] locomotive [illegible] classed as [illegible] by experi- [illegible]

M. [illegible]

[illegible] ENGINES

[illegible]

somewhat as a [illegible] the fact that the com- pound engine has no theoretical superiority over the simple engine with the same expansion. Surely this fact is too obvious to require stating. The greater economy in practice (as expressed in an indicator diagram), is owing to a cause which "Engineer" leaves entirely unnoticed when he proceeds to answer the question—What are the advantages of the compound principle?

The main advantage is that the steam, at boiler pressure and temperature, enters a cylinder which has not just been cooled down to condenser temperature, but only to comparatively high temperature, at which it passes away to the second cylinder. Less steam is wasted at each admission *in re-heating the cylinder*, and this is the central fact of the compound engine. "Engineer" is right about the lessened strains upon the crank-pin, but he omits to notice another practical advantage of the compound engine. Instead of having a *large* slide-valve working under full boiler pressure, the compound engine has a small one, its large valve works under a much lower pressure. The gain in friction saved is a much larger percentage of the total indicated power than many engineers are aware of. Of course in this respect the disadvantage of the simple engine can be mitigated by balanced slide-valves, but the remedy is not without drawbacks, and it is better not to require it. Similarly, steam jacketing lessens the comparative waste of steam in re-heating the cylinder in a simple engine, but it does not abolish it entirely, and the saving is only the difference between the waste of steam in the cylinder and the lesser waste which is substituted for it in the steam jacket. Such numerical estimations as this of "Engineer's," without mathematics, are valuable to many readers, and it is to be hoped he will continue them, with due correction.

M. H. B.

LOND N AND MANCHESTER EXPRESS TRAINS.

[22147.]—Your correspondents "Lincoln," p. 282, and H. Bill, p. 290, have both furnished some interesting details relating to the speed of express trains between London and Manchester; but unfortunately, they both give the distance via the Midland Railway incorrectly.

On Monday, 2nd August, 1880, all the Midland Company's main line trains ran to and from the new Central Station, Manchester, instead of to London-road as formerly, thus increasing the distance by [illegible] miles 44 chains, and as the journey was performed in the same time, there was a considerable acceleration of speed. The Midland Company has three routes from London to Manchester Central, the distance being as follows:

	miles.	chains.
St. Pancras to Manchester Central, direct	190	39
St. Pancras, via Derby Station	191	9
St. Pancras via Derby and Trent Stations	191	69

[illegible] first, or shortest, route is not used by any of the ordinary passenger trains. The majority of the express trains run via Derby, 191 miles 9 chains, [illegible] the [illegible] newspaper express from St. Pancras and some others run via Derby and Trent stations. The positions of the various junctions will at once be understood by reference to Airey's Clearing House Railway Junction Diagrams. The question of railway speed between Manchester and London [illegible] special attention [illegible] competition is as very keen. A [illegible] passengers with a view [illegible] have decided that [illegible] by the fastest trains—that is, [illegible]

[illegible]

are carefully made, showing the number of passengers in each train by each route daily. It must, however, remembered the three lines are of different lengths, and run over various gradients; it is therefore possible that an amount of traffic which would pay one company might be a loss to another. There can be no doubt that the returns of such traffic when completed to the end of the year will form an important basis upon which to regulate the Manchester and London express trains.

Clement E. Stretton.

Saxe Coburg-street, Leicester, Dec. 1[illegible].

CONTINUOUS BRAKES—PARKER-SMITH'S.

[22148.]—"Meteor" (letter 221[illegible], page [illegible]) is good enough to notice my remarks on Mr. Parker-Smith's continuous mechanical brake, but there are one or two things he says which should not pass without comment.

He says the vacuum on the G. W. R. brake is maintained by a pump worked from crosshead of engine. True, and that means some extra work for engine to do, and, of course, consumption of steam and fuel; but he says nothing about the use of the ejector necessary to release this brake before starting after every stop made with it, and he adds "thus the amount of stopping power stored up by the train is proportional to the velocity;" but he cannot mean this, for the velocity may be anything up to 60 or 70 miles an hour, and, as the stopping power is limited by atmospheric pressure, the two things, one strictly limited, the other not, cannot be proportional. "Meteor's" conclusion is unscientific, and does not follow from his premises.

To those who might accept the above assertion, "a constant brake power of, say, [illegible] per coach" may seem a big figure (it would need large drums or bellows and a good vacuum); but its efficiency is, of course, only relative.

Again, the illustration in the case of the Parker-Smith brake, which "Meteor" is illustrating against when he cites the G. W. R. vacuum brake, as to the power varying from nought (0) upwards with the speed of the train is not a happy one. The power at nought would not be a power (Hibernice!) and the train would be at rest, but let the train be on the move ever so slightly, the brake power depending upon its momentum would be at hand, more than sufficient, and would be proportional to its velocity *without limit*, except strength of materials previously alluded to.

"Meteor" is only generalising when he says the using the momentum to create brake power holds well theoretically, and may have arguments in favour of it; but when he comes to give us his practical illustration, instead of its being to the point, he gives us part of the modus operandi of an entirely different system—viz., the G. W. R. vacuum brake. Criticism, as well as "practical illustrations," should be to the point.

In passing, I may say that I look upon the Sanders and Bolitho G. W. R. vacuum brake, which "Meteor" is referring to, as about the best all round fluid brake, notwithstanding the objection that its power is so limited, but he should be just when advocating it to the disparagement of another system.

Traffic.

[2214[illegible].]—In my letter [illegible] I pointed out the importance of a "brake failure" depending on the class to which it belongs. I have now [illegible] up a list from the last return for the half-year ending June 30th, 1880, showing all cases of "failure or partial failure of the brake to [illegible] act under ordinary circumstances [illegible] when required." The returns [illegible] We have therefore [illegible] as follows:—

	No. [illegible]
Smith's vacuum, non-automatic	[illegible]
Clark and Webb's chain, non-automatic	[illegible]
Wilkin and Clark's chain, non-automatic	[illegible]
Barker's hydraulic, non-automatic	[illegible]
Westinghouse, automatic	[illegible]

Total. [illegible]

We have been told [illegible] the more simple a brake [illegible] that automatic brake [illegible] non-automatic." Now [illegible]

FAILURES.

	No. [illegible]
Non-automatic systems	[illegible]
Automatic systems	[illegible]

[illegible] non-automatic [illegible] brake. [illegible] the [illegible] automatic brake [illegible] when they [illegible] the figures [illegible]

the vehicles. These six cases are clearly
ie neglect of the couplers, and of the guards
isting the brakes as required by the railway
.es' regulations.
'orth British Co. reports "A pump did not
air pressure, as the air chamber of suction-
as filled with dirt, through want of atten-
. driver's mismanagement." The last case
Midland, where a rod broke on a tender,
brake was only out of order on this tender
train did not overrun the station. Now,
es the eight cases amount to? Simply
stances of "neglect of servants" and one
od, and even of these we find that in two
e was only affected upon one vehicle, and
trains did not overrun stations, so that in
fact the brakes did not "fail to stop a train
quired." I feel convinced the readers of
LISH MECHANIC will agree with me that
ts disprove the statements which have been
ainst automatic air-pressure brakes.

MICROSCOPIC TEST OBJECTS.

.]—THE letter of Mr. Edward M. Nelson
34) is one of the very highest interest, as
ses some hitherto entirely unknown and
ted facts in microscopy. After many
anxious consideration of the subject of
ion, latter-day microscopists had begun
atulate themselves that at last they had
the rationale of oblique illumination, and the conditions under which it was, not merely of service to, but a necessity for, microscopists.

This, however, is now all swept away at one blow, and, unless Mr. Nelson comes to our rescue, we shall be relegated to the old state of Cimmerian darkness, for he tells us he has discovered (1), That oblique illumination must be entirely abolished in favour of central; and (2), that by so doing we shall see the *true* structure of the objects.

I feel sure that he will not refuse to tell his brother microscopists how he has come to recognise these startling truths. It is not, of course, for me to dictate the form in which he should do this; but I feel that it will be very much more profitable (if he will forgive me for saying so) if he will go a little beyond the customary *sic credo stat pro ratione opinio*, and show us the various steps by which he was ultimately brought to realise the validity of his present view. We should all be able, I imagine, to follow him so much better, too, if he would not mind at the same time throwing in a little demonstration of where the fallacy is in the accepted notion that when central light has exhausted its powers of resolving given sets of lines, oblique light will show still more; and what must evidently be the still greater error of the current belief that with the objects of which he writes there can be no determination of structure as "true," and that oblique illumination must of necessity give us a nearer approximation to truth than central.

Thanking Mr. Nelson in advance for the interest which his communication will awaken.

Monachus.

SOCIETY FOR PSYCHICAL RESEARCH.

[22152.]—THE above-named Society has collected a very large number of cases where some marked event—usually either death or serious danger—happening to a person at a distance, has coincided either with the apparent perception, by some friend or relative, of that person's bodily presence, or with an exceptionally vivid and haunting dream of him. The reality of these coincidences is beyond dispute, and their number also is far greater than anyone can be at all aware of who has not taken special pains to procure first-hand evidence of them. It may, however, be argued that the coincidence, though real, is in every case due to *chance*. Now the force of this argument must clearly depend on the *frequency* of hallucinations of the senses, or of this particular sort of haunting dream, among sane and healthy persons. If they fall to the lot of everyone, or nearly everyone, then their total number must be enormous, and according to the law of chances it might naturally happen that one of them here and there would fall on the same day or night as the actual event. If, on the other hand, such experiences are comparatively rare, then the cases which have been simultaneous with the actual event form too large a proportion of the whole number for the coincidence to be attributable to chance. For the decision of this point, it is of fundamental importance to ascertain how far the number of those who have *not* had these experiences exceeds the number of those who *have* had them. An accurate result is far from easy to obtain, however wide the range of inquiry may be made; for those who have nothing of positive interest to relate are naturally less communicative than those whose experience has been to some extent remarkable. For our purpose it is, of course, essential to obtain a due proportion of *negative* answers, and with this object we have framed our inquiries in such a manner as to require no answer but "yes" or "no."

The questions to which we are desirous of obtaining a very large number of such monosyllabic replies are:—

(1) *Hallucinations.*—Have you ever, when in good health and completely awake, had a distinct impression of seeing or being touched by a human being, or of hearing a voice or sound which suggested a human presence, when no one was there?

(2) *Dreams.*—Can you recall that you have ever, in the course of the last ten years, when in good health, had a dream of the death of some person known to you (about whom you were not anxious at the time) which dream you marked as an exceptionally vivid one, and of which the distressing impression lasted for as long as an hour after you rose in the morning?

If any reader of this letter, in the course of the next six months, will repeat the above two questions *verbatim* to 20, 50, 100, or more trustworthy persons, *from whom he does not know which answer to expect*, and who have not already been interrogated by someone else, and if he will communicate the results, these will be most gratefully received and acknowledged, and he would render further aid by inducing others to do the same. In any case where a vivid impression or dream *has coincided* with the real event, it is particularly requested that the person who has had this experience will send me an independent account of it. In every other case where the answer is *affirmative*, a simple "yes" will be sufficient; but I should desire to have (not for publication) the *name and address* of any person who answers "yes," as well as of the collector. In the case of *negative* answers it will be sufficient if the collector will send (not for publication) his own name and address, with words "Hallucinations, 20 noes," "Dreams, 100 noes," or whatever it may be, on a postcard.

Edmund Gurney (Hon. Sec.)

HIDDEN LIGHT v. HALO.

[22153.]—A GASLIGHT has this misty circle round it; but on closing one eye and covering the flame with a finger held up between it and the open eye, the halo disappears, with a perfectly clear space apparently increasing the illumination. A fish-tail burner viewed edgewise is the easiest. It is very curious that the same light reflected in a mirror will not dispense with the halo, though treated in the same manner, neither will the moon when covered with a disc. How is this? Again, when the gaslight is covered with a straight folded piece of paper, so that the edge of flame and paper shall be coincident, the air motes are to be seen, very numerously attracted by the heated flame, yet never enter it, flying upwards with rapid velocity. I suppose these motes are the light reflectors popularised by Tyndall. I only mention them to show the contrast between their action and that of the hidden motes or particles shown in phosphene, letter 22081.

Fiddler.

"HOW TO MAKE A CHEAP LATHE."

[22154.]—WITHOUT being accused of finding fault with these excellent articles, may I be allowed to point out that the usual way in most toolshops of fastening the hand-wheel to spindle, Fig. 38 and 41, is not by a bit of $\frac{3}{16}$ wire driven through the boss, which would be considered a bungling job, but by boring the collar, Fig. 39, say $\frac{1}{2}$in., the spindle being left correspondingly large? The hand-wheel bored $\frac{1}{2}$in. is thus forced by the outside nut against a true shoulder, and if a good fit needs no pin or key.

I hope the writer will take this remark in the spirit in which it is intended, and if, at the conclusion of the Lathe Articles, he will give us "How to make a cheap Self-feeding Bench Drilling Machine," I feel sure he will earn the gratitude of others beside myself, who desire to see the "E. M." as in the days of old, when it was more mechanical and less of astronomy.

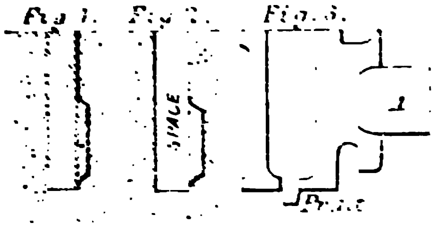
W. F.

LATHE MATTERS.

[22155.]—"WHEN a boss is cast on a stem or plate moulding vertically," it is only necessary to pin it on loosely with a wire, *provided*, however, that it is easily accessible, and that it be somewhat less in thickness than the space through which it is to be drawn. The annexed sketches will, I hope, make my meaning clear. Fig. 1 shows a plate and loose boss in the sand. When the sand is rammed round the boss, sufficiently to hold it in position, independently of the wire—the loop only of the wire being left exposed, the moulder draws the latter away, and completes the ramming up. That is the reason why I always use "wires" or "skewers" in preference to clasp nails, the former standing farther away than the latter, thus allowing of more complete envelopment of the boss in sand, and affording also a slight leverage to the finger in the act of withdrawal. When fully rammed up, the main pattern is lifted out and the mould has the appearance of Fig. 2. Then the moulder thrusts down a bit of bent pointed wire, generally his vent wire, or a nail, and sticking it into the boss, draws it out.

Now, another study of the sketches will show where loose pieces are inadmissible. Supposing the boss had been twice its present thickness, it could not have been drawn into the space left by the plate. In that case we should either cut the boss into two thicknesses divided longitudinally, and withdraw each thickness separately, or we should place a "drawback" against that face, that is a cast-iron plate upon which that portion of the mould is made, and drawn back, to be replaced when cleaned and finished, or we should core over the top of the boss. A case of this kind is illustrated in the "E. M." Vol. XXXVII. p. 427, Fig. 44. Or supposing the mould had been very deep, say three times what it appears to be in sketch, then a thin boss could not have been withdrawn because of the difficulty of reaching it. Then a drawback, a core, or a joint made in the mould across the centre of the boss, would get over the difficulty. The bosses on the back-gear arms of a headstock, being thin and the arms not very long, will in ordinary cases come into the mould easily, and so also will the V strips of lathe-bed castings when the bed is cored out. But when a lathe-bed pattern is made like the casting, either the middle sand, or the outer sand must be removed before they can be taken away.

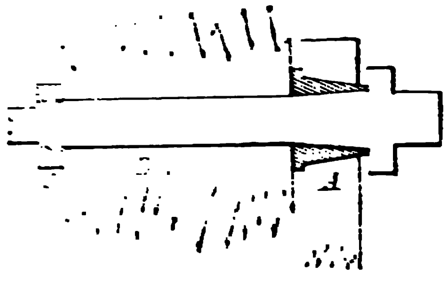
An article of mine in MS., in the Patt. Making series, is specially devoted to "Cores and Drawbacks," and will contain information on the moulding of patterns, the philosophy of pattern making, if I may use so high-sounding a term in connection with my little-known craft.



The bed you figure might be moulded with the V face downwards; but I should not make it so. I should mould it in the usual way, flanges downwards, coring out the inside, and taking out the recess in front with a core, the print for which, Fig. 3, A, should be wide, to balance the core well. There is not the slightest difficulty in making it thus. J. H.

LATHE MANDREL.

[illegible]—Lathe matters being to the front, I venture to send a sketch of a mandrel which I designed some time ago, but never had the opportunity to make. It is so simple that I hardly think it can be new, but I do not remember ever seeing anything like it in "ours." The objection to that class of mandrel running in one cone and a back centre, is that it is impossible to have a good shoulder for the chucks without having an abnormally large cone bearing. This mandrel does away with that objection, and has, I think, one or two other advantages. The sketch, which is not to any scale, explains itself. A conical bush or collar A is fixed [illegible] the shoulder of the mandrel, then the cone pulley B goes on, and the nut C screws up and makes all firm as one piece. The pulley would scarcely want a key, and if it did, it would not have to be fitted so tight as to require driving on and off, as has to be done where there is nothing to hold the pulley endways on the mandrel. Of course this would not apply to a back-gear lathe, as then the nut would have to go next the bush A. Another advantage is that it does away with the difficulty of hardening the mandrel, as the bush is much simpler to harden, [illegible] [illegible] [illegible] to make another. Also, the mandrel can be the whole length of headstock, as there would not have to be space enough to slip it back out of the front [illegible] [illegible], as in putting the mandrel in the bush would be put in its place, the cone pulley behind, and the mandrel slipped in from the front. The bush should fit on the mandrel slightly taper, and be [illegible] to its place after hardening. But this is only a detail of fitting. Will some of our lathe correspondents please criticise? Wessex.



AMATEUR WIND INSTRUMENT MAKING.—III.

[illegible]—In my previous paper I gave the sizes of wood to be employed for making the body of the instrument. Now as these sizes are only about one-eighth of an inch too long, it would be better to have them a little longer, as the [illegible] [illegible], and glass paper usually make the hole a little too wide at the end they are entered, so if an inch more is allowed it can be cut off afterwards. Those who wish to make the instrument in five pieces, viz., mouthpiece, socket, top and bottom joint and bell, the following will be about the sizes for C clarionet, allowing a quarter inch for dressing at each end:—Barrel, 2¼in. long; top joint, 8¼in. long (this includes two male joints); bottom joint, 9½in. long, includes the male joint for bell.

It must be noted that the barrel has two sockets, the upper for the mouthpiece, the under receives the upper joint. Figs. 5 and 6 show the complete instrument and the general arrangement of keys, &c.

It will be noticed that the body is not quite parallel, and although this is a matter of taste, yet if the diameter is much altered, the distance of holes from mouthpiece will require alteration. As increased thickness of wood in the body makes the air passage larger, consequently to maintain the pitch, the holes must be placed a little higher up. The diameters of body are for C clarionet as follows:—At mouthpiece, [illegible]; middle of barrel or double socket, [illegible]; tapering down to [illegible] at the middle of the instrument, and again increasing gradually to [illegible], where it joins the bell. However, the instrument looks quite as well when made parallel, say at [illegible].

The diameters of the B-flat clarionet are the same as for the C. The joints are cut in the body thus:—A rod of iron or brass about [illegible] long and [illegible] diameter is turned up parallel to fit the bore

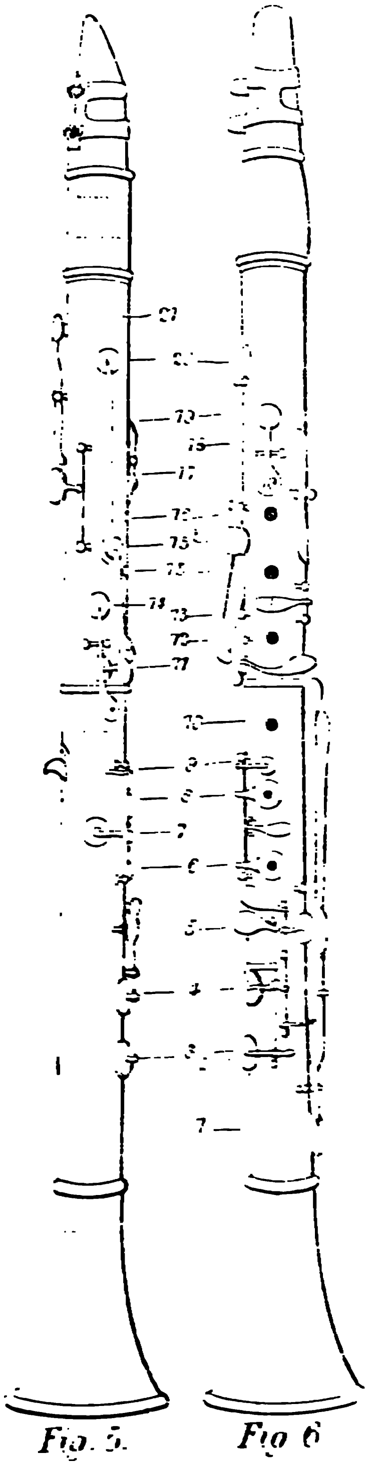


Fig. 5. Fig 6.

(14mill.) and polished: a slot is made
from one end and in this is fitted a s
secured by a screw (see Fig. 7); this all
adjusted to fit any size. The end is scr
lathe socket, and the joints are cut, the

compared to those immediately below

The reasons why holes on a clarionet
the same size, like the Boehm flute,
small holes increase the facility of exec
performer's confidence, the tones as th
the reed become more wild and un
small holes tend to steady this defect
harmonics and upper register have to b
and a hole has sometimes to perform
parts, acting sometimes as a harmoni

sounding, and occasionally ventilating those above. Now a question arises of some importance: Some holes being badly ventilated owing to those below them being closed, as it is clear that some of the sound travels past them in a straight line, they will be more or less flat even if pierced at their correct places. There are two methods to remedy this: either to pierce them higher up, or to make them wider. If a hole would be very flat, its position must be raised, but if the tone is feeble or of poor quality it will generally be found best to widen it. The lowest hole on the clarionet when open sounds F, the position of this note will be found on the 24¾in. line as measuring 47·1cent. from reed, and as the thickness of wood is 7·mill. the hole would be placed at 46·4; but as it is impracticable to make this hole larger than 12·6mill., and allowing 2·6mill. for the flattening influences of the bell, and also the key hanging over, the correct distance is 46·0cent. Now the hole marked 19 on Figs. 5 and 6 is usually about 6mill. diameter and is placed at 16·3cent., the theoretical length, on the 23¾in. scale being 18·65cent., so it is about 23·5mill. too high, which is thus accounted for; 7·mill. for thickness of wood, 8·mill. for the difference in size, 2·mill. for pad, and 6·5mill. for the influence of tube below it, and bad ventilation owing to the half-tone below it being closed—viz., the G sharp. **Vulcanite.**

SLIDE VALVES—HOW TO SET THEM.

(*Continued from page* 601, *last Vol.*)

[22158.]—I AM sorry to have been so long sending this letter, as I promised to send it the following week. I must first inform our many readers that I have been out of work for a short time, and had to knock about the country, so I have been rather unsettled.

Well, to set valves with the trammel, you require a tool like Fig. 4. A is a valve template made of two pieces of steel 2½ long, ⅝ wide, and ⅛ thick; one is bent square, as shown in sketch, and then the two are riveted; this must be exactly ⅛ thick at B. The next tool is a one-legged trammel; they are best made of sheet steel like sketch, as they are handier to handle. This will have to be made to your own length, according to the class. We will now start to set them. They have to be marked off first. Put one spindle and valve in temporarily; you then get valve template (Fig. 4), and put the piece B in port C against face. Suppose it is in back port, push valve up against the template at D; if the spindles come the cover at front, mark them there; if not at back end. You then take the trammel, put a centre dot in cylinder, and with valve up against D, mark the distance with trammel in centre on the spindle (see Fig. 5). Take template out and put it in front port, pull valve up against template D as before, and mark it off with trammel. Put a small centre in each of the scrat marks on spindle. (Mind, I am speaking of inside cylinders with valves between.) Take that spindle out and mark that off the same. Be sure and take care of centres in cylinders and on spindles. When they are marked off, you can box all up, put cover on, and buffer plank on; then get wheels under, set one side at a time, put one back and one fore-gear rod up. You can now proceed the same as with calliper, only instead of having to put your hand down port, you can see how much the valves travel by the marks on spindle. I will now tell you how to work with these marks: say, for instance, the eccentric is full throw on front centre; you take your trammel and mark the distance from centre dot in cylinder on the spindle. You then get a small pair of compasses, or spring dividers are best, open them out, and get the distance from back port centre dot on spindle to the scrat mark on spindle which you have just made. You then get a piece of tin, same as I have told you, and make a half circle; then turn wheel till eccentric comes full throw on back centre, and proceed as before. I think I have made this pretty clear. Anyone with the least knowledge about the slide-valve can go on all right. If I have made any errors I hope someone will point them out, and I will rectify them. I would advise those who have a lot of valves to set, to get into this way. Of course use is second nature; but when you get used to it you can have the wheel turned one revolution, and you can see which rod wants altering. Now to try the lead: proceed the same as I told you in my last; get crank on back and front centres; when on the centres, if the trammel when in centre dot on cylinder comes into the dot on spindle, the engine has got ⅛ lead. You will be able to find whether it is more by a little looking at. Before I draw to a close, I should like some of our correspondents to tell us how to set eccentrics on crank shafts before putting them in. **Camomile.**

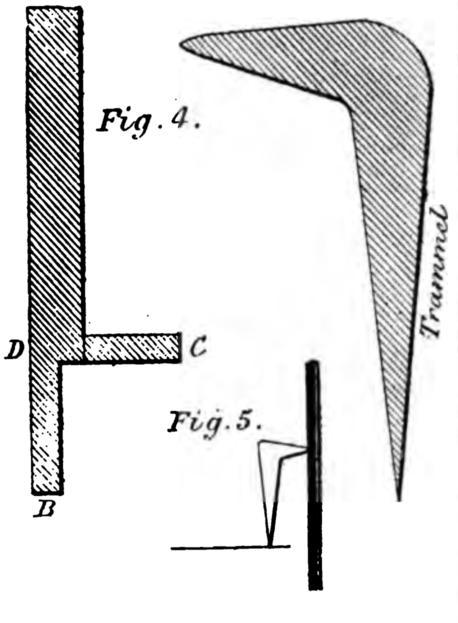

Fig. 4.
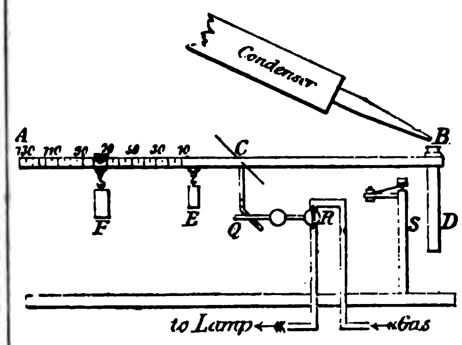
Fig. 5.

DISTILLING DEFINITE QUANTITIES OF LIQUIDS.

[22159.]—I INCLOSE you a sketch of a little contrivance which I devised some time ago for use in distilling off definite quantities of liquids, by which the lamp under the retort is automatically extinguished at the proper moment.



I do not know if the idea has any claim to originality; but it has proved so exceedingly useful in laboratory operations, that I think some of your readers might also find it of service.

A B is a beam turning on a pivot at C. The receiver D is counterpoised by means of the weight E. A sliding weight moves along the graduated portion of the beam. The beam is so graduated that 10cc. of water in the receiver just overbalances the counterpoise when the latter is placed at the figure 10 of the graduation. 20cc. in the receiver just overbalances the counterpoise when the latter is placed at the figure 20, and so on. The overbalancing of the beam releases the wire Q, which being loaded with a weight and attached to the stopcock R (supplying gas to the burner under the retort), shuts it off and stops the distillation.

The pillar S contains two wires in connection with an electric bell. When the distillate overbalances the counterpoise, the bottom of the beam presses on a feeble spring, which causes the completion of the electric circuit, so that the bell alarms simultaneously with the extinguishing of the lamp.

Anyone in the habit of conducting such operations as Wanklyn's ammonia process, in which successive portions of liquid have to be distilled off, will readily appreciate the nature of this automatic arrangement, obviating, as it does, the necessity for continual supervision.

Francis Heron.

LANTERN AND LIMELIGHT MATTERS —MICROSCOPICAL MOUNTING.

[22160.]—As I see recent letters on lantern and limelight matters are still referred to, I send a few practical remarks upon them, though I must refer to the substance of the queries from memory only.

The first query was as to the comparative optical conditions of wick'd lamps and the limelight. That is easily elucidated. If the light emanates from a *point* A in one conjugate focus of the condensers C, Fig. 1, the rays will converge (disregarding aberration) to the other conjugate focus B. It will be seen that the slide S can readily be placed in the converging cone of rays so as to take up all the light, and that a focussing lens F can also be made readily to take up all the light and transmit it to the screen. In practice the best limelight is not a point—would that it were so: my pending experiments with the microscope would then present far fewer difficulties—but it is sufficiently near it for these theoretical conditions not to depart grossly from the truth: and the consequence is, that even a *small* objective, say 1½in. diameter or less, will transmit all the light, and give a bright picture. Supposing that with any given objective part of the cone does, as the lantern may be set by chance, pass outside the lens, a little withdrawal of A from C brings the luminous cone down smaller, so as to pass through the lens.

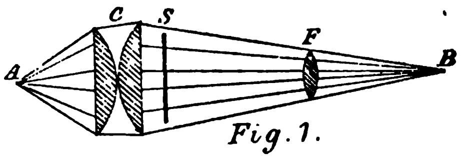


Fig. 1.

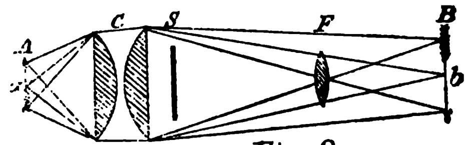

Fig. 2.

In practice this is done as follows, and I only mention what will make most lanternists smile, because it has been found that some lecturers really do *not* know about it, incredible as this may seem. Any slide is put in the stage, and focussed on the screen, without any trouble as to adjusting the light: we only want a bit of image, sharp, to be sure the objective is in its working position for that occasion. Then the slide is withdrawn, and the jet is carefully centred, and advanced or withdrawn, until the blank disc of light is centrally illuminated with an *even* and *maximum* brightness all over. The lantern is then "set" for that particular screen distance. With very long focus lenses the cone will "spread" a little, and for that very reason such lenses are better not less than 2in. diameter, though 1⅝in. will perform very well up to 10in. or 12in.

But Fig. 2 will show that with oil lamps the conditions are very much changed. The same letters refer to the same parts as before. The radiant or lamp A, now, is of considerable size relative to the diameter of the condensers, and the result is, that while any one central point *a* converges, as before, to the conjugate focus *b*, it is the same with every other point, and we get an *enlarged image* of the lamp-flame at B. Tracing the rays only from each extremity of A to the extremities of B, it will be seen how the effect of this is greatly to "spread" or scatter the cone of rays from the condensers. It begins to spread even at the position of the slide S, and by the time it has reached the objective F, no lens of reasonable size can include it all.

In practice these evils are met in three ways. 1. The best form of condenser for the limelight—the Herschel—is superseded by the double-plano form, which allows the slide to be brought *close* to the condensers, and so nearly avoids scattering of the light outside the slide itself. 2. The great breadth of the wicks practically *withdraws* a portion of the light A back from C, and so increases the convergence of the cone. 3, and chiefly. It is *necessary* to use larger objectives. Less than 2in. will not give nearly the best results with these lamps, and 2¼in. will give appreciably better. It will also be understood why these lanterns work best with condensers of a little longer focus.

A good 4-wick lamp like the Pamphengos will show a good bright picture on a 12ft. disc, with a 2in. lens; with a 1⅝in. lens the edge will be a little dim. On the other hand, none of these lamps can, from the nature of the case, give such sharp *definition* as the limelight. There are transmitted through the slide all sorts of crossing rays; and these must, and do, slightly blur the image; but on most slides this effect is not very observable, and chiefly comes out in hymns and sharp line diagrams.

A word further on condensers. I am surprised to see opticians go on repeating the old style by rule of thumb, making the lens next the light the same size as the other. Whichever make be adopted, this is wrong, as the light sent through the margin of the first lens passes outside the other. For a 4in. lens next the slide, 3½in. is sufficient next the light. This not only allows of thinner glass, but of somewhat *shorter radii* in the curves, either meniscus or plano, and even a little difference in this respect materially *lessens the aberrations*. I am quite certain that any optician who adopts this simple modification will find the result improved perceptibly, whether he employs the Herschel or plano form.

Now as to lime-jets. Several seem to wish both gases mixed in one bag, and speak of the "increased light." I do not believe there would be any increased light, to begin with: it is quite certain—and I make the statement most advisedly—that skilful modern operators get *more light* than was done in the old days. And if there were a little advantage, the danger would be ever present. The "safety" packing of lengths of wire described by one correspondent—Hemming's form—has repeatedly been known to explode. A more safe form was Gurney's, in which the gas was passed through *water* before being burnt; but explosion has taken place even in spite of that. I believe the safest packing would be Mr. W. Broughton's admirable granulated pumice-stone; but why run the risk? It is true that no explosion can take place *while pressure is kept up;* no packing at all is needed with that proviso. But weights may slide off at any time, and there is an appalling amount of risk from sheer mischief, as all who have shown to juvenile audiences well know. No; what we must look for is, some day to get compressed gases in bottles *cheap.* Whenever that comes to pass, as an experienced lanternist said to me the other day, our difficulties will be over; for we can then use a pair of *very small* bags with the *bottles for weights,* and thus keep all compact, and the pressure uniform. I do think we ought to be able to get oxygen at 3d. per foot. At that price there would be an amazing trade in large cities, and I fancy it would pay; as for 8ft. there would be 2s. received, while the chemicals cost 1s. 3d. only.

For several years I have been trying to persuade almost every optician I met with to bring out a jet, which should *raise the lime* the proper distance whilst revolving, so that the operator might just turn his lime steadily on through the whole evening. This was a want I had felt constantly, as others must have done. Last December Mr. Place, of Birmingham, told me he would, if he could find time, "have a try" for next (this) season, and I am glad to say he has lately sent me a jet which answers the requirement exactly, turning the lime in a continuous spiral, which rises $\frac{3}{8}$in. at each revolution, and gives 9in. of unbroken lime travel. It is also about the cheapest mixed jet in the market, costing only 18s. 6d. with cog gearing. The only drawback it has—with some lanterns only—is, that the lime-pin when down projects an inch below the jet; but I have been thankful to cut my lantern to allow of this. The only further improvement possible would be a screw adjustment, to approach or withdraw the lime while *on the screen,* so as to get the maximum of light, and this can be added for those who desire it. I have so long felt the want of a lime-movement of this kind, naming it in these columns long since, that I hope to be excused mentioning the matter now the want is supplied.

With any good jet, it is advisable to have an extra nozzle of different bore. More aperture is needed for a 20-ft. disc than for 14ft. Such extra nipples can be had for about 1s. 3d. each. And the operator will find it worth while to spend a little time and trouble over his own nozzles, seeing that they are perfectly smooth and true inside, and brought down to nearly a knife-edge outside; all clumsy nipples mean *shadow* on the condensers. One thing more: the brightest part of the lime extends from about $\frac{1}{32}$ *below* the nozzle to $\frac{1}{4}$in. above it. By *tipping forward* the whole jet and lime about 15 degrees, the nozzle is kept more out of the way, more of the brightest radiance bears on the condensers, and the light is increased nearly 10 per cent. For some purposes this expedient is well worth the ugliness it gives to the jet. A "tip" of more than 15° may increase the light a little more, but there is danger to the condensers.

Before laying down the pen, may I mention one or two matters *in re* "microscopic mounting." 1. To me, all *corked* bottles are very disagreeable and dirty for balsam work, and all who try them will soon prefer the wide-mouthed bottles, with ground external hollow caps, made for the express purpose, and which cost 1s. 3d. each. Failing these, the better gum-bottles with ground caps, or an ether-bottle or spirit lamp with the cap only, are nicer than corked bottles; but the wide-mouthed capped bottles are best. 2. In my opinion balsam in benzol is for almost every purpose far better than in chloroform. The unpleasant smell spoken of is unknown if really good benzol is procured, and preparers are not half particular enough about this. I have bought solution at a first-class shop (Beck's), which was useless, and smelt abominably; but what I use largely for mica work is quite free from objection on this score. I have found slides (purchased and others) prepared with chloroform particularly liable to disintegrate and show a multitude of spots, which I never knew with benzol. Moreover, chloroform evaporates almost too rapidly for any subject that needs time, while benzol is more moderate in this respect. 3. How is it that it is now almost impossible to procure insect preparations—such as the proboscis of a blow-fly—mounted in a really *first-class* manner? I have looked over many, and have one (given me by a friend) mounted *by the late* Mr. Topping, which is better than most, *and the best one I can get: but a* first-class one, such as I want, I can get *nowhere, at any price.* Go to a shop, and you can have your choice; but if they are showing you a lens, they will use one as a test, which you will find you *cannot buy.* At least, that is my experience, and I know one maker who is prepared to pay 5s. each for this particular preparation, prepared up to his standard, which is simply old Mr. Topping's *best* half of those he made. All that can be got now have far too much brown matter left in them; and in projecting a tongue with the lantern 6ft. long (a task I am now engaged upon, with, I am happy to say, very fair success so far), clearness and transparency are of great importance, the screen magnification representing 500 to 600 diameters. Still more important is it when showing parts of the organ on double that scale; it can easily be done with a good one, but scarcely at all with the trash usually sold now. To show I am not alone in this opinion, let me quote a few lines received this very morning from one of the first micro-photographers in the kingdom. He writes: "I shall be glad to hear how you get on with the fly's foot. Did you ever see a really good *transparent* mount of this object? I want one specially for photography, and have never succeeded in purchasing or borrowing one to my satisfaction." I am not sure if this correspondent really meant "foot" or "tongue," as I had only named the latter to him; but it comes to the same thing. Now and then I have seen one or another preparation by old Mr. Topping which were magnificent; but his art seems lost. Probably it is the multiplication of microscopes, and the demand for plenty as matter of trade. Still, it seems a pity that when a really good specimen, after the old style, is wanted, it cannot be got even by paying more for it. Would it not be worth while for some mounter to make—say at 2s. 6d. each—a few equal to what Mr. Topping used to sell to the trade for 8s. per dozen?

Dec. 14. **Lewis Wright.**

A SUGGESTION.

[22161.]—IT may, perhaps, be considered an error to place the cart before the horse, but I think the best place for the horse will be found inside the cart; and that he may use his strength in propelling instead of drawing the vehicle, is, I believe, the best way to utilise the power.

When we consider the great distance men are able to propel themselves on the tricycle, and the comparative ease with which their long journeys are performed, we may feel certain that the horse will be equally assisted by being placed in similar circumstances. A moving platform for him to drive backward as he pushes his neck into a fixed collar, may be connected with the wheels, and drive the whole like the tricycle.

Could not the wheels of bicycles, tricycles, and other carriages be made with tires of flat steel hoop, so as for them to bind on the ground, having all the weight suspended by the upper part of the wheel by the wires connecting the hub and tire, and making a spring to support the whole: and may not a very light and cheap vehicle be made by using one larger wheel between the shaft, like a wheelbarrow, when drawn instead of being propelled, and the shaft, being fixed to the saddle on the horse's back, would be held firmly, just as a man holds a wheelbarrow when drawing it, and the seat being placed on the level of the shaft, the centre of gravity will be so low as to cause little strain on the shaft at any time.

I believe a good-sized bicycle may be readily made into a gig of this sort by getting two pieces of $\frac{3}{8}$in. iron rod, each a foot long bent at a right angle, 6in. from one end, and then that bent piece again bent to go through the opening in the crank, where the pedal has been fixed, and screwed firmly into and against the crank, just as the pedal is fixed, so as to make a continuance of the axle 7in. outside the crank, and the space between the crank being 10in., the axle will be 2ft. long.

A frame of 2in. square deal 10ft. long and 20in. apart, having a crossbar mortised into it just as far from the end as to be before the wheel when the axle was 3in. from the ends, and having another cross-bar just so far before it as for the seat to be between them, and on a level with the axle, and the legs of the driver to be between them and the ground. The ends of the frame forming the shafts of the gig may then be fixed to the horse so firmly as to prevent either from rising or falling, and the rider will be safe from accidents if the horse is steady. **Philip Vallance.**

PARAFFIN AS AN INSULATOR.

[22162.]—A REMARK in the letter of Mr. B. Harcourt, on p. 325, that tissue paper cracked and broke after paraffining, suggests a suspicion that he has not been using paraffin, but some compound in which stearin formed the principal ingredient. Pure paraffin at any ordinary temperature has never cracked under my hands, though it might possibly become brittle at minus something or other of Fahrenheit's thermometer. Tissue paper, too, is not the right stuff; it should be what is called bank post, a very thin, but strong paper. The paraffin can be ironed in as "Os" says, but for some purposes it is better to soak the sheets in a bath of melted paraffin, and for others to dissolve the wax in benzoline—that will go almost anywhere, and evaporating leave the paraffin behind. At one time it was tolerably safe to buy a paraffin candle; but nowadays the wax itself must be asked for when paraffin is wanted. **Nun. Dor.**

TRICYCLES—APPARATUS IN AID OF HILL CLIMBING—A SUGGESTION.

[22163.]—IT would, of course, be a most desirable achievement if there were produced a sufficsently light apparatus which should form part of a trcycle, and be capable of its own force of either propelling the machine uphill or materially aiding the rider when making a steep ascent. Subject to the consideration of weight, there is no doubt whatever that such a desideratum could be accomplished by the proper adaptation to the tricycle's axle or otherwise of a powerful spring coil, which upon being wound up by suitable appliances, and being kept wound up in reserve for the occasion requiring its aid, should upon being released so act that its uncoiling would cause the driving wheels to revolve. Some time ago, a successful attempt was made to obtain a motive power of that description with the ultimate view to the propulsion of tramcars thereby. Large and powerful spring coils of a very tough material were made for the purpose, and they were to be wound up by stationary steam power at intervals along the route to be traversed by the tram-car. Successful preliminary trials of the spring coils were said to have been made in their application to some railway trucks; but as nothing more appears to have been heard of the matter it would seem probable the invention was not further prosecuted. The idea, however, in connection with tricycles seems sufficiently feasible if only some enterprising machinist would turn it to account. If it should add some 20lb. or 30lb. to the weight of a tricycle, the addition would be of little consequence, provided it relieved the driver when ascending steep gradients, for the propulsion of a tricycle along the level or up a slight incline needs but little labour. Supposing the apparatus could not be so applied that it should be wound up by the revolution of the machine's axle when going downhill; and even if it involved the necessity of its being wound up by the rider at the foot of every steep ascent, yet would the saving in muscle and backbone power on the rider's part be considerable. Irrespective of the level at which a tricyclist over ordinary roads in a country not mountainous begins and ends a journey, it may be taken that the total of his ascents upon that journey will, in vertical measurement, be exactly equal to the total of his descents; so that if he travels, say, 40 miles in a day, then 20 miles of the distance will be performed uphill and 20 down. As the downhill part of the journey needs but little exertion, it is plain that a very large proportion of the tricyclist's labour up those 20 miles of ascent would be saved if only some apparatus were devised that should afford material aid in propelling the machine uphill.

R. M. B.

TRICYCLES.

[22164.]—So much has been written on differing tricycles in "ours," especially on the subject of front and rear steering, that a little quite impartial criticism from experience may be useful. Up to last summer, I had generally ridden a rear-steering single driver, principally round London, and found it very satisfactory for speed, but very liable to sudden upsets, or narrow escapes if using the brake or back-pedalling suddenly. In either of these cases the momentum of the body will often cause the rear wheel to lift slightly, when away goes all steering power; and if there is any strain on the chain at the moment, either forward or backward, a sudden twist round and upset is the result. Even *relieving* the pressure on the back wheel, which *must* occur every time back pedalling is applied, is liable to cause unsteadiness. With such machines you must have a double brake, and when applying same suddenly, be careful not to back-pedal at the same time. In fact, they are not at all safe in case of a hurried (and flurried) stop being necessary. They are also very bad on slippery roads, especially up-hill, as they tend to twist round constantly. These defects made me resolve to adopt a double driver of some sort, and as the few trials I had had on the Cheylesmore had made me think I could never feel at home on a free pedal, I selected a front-steerer when three weeks' holiday gave me an opportunity of doing a little touring. I had one of the very best machines made, and expected to enjoy it hugely. I can only say I was disappointed. For shooting hills it was certainly splendid, but I found it bad at uphill work, and on the level could not get anything like my accustomed speed out of it; in fact, I could not keep up with my brother, riding the Cheylesmore I had despised. Of course, my machine was geared rather low—front-steerer [illegible] for 140 Miles.—To Mr. [illegible] a difficulty in working [illegible] but you may overcome [illegible] combined with others. As to [illegible] transmitter, you can use [illegible] spark coils, removing condenser and everything else really besides the bobbin [illegible] primary, and secondary wires. I would [illegible] to the platinum foil or sheet [illegible]. You can never entirely depend upon the latter.—W. J. LANCASTER.

[illegible]—**Diaphragms.**—To MR. LANCASTER.—When you have made the diaphragms, then well paper them with emery paper, and bronze them with a solution of nitrate of silver—say, 1drm. of silver and 2oz. of water; distilled water if you can get it—if not, clear rainwater. Hold the diaphragm with a wire hook, and heat it in a Bunsen flame or on a lacquering stove; then dip it into the bronzing liquid, take out when black, and cover it with powdered blacklead. This you can polish with a blacklead brush when nearly dry, and afterwards lacquer the diaphragms with a colourless lacquer.—W. J. LANCASTER.

[51907.]—**Turbine.**—To MR. LANCASTER.—I have no idea what such a turbine would cost, but I should not advise the use of a turbine unless you can get at least twice the power required by the dynamo when giving its full energy. If you will tell me what you want to do, I will tell you the best way to do it.—W. J. LANCASTER.

[51918.]—**Eyepiece.**—You may use the following lenses, beginning with eye lens and going to field lens of erector:—(*a*) Eye lens ¾in. diameter, 1½in. focus; (*b*) 1½in. diameter, 2½in. focus, 2in. apart; (*c*) ¾in. diameter, crossed convex, 2½in. focus, most convex surface towards eyepiece; (*d*) 1in. diameter, 2¼in. focus, plane side towards o.g. *a*, *b*, and *d* are all plano-convex; (*a*, *b*) should be 3in. from (*c*, *d*)—that is, really there should be 3in. between *b* and *c*. This distance may be lengthened to 5in. by mounting *a* and *b* in a tube which slides into tube containing *c* and *d*. You must have a diaphragm in eyepiece ⅝in. diameter, 1½in. from eye lens, and another diaphragm in erector ⅛in. diameter, 2¼in. from field lens of erector. Write again if you want further information.—W. J. LANCASTER.

[51953.]—**Electro - Motor.**—The amount of wire for the motor you mention would make a fair working instrument, but you would gain by using 18 wire for the armature instead of 16. Four of the cells you name would drive the motor well; six of them would give maximum power. It ought to drive a dentist's lathe easily, and of course would drive a sewing machine. The zincs of the bichromate batteries should be thicker at the bottom than the top, taper from bottom upwards.—W. J. LANCASTER.

[519[illegible].]—**Wasps' and Bees' Stings.**—I am not capable of giving to "F. G. A." any scientific disquisition upon "stings," but seeing that no one has replied to the query, I am able to assert that the irritation caused by the bite (or sting) of a flea (? sharp) is allayed by the application of a cold, damp cloth or sponge for a couple of minutes, just as the sting from a nettle is cooled off by the use of a few cold docken leaves. I hope this hint will be remembered by those who have the care of little children, to some of whom a flea-bite gives actual torture.—H. G. B.

[[illegible]]—**Oxy Hydrogen Microscope.**—To MR. LANCASTER.—I would advise you to do away with present form of jet and have a modern [illegible] jet with a platinum nozzle. Do not attempt to [illegible] gases in one bag or you will [illegible] the pages of "Ours." [illegible] and use two bags, [illegible] or say a little [illegible] the ratio of 2H. to 1 [illegible]. [illegible] I have no doubt [illegible] of a pair of [illegible] the pair [illegible] the light [illegible] W. J. LANCASTER.

[[illegible]]—To MR. LANCASTER.—[illegible]

[illegible] Medical Coil.—Build one [illegible] independent of

the primary. The latter should be built on a tube of either brown paper or thin ebonite; this should be fastened firmly to the two discs at each end. The brass tube should slide out smoothly.—W. J. LANCASTER.

[52043.]—**Limelight for the Lantern.**—You cannot do what you want without a train of wheels, and then there is the annoyance of the clogging of the wheels with lime dust. Better use the two bevel wheels with a nut outside for turning, and turn, say, one-fourth round every ten minutes. I have tried all kinds of motion for moving limes, but a pair of bevel wheels and the lime holder screwed is the best thing you can have.—W. J. LANCASTER.

[52103.]—**Engine.**—I have read the letter of "Engineer, Dewsbury," on p. 324, and can now reply to his question on p. 287. A greater theoretical power can always be obtained from a compound than from a single cylinder engine, all other things being equal. Steam engines are heat engines, and one is more economical than another in the proportion of heat-units passed through it without loss, as has been explained over and over again in this paper. I need not repeat, for on p. 329, reply 52393, by "Labor Omnia Vincit," he will find where he has lost himself.—ESSAR.

[52131.]—**Boiler Query.**—No doubt, as "Essar" says, "if you fill a boiler with water, as much as it will hold, and load the valve to four times what you would like to work at, and then light the fire, and if the valve lifts without the boiler showing signs of strain or leak, you may safely work at one-fourth the pressure indicated by the weight on the valve." But is it not possible that this would strain the boiler severely—in fact, make it weaker after the testing than it was before, and so tend to wear it out in a much shorter time than usual?—MACHINA.

[52165.]—**Slide-Rule Formulæ.**—On p. 269 of 974, Mr. F. A. Sheppard having made free use of your "Replies" columns of correspondents for decrying "all published works upon the slide rule" because of their being "overladen with gauge points" which he states have been the chief cause of the slide rule not getting into more general use, and the host of which gauge points he says "his improved double slide-rule for cubing quantities does away with, except in the most abstruse cases, which seldom occur." As I am the author of one of the maligned works, I take the liberty of challenging the soundness of Mr. Sheppard's conclusions, and of questioning the utility of his instruments and system of working. For the term "gauge point" meaning simply the multiplier or divisor number for converting money, weight, or measure, &c., of one denomination into another, 12 being the gauge point for shillings and pence or feet and inches, 112 for cwt. and lb., 144 for square feet and square inches, ·7854 for square and circular areas, 183·3 for square feet and circular inches, &c., inasmuch as the memory of any computor would have to be heavily taxed to keep in mind the gauge points relating to even the system of English weights and measures alone, so writers on arithmetic and on slide-rule calculations have generally provided such authentic tables of gauge points as they thought most likely to be useful for general calculations, and, taken for granted that computers would get off "by rote," such as were likely to be often wanted. And as for the example given by Mr. Sheppard, viz., to find the diameter of a pump for discharging 30 cubic feet of water per minute with effective lift of bucket equal 120 lineal feet in same time, his duodecimal rule is not adapted, and by his decimal rule and system of working he says: "As this question involves two operations we must prepare the rule by turning the upper slide so as to bring the line of square roots under the line of lengths," and then, 1st, place 30 on lower slide over 120 on lower fixed line to find 36 square inches area of pump over 144 on lower fixed line, and 2ndly, place 1 on lower slide over ·7854 on lower fixed line to find 45·57 for the inches squared of pump's diameter on lower slide over 36 on the lower fixed line; then, 3rdly, having placed the line of square roots exactly under the upper line of lengths, the diameter 6·75 inches of pump being on same square root line under the 45·57 on upper fixed line." As in conclusion Mr. Sheppard says, "Thus solving the question without the use of any gauge points, that is, by common arithmetic instead of by slide-rule arithmetic," it would be interesting to many of your readers to know, what but gaugepoints are the 144, ·7854 used by him in his calculation; and to compare his system of working with that usually applied to the solution of same question on even the single slide rule of Routledge by using the gauge point 183, when merely by

setting 120 on slide $\frac{B}{C}$ opposite 183 on A,

opposite 30 on do. $\frac{B}{C}$ is the ans. 6·76in. diam. of

pump on A, at a glance from a single setting. And, again, as according to Sheppard's circular, he says, respecting his "duodecimal rule," "If the question involves a greater cube quantity than 100ft., then one dimension must be halved, or otherwise divided, and the result similarly multiplied," whereas by the triple radius double slide-rule made by Stanley (which arrangement was in general use years before Sheppard), is adapted for cubing quantities to any extent, and for solving questions of simple and double rule-of-three, interest, involution, evolution, common and hyperbolic logarithms, trigonometry, and such questions as—

$$\sqrt{\frac{8{\cdot}5^3 \times 39 \times 66}{73 \times 97}} = 14{\cdot}95 \text{ very nearly.}$$

Or—

$$\sqrt[3]{\frac{9{\cdot}7^2 \times 59 \times 36}{91 \times 31}} = 4{\cdot}14 \text{ very nearly.}$$

at a single settling, and leave all the positions and results open for inspection at last; and a single rule suffices for all calculations made on the decimal system. I leave your readers to judge of the utility of the instruments thus brought to their notice, and the systems of working without and with tables of gauge points.—THOMAS DIXON.

[52166.]—**Engine Power.**—I think that if "Gossan" will look again at my answer to the above query, he will see that I am right. Let me remind "Gossan" that all calculations upon expansions must be reckoned from pure vacuum line, or 15lb. below atmosphere. In my calculation to the above query I took the engine to be a condensing one, with a back pressure of 3lb. in condenser. Then 50lb. boiler pressure and 15lb. atmosphere = 65lb., and 65lb. initial gross pressure upon piston, cut-off at half stroke; so if we divide the length of stroke by the point of cut-off, we shall get the number of expansions in the cylinder; or, 16 ÷ 8 = 2 expansions, and the hyperbolic log. of 2 expansions is ·693 + 1 = 1·693: then multiply 32·4 terminal by 1·693 = 55lb. But as the engine is a non-condensing one, instead of deducting 3lb. in condenser as back-pressure, deduct 15lb. for resistance of atmosphere, 55 − 15 = 40lb. effective average pressure throughout the stroke; the horse-power will be 143·139 × 192 × 40 ÷ 33000 = 33·3 horse-power. I think this will be sufficient to show how "Firer" got a greater average on piston than that stated in boiler.—FIRER, Dewsbury.

[52177.]—**Outer Walls of Houses.**—This querist should procure the Building Act, for the thicknesses vary with the length as well as the height of the walls. For length up to 30ft. and not more than 25ft. high, the party and external walls must be—footings 17in., remainder not less than 8½in.; if longer than 30ft., then footings 26in., 13in. below topmost story, and 8½in. for topmost story. For a house of three stories above basement, not more than 40ft. high and wall not longer than 35ft., footings 26in., below two topmost stories 13in., two topmost stories 8½in. If wall is longer than 35ft., then 35in. footings, 17½in. up to first story, intermediate 13in., and topmost story 8½in. If "Leo" requires further particulars I would refer him to the Act, or to B. Fletcher's "Textbook," published by Batsford, High Holborn.—S. R.

[52180.]—**Electro-Magnets.**—This query cannot be answered fully without making the experiment. You can excite a number of magnets in series, but it is doubtful whether they would all sustain the same weight. It would require very nice calculations to get the resistances, &c., so exact as to make the magnet at the negative or outgoing end the same strength as the positive, or end at which the current entered. I don't see how you could regulate the pull by current from an accumulator.—E. M. F.

[52181.]—**Balance Gear of Omnicycle.**—Seems strange that you cannot make out the gear with it before you. Is it not what is known as Starley's? which has been frequently described.—E. G. M.

[52199.]—**Ornamental Flower-pots.**—Has not "M. W. S." made some mistake? What sort of pots does he mean that they are moulded? The usual run of flowerpots (ornamental) are thrown on the wheel.—HANLEY.

[52201.]—**Discharging Water from Tanks.**—Is it impossible to arrange the tanks so that their levels could be altered as desired, and the water run from one to the other by gravity or by a siphon? If the levels cannot be alternately changed, best way would be to put one tank higher than the other, and then pump the water from the lower when wanted in the upper.—ESSAR.

[52259.]—**Acoustics.**—By the "pressure of steam" I presume is intended "pressure of hydrogen gas." There is also an important datum absent—viz., the density of mercury, which may be taken at 13·6. The fundamental formula for the velocity of sound in any medium is

$$v = \sqrt{\frac{e}{d}}$$

Where v is the velocity of sound, e the elasticity of the medium, and d the density, all measured in absolute units. The elasticity of the perfect gas, that is a gas perfectly obeying Boyle's law, is equal to the pressure if the gas is a perfect conductor of heat, or is equal to the pressure multiplied by 1·4, the ratio of the two specific heats, if heat cannot pass from one molecule to another in any way. In the case of the transmission of sound, the successive heating and cooling due to respective condensations and rarefactions take place so rapidly that the heat has no time to sensibly pass from one molecule to another, and we have the latter condition fulfilled. Therefore—

$$e = \text{height of barometer} \times \text{density of mercury} \times 981 \times 1{\cdot}41$$
$$= 73 \times 13{\cdot}6 \times 981 \times 1{\cdot}41$$

and—

$$d = {\cdot}000089 \times \tfrac{73}{76} \times \tfrac{273}{293}$$

the factor $\frac{73}{76}$ being that due to the law of Boyle and $\frac{273}{293}$ that due to the law of Charles. Dividing e by d, and observing that the number 73 cancels out, thereby indicating that the pressure makes no difference in the result, and taking the square root, we get—

$$v = 131304$$

which is 1313·04 metres or 4307·94ft. per second. The second part of this question can only be answered approximately. If t denotes the tension to which the string is subjected, and m its mass per unit of length, the number of vibrations executed in a second varies as the fraction $\sqrt{\frac{t}{m}}$. Let l and l' be the lengths of the string, best determined by experiment, when subjected to stretching forces F_1 and F_2 respectively. Then t is equal to F_1 in the first case and F_2 in the second. Also since $m\,l = m^1\,l^1$, we have $m^1 = \frac{m\,l}{l^1}$, and we obtain for the ratio of the number of vibrations in the first case to that in the second—

$$\sqrt{\frac{F_1 l}{F_2 l^1}}$$

If F_1 and F_2 do not differ much, we may assume the formula—

$$l_1 = l + cF_1$$

or the length of the string when subject to a tension is equal to its original length added to the product of a constant c and the tension F_1.—Nabla.

[52269.—**Acoustics.**—(1) The velocity of sound in any medium is given by the equation—

$$v = \sqrt{\frac{e}{d}}.$$

Where v is the velocity of sound, e the elasticity, and d the density of the medium In the case of a perfect gas, that is, a gas strictly obeying Boyle's law (and hydrogen does so sensibly) the elasticity is numerically equal to the pressure, as long as the temperature remains constant throughout the gas; but in the case of a gas subject to rapid alternations of compression and rarefaction, whereby heat is as rapidly evolved and absorbed at every point without having time to pass sensibly from one particle to another, the elasticity is represented by the product of the pressure and the number 1·41, the ratio of the two specific heats. In the case before us the pressure is equal to the product of the height of the mercury barometer, the specific gravity of mercury (13·6), and the acceleration due to gravity; hence,

$$e = 73 \times 13{\cdot}6 \times 981 \times 1{\cdot}41$$

and

$$d = {\cdot}000089 \times \frac{73}{76} \times \frac{273}{293}$$

the factor $\frac{73}{76}$ being the correction for pressure according to the law of Boyle, and $\frac{273}{293}$ that for temperature by the law of Charles. Dividing e by d, and taking the square root, preferably by logarithms, we get,

$$v = 131304 \text{ c.m.}$$

Or, $$v = 4307{\cdot}94 \text{ feet.}$$

It will be observed that before multiplying out the common factor 73 cancels. We might have expected this, since the velocity of sound in a gas does not depend upon the pressure. (2) The number of vibrations per second executed by a stretched string varies as the expression $\sqrt{\frac{t}{m}}$, where t is the tension, and m the mass per unit of length. Hence we must take into consideration the change in dimension of the string. If l be the original length and a be the increase in length produced by a force of one unit, then as long as F_1 and F_2 are not very great, the lengths of the string in the first and second cases will be $F_1 a + l$ and $F_2 a + l$, and the ratio of the mass of unit length in the first case to that in the second is $\frac{F_2 a + l}{F_1 a + l}$, and consequently we have for the ratio of the numbers of vibrations per second—

$$\sqrt{\frac{F_1\,(F_1 a + l)}{F_2\,(F_2 a + l)}}$$

It is thus seen that an increase in tension raises the number of vibrations in two ways; by increasing the tension and by diminishing the mass of the unit length.—Nabla.

[52271.]—**Lever Watch.**—I had formed two opinions myself as to the probable cause of the stopping of the lever watch, but have deferred sending a reply, in expectation that the important question of "Vulcan," would have received the consideration it deserved. In this I was rather disappointed. The single reply that appeared in the next issue was exception to by J. Sumner, who states that his experience of hundreds of cases is dead against its validity; at the same time, giving it as his opinion that the fault was to be found in the undue largeness of the balance holes. Having myself a great deal of experience in watch jobbing, I must say that I do not consider the reply of J. Sumner to be at all satisfactory, for it would be difficult to reconcile such an explanation with the fact that the watch is affected in different positions. It is the case, no doubt, that the guard-pin approaches unpleasantly near the roller, and for this reason I would consider that a steel guard-pin, not being so easily bent, would be more suitable than one of brass. The opinion I would offer myself, as the most reasonable one, is simply that the lever is "out of poise," so that in certain positions the balance is encumbered by having to overcome the excess of poise at every alternate vibration. When the lever is thus unevenly balanced on its pivots—as I have found it to be not unfrequently—the watch is still more liable to be stopped by any sudden shock or jerk it may receive, till perhaps some time afterwards another jerk may put it going again. With this defect the lever watch is liable to deceive, but when properly finished it excels all other kinds, even the chronometer, in being able to endure shaking and jolting without effect. In the present age of railway travelling, of course, such an advantage is of great account, and, therefore, it is that railway watches are fitted with the lever escapement. The next opinion I have to offer is, that perhaps the fault lies in the fusee getting bound in one of its holes when the watch is held in a certain position. My experience induces me to advise workers to make the fusee very free in its holes, if they are anxious that their watches should not stop, and not to be in favour of an exact fit, it being always attended with some degree of compression. The fusee should have perceptible end-shake and side-shake in its holes, because, on account of the great strain with which it is pulled round by the chain, it requires more freedom of movement than if it were turned like the other wheels of the train.—Watch Jobber.

[52281.]—**Boiling Silver Articles, &c.**—Better make them red hot with the blowpipe, and then boil them in sulphuric acid 1 part and water 8 parts, in a copper or stoneware vessel. Parts of jewellery, such as swivels, &c., containing a spring, should be first removed, or the spring will be spoilt. After boiling, scratch brush them.—J. E. A.

[52281.]—**Boiling Frosted and Chased Silver Articles to Whiten Them.**—You should boil solution of cyanide of potassium in an earthenware pipkin or enamelled iron saucepan, rinse silver in clean hot water, and dry in sawdust; keep the articles away from soapy water. Try this: Boil some water and dissolve some sal-enixon in it; then make the articles scalding hot and dip them in the hot solution of sal-enixon (crude sulphate of potash). I do not know the proportions, but I saw a jeweller cleaning frosted silver in this way, and he got splendid results.—Galvanoplast.

[52281.]—**Boiling Frosted and Chased Silver Articles to Whiten Them.**—To H. J. Sayer.—A tin saucepan, or inferior silver, may be the cause of failure. After cleaning the chain, boil well for five minutes in a jeweller's boiling-pan. There is another way. Heat the articles in the copper pan referred to, and drop into dilute sulphuric acid. I have used both processes successfully, but with sterling silver. I may add silver chains and necklets are made and sold at 2s. 6d. per ounce, and electro-plated to give them a finish. Seeing that unmanufactured sterling silver is worth about 5s. per ounce, I do not know whether so low a quality would "bleach" to look well. If "Young Jeweller" has any further difficulty, and will advertise his address, I shall be pleased to assist him.

[52284.]—**Telescopic Field of View.**—My thanks to "F.R.A.S." for his replies to my queries on page 273. To save space, I curtailed query 52284, p. 273, too much. I did not mean to ask method of finding diameter of field of an existing telescope, as I am well enough acquainted with that. (Arthur Mee, please notice.) I wanted merely to know (with regard to having a telescope made) what data would determine size of field? Delambre's formula, given by "F.R.A.S.," tells this.—E. M. R.

[52285.]—**Focal Adjustment of Astronomical Transits.**—Inasmuch as the astronomical transit has its system of wires fixed in the stellar focus, how is one supposed to adjust on a meridian mark 30 or 40 yards off? Distinct vision may be got by sliding eyepiece, but the wires won't be in focus. Query.—Would contracting the aperture of object-glass by a stop be of any use in getting rid of parallax of wires?—E. M. R.

[52297.]—**G.E.R. Engines.** — Another new goods engine (like 440) was built at Darlington this year, and numbered 497, I am told the cylinders of both these engines are 17 by 24, and wheels 5ft. Mr. McDonnell is altering the chimneys of the N.E.R. engines to a pattern somewhat after the Midland style. They are also to be painted an olive brown, with yellow and red lines. If not so "showy," they look handsomer than they used to.—Meteor.

[52298.]—**Bunsen Battery.**—I notice in his directions for making a bichromate battery "Electrician" states that the sulphuric acid should be placed in the cell with the carbon, and the bichromate with the zinc. It may be due to my ignorance, but I certainly fail to see the use of this combination. The bichromate is only used to prevent polarisation by oxidising the hydrogen, which being formed at the zinc is evolved at the carbon plate, and which, unless it is removed, would affect the strength of the current. Firstly, by the increased resistance, as bubbles of gas are bad conductors; secondly, because it sets up an opposite electromotive force, for hydrogen is almost as oxidisable as zinc, and would tend to produce a difference of potential which would start a current in the opposite direction to the true current, and so partially neutralise it. The reason bichromate is not placed in the cell with the zinc is because it attacks it so violently that the plate is very soon eaten away; therefore, in order to obviate this, it is separated from the zinc by a porous cell in which it is placed, together with the carbon, while the zinc is immersed in dilute sulphuric acid. Of course, the bichromate may be placed in the outer cell, but in that case the zinc and acid are in the porous pot. Sulphuric acid has no action on carbon, and cannot oxidise the hydrogen, which oxidation would be effected in its passage through the bichromate. Therefore, it stands to reason that the acid fulfils no useful purpose whatever, and can be dispensed with if used in the manner that "Electrician" proposes. In that case, you might just as well do without the porous cell, and place both plates in the same bichromate solution. Of course, you would have to remove your zinc plates when not in use; but you would have to do the same thing if you made use of the plan as proposed by "Electrician." What you had better do is as follows: I have had batteries in constant use for months for lighting purposes, and can speak from experience. Make a solution of bichromate of potash of the required strength, add to it sufficient strong sulphuric acid to combine with the potash, forming sulphate of potash and free chromic acid, which is a very powerful oxidising substance (or you can use it in the first instance, and in that case you would not follow the latter part of the instructions). Next make a solution of sulphuric acid, and, when cold, add sufficient sulphate of soda until a hydrometer shows it to be of the same specific gravity as the bichromate. Then in a large porous cell place the acid and zinc, and in the other the carbon and bichromate. If this is done properly, you will find that very little bichromate will transfuse. For incandescent lighting, you must couple the cells for quantity—of course, having due regard for the electromotive force required. Two cells, made somewhat in this manner, have lighted two 5-candle lamps for some time without recharging. With respect to Fuller's cell, the only one I know is that which is used in the Post Office, and that is simply an ordinary two-liquid bichromate battery, the outer cell containing the carbon and bichromate, and the porous a cone of zinc in sulphuric acid and water, while at the bottom of the pot some mercury is placed to preserve the amalgamation. This can, however, be achieved by other means, and with more advantage, as metallic mercury is expensive. The best zinc is cheaper in the end, as it lasts longer. Cast zinc should not be used; rolled plates are the best.—William E. Dawson.

[52299.]—**Ice and Skating.**—The ice should certainly always rest on the water, and on a large piece of water it will always do so, even if the water falls in level, except, perhaps, near the edges, where it will slope up to the bank. If such is the case, it is best to break it at the edges, as such unsupported ice over a deep edge is most dangerous. But if the ice is level, and the water close up to it, it is certainly best to leave the edges whole. I know of no worse plan of strapping than that recommended by "T. P." page 289. I tried it myself for a long while. It throws the strain on the arch of the foot, and is very tiring, besides which, the extension of the strap "fore and aft" is mathematically against its holding the skate tightly to the foot, even if strapped tightly. There is nothing like the broad toe-strap, with heel-strap if found necessary.—Guido.

[52302.]—**The Cheapest Food.**—As "Machina" was unable to give "S. R." the name of the pubthird in the same way. It is also a very good plan to apply the solutions of ferro-cyanide of potassium and bichromate of potash to the printed picture with brushes, as these solutions cannot be used again after a print has once been in them. These last two solutions should be allowed to remain on for about a quarter of a minute before washing them off. Be careful to use a different brush for each solution, and also to apply the ferro-cyanide of potassium quickly and evenly, or there will be a mark if it does not touch all the paper nearly at exactly the same time. Remember that the print is not to be washed on coming out of the printing frame; but the ferro-cyanide is to be applied before water touches it. The best light for the dark room is the same as that used to tone silver prints by—namely, diffused daylight. If any other reader of "ours" wants to know anything more about this, I should be happy to give him any further information that I am able.—Machina.

[52372.]—**Chemical.**—The precipitate you obtained is most probably oxychloride of lead ($PbCl_2+PbH_2O_2$). Chloride of lead is not a very soluble salt. At 17·7° water dissolves 0·946 per cent. Pure HCl, 2·90 per cent. It is more soluble in hot solutions. Chloride of lime, Ca(Clo)Cl, dissolves in about 10 parts of water; but the commercial bleaching powder contains a certain amount of lime, which is insoluble. Permanganate oxidises organic matter more powerfully than bichromate, which is not affected. On salts of iron, the action of permanganate is more powerful. The latter parting with more oxygen. The reaction is as follows:—

Bichromate—

$$6FeO + K_2Cr_2O_7 = 3Fe_2O_3 + Cr_2O_3 + K_2O$$

Permanganate—

$$10FeO + 2KMnO_4 = 5Fe_2O_3 + 2MnO + K_2O.$$

—William E. Dawson.

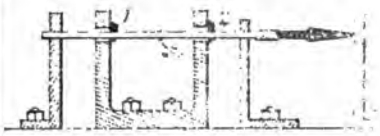
[52390.]—**Dynamo.**—Thanks to "W. H. E." for his answer to my query. I have tested the armature and F.M. I find I have the F.M. all right. I tested the A. with compass-needle, and it gives N. and S. poles in a line with the brushes. The A. is simply a light framework of iron wire to hold the coils in position, and screwed up between two wood ends on a solid steel shaft. I have tried the machine at a little over 1,000, and I find there is magnetism enough to start itself—only very little deflection. Will "W. H. E." kindly say if I am right in my dimensions of wire? Also if my connections to the collector are right, the inner end of one coil and the outer end of the next, following the direction of rotation? Does it matter which way it revolves, so that I connect the positive brush to charge the F.M. always in one direction? Will he kindly say if the fault is due to not having sufficient iron in the armature? I intended to build it with as little iron as possible. I have not run the machine above a minute at once.—Faulty Dynamo.

[52392.]—**Gravitation.**—There is an error in the working of this problem, due either to the querist or to Newth. When correctly done both methods lead to the same result, thus: Space body would traverse by its initial velocity = 120 × 4 = 480ft.; pace due to gravitation in same time = 16 × 16 = 256ft.; difference = 224ft., which is the actual height of the body after 4secs. Adopting the other method, we get time the body would rise is v/g = 3·75secs., in which it would reach 225ft. There would then be left ·25sec., in which it would fall 1ft., making actual height 224ft. as before.—Wm. John Grey, Newcastle-on-Tyne.

[52393.]—**Zinc of Battery.**—There could only one of two things result from gilding: either the zinc would be protected from action, in which case it would be useless; or its consumption would be greatly increased in pure waste. The effect of amalgamation is altogether different: it protects the zinc, and also increases its E.M.F.—Sigma.

[52394.]—**Electrical.**—By gilding your plate you would cover the zinc with a metal on which soda does not act, and, therefore, the solution being unable to attack the plate, you would get no current whatever. A patent was taken out some time ago for gilding zinc plates, but as they afterwards amalgamated them, it only had the effect of removing the gold and leaving a simple mercury amalgamated zinc. You do not want to prevent the action, but waste; because the more it is attacked, the greater the current. If you get pure zinc you will find that they will be more durable. It is the local action arising from impurities in the zinc which causes them to waste so rapidly. Vieille Montagne is the best. I have used it for a long time, and find it answers better than any other.—William E. Dawson.

[52411.]—**Cheap Lathe.**—How would this do? Fasten your headstock on to bed, get two angle-plates with holes ⅜in. or so dia. bored smoothly in them at the height you want your centres to be, bolt the angle-plates on to bed, one at each side of headstock, and pass the bar through holes in plates and holes in casting. The bar should have two small slots in it to fix cutters in, and one end of it should be squared, and a small hole drilled in it. Then bolt another plate behind this, with another shallow hole sunk in it; get a bit of pointed iron—¼in. or $\frac{1}{16}$in. dia. will do—and screw it for a good distance at the opposite end to the point: get another bit, and drill it for a good distance to same size as screw, tap it, and point opposite end. This outer sheath should be squared to fit a spanner same as boring-bar. Then put one point into hole in bar, and the other into hole in plate, and screw out sheath so as to press the cutters to the job, and then turn boring-bar, tightening it up occasionally by screw. The illustration shows all clearly if Editor cares to put it in.—George Pardoe.



[52413.]—**G. N. Engines.**—The last lot of 8ft. singles, No. 662-671, were started in 1880, and 671 came out at the beginning of this year. Since then, none have been built. I have no further dimensions of the coupled engines than cylinders 17½ by 26, and coupled wheels 6ft. 7½in.—Meteor.

[52418.] – **Photographing in Natural Colours.**—A series of these productions was exhibited at the Royal Society's conversazione about three years ago. The prints are really multi-coloured Woodburytypes. The method is as follows:—Several zinc matrices are made, each containing a part of the picture of a uniform colour, such as a sky, the green foliage of trees, grass, &c., the browns of dead leaves, earth, &c., and so on. The next step is the same as pursued in chromo-lithographing. The only superiority of these photo-chromographs being that the forms are an exact reproduction of Nature coupled with artistic colouring.—P. Ward.

[52426.]—**Chloride of Zinc and Manganese Battery.**—I do not think it is as good as when charged with sal-ammoniac: it will have lower force and lower capacity for current, and will be of use only for very small currents.—Sigma.

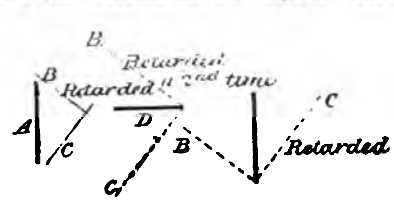
[52433.]—**M.R. Engines.**—To "Historian, M.I.M.E."—No. 45 was built in 1874 at Derby, and was rebuilt in 1876. The coupled wheels are 6ft. 8½in. in diameter, and cylinders 17 by 24. The engine has inside frames to coupled wheels, and outside to leading. It is stationed at Sheffield. 133, a single engine, was built by Stephenson, 1852. There were 6 engines of the class: Nos. 130—136. 130 was renumbered as No. 4, and most of the others are on "A" list. They have 6ft. 8in. wheels, and cylinders were (when the engine was built) 16 by 22. It was rebuilt in 1875, and possibly larger cylinders were put in. 142 and 145 were 4-coupled (leaders), trailing bogie, side tanks, built at Derby in 1875 for Metropolitan traffic, for which they are fitted with condensers. They have 5ft. 6in. coupled wheels, and cylinders 17 by 24. They are in most respects like 1252–1281 class (by Neilson and Co.), but the latter have covered-in cabs. I have the dimensions of 1252 class, which, if "Historian" likes, I can give. I believe 142 class are same. 119 is a 6ft. 8in. single engine, rebuilt 1875. It was stationed at Lancaster for many years; but I do not know where it is now. I have no further particulars of this engine. 129 is (or was) also a single engine at Birmingham; but I have not heard anything of it for some time. The Midland single engines, as originally built, had 16in., and 16½in. by 22in. cylinders at first, and the later classes (31 and 97 classes) 16½ by 24. In a back volume, Mr. Stretton stated that three had been rebuilt with 17 by 24 cylinders. I do not know which; possibly Mr. Stretton will oblige with the numbers. Mr. Johnson has rebuilt several with large boilers, and they now are splendid engines. I believe, when rebuilt, the trailing wheels had additional weight put on to them. Can anyone say whether Mr. Johnson has put larger cylinders into those rebuilt—e.g., 33, 36, 39, 24, 97—100, &c.? The weight of the original 130 class (Stephenson's) was:—Leading wheels 10 tons, driving wheels 12 ton 3cwt., trailing wheels 5 tons 17cwt., total 28 tons.—Meteor.

[52435.]—**Extraordinary Phenomenon.**—May not the following be a solution? The electric state of the atmosphere has lately been at very high tension, necessitating a difference of temperature in various layers of the air, and consequently different degrees of degrees of density. The rays from the sun (when setting or rising) striking obliquely on the layers of different densities cause different degrees of refraction, and the watery vapour dispersing the rays (as through a prism) cause the colours to appear at varying distances from each other.—Electricum.

[52435.]—**Extraordinary Phenomena.**—I make the word plural, because evenings and mornings for the past several weeks the appearance of the sky has continually varied—one evening a furious red glow, far up towards the zenith, and beyond the west point of the horizon; next evening the glow, more of an orange tint, towards the south, and extending a good way eastward; another a spreading mass of flaming red, behind which glowed bright yellow and orange light, just as described in a newspaper letter from Athens the same week, perhaps the very same day of the month. The "sea-green tint" mentioned by "Hammer" was very remarkable here (extreme South Lancashire), so that the crescent moon shared it, and caused several of my acquaintances to revert to our old nursery legend about "green cheese." But surely "Nun. Dor." is *poking fun* at "us" when he suggests that the seeing of wonderful colours is due to the "colour-blindness" of the *seers!*—H. O'B.

[52440.]—**Water Power.**—A turbine will give the power if there is sufficient water. One horse-power requires about 31 cubic feet, or 194 gallons of water per minute at 24ft. fall. It would require a very extra large spring to give the quantity which of running quietly over a sill 1ft. wide would have a depth of about 3¾in.—J. Brown, Belfast.

[52442.] — **Complementary Colours in Polariscope.**—Most, if not all, the textbooks pass over this with "of course." I will endeavour to make it plain with the aid of a diagram. A is the plane of vibration of the beam of light on emergence from the first Nicol; BC represents the two planes into which this is divided by the double refracting selenite, the vibrations in B being retarded more than in C, and consequently a portion of a vibration behind; D is the plane of vibration of a crossed Nicol, and the dotted lines indicate how the light in the two planes of the selenite impinges upon the Nicol. These rays enter the second Nicol prism at right angles to each other, and consequently are again one retarded more than the other during their passage and resolution into a single plane. If the beam B again is most retarded, we have a double retardation while the prisms are crossed, but when D is rotated to E, and the prisms are made parallel, the plane B is necessarily on the other side of the plane of vibration of the Nicol; therefore the light travels more quickly in it, and C becomes the more retarded beam. Thus the difference in the phase of vibration is in one case an addition of retardation, and in the other difference of retardations. If the thickness of the film of selenite is such that the doubled retardation is half a wave-length of red, then the red is extinguished, and the complementary colours remain. Upon rotating the prisms, the retardations being mutually corrective to a certain extent, we have a shorter total retardation, consequently the shorter waves will now interfere, and the longer red remain. I have supposed the whole effect produced by the analysing prism, whereas it is really the effect of analyser and polariser combined. I think, however, anyone who has mastered thus much will have no difficulty in applying the principle to the resolution of the polariser instead of the analyser, and so comprehending the whole. I may as well add that the beautiful colours visible by polarised light are not pure, but always more or less mixed.—Edwin Holmes.



[52443.]—**Overworked Brain.**—I do not prescribe for "B. M.," I only make some suggestions. We all receive the seventh-day rest as a blessing for body and mind, and also on the score of economy. Why not accord the same rest to the stomach? The fast day need not be on Friday, but according to circumstances. An old-fashioned thinker advises a bread-and-cheese dinner once a week as an adjunct to good health; but this would not give the stomach rest. When we feel ill we send for those nasty bilious pills or castor oil, that always have a sickening reaction. By practising total abstinence from all diet, we can rapidly reduce the bile to submission, and act as nature intends. Supper is an abominable institution to precede sleep, perchance to dream, and more honoured in the breach than observance. I am rather inclined to think, then, that a fast day is of more benefit than our modern Gargantuas are inclined to admit.—Fiddler.

[52444.]—**Electric Current.**—It would be generated if the wire were wound upon the steel [illegible] The telephone [illegible]

[52411.]—**Greek Inscription.**—If "Student" [illegible] would probably find the inscription [illegible] Mure's Critical History of the Language and Literature of Ancient Greece, [illegible] the tablet in question, [illegible] the Digamma, he writes [illegible] Digamma [illegible] of the words known to have been susceptible of digamma [illegible] III., p. 51; "I write the words in Roman characters; I cannot say where a translation of the inscription is to be found." [illegible]

[52419.]—**Greek Inscription.**—The inscription referred to by "Student" on a brazen tablet relates to a treaty between the Eleans and the Heræans, entered into, as Mr Payne Knight conjectures, about the period of the XLth Olympiad, which would be B.C. 620. It has the advantage of being the most ancient inscription ever copied in Greece, or brought to this country, and is also one of the most important for illustrating the use of the Digamma. The nature of the inscription does not appear, but reference to it may be found perhaps in the work of Colonel Leake on "The Morea" (a work possibly in the British Museum Library, or at the Guildhall). The tablet itself is in the British Museum; it is therefore possible that full particulars concerning it may be obtained through that source.—Geo. H. Lancaster.

[52454.]—**Butcher's Ice Room.**—Make a skeleton of deal 3in. square, of any dimensions, with door not less than 12in. from bottom, the top to extend higher than door, to leave room for ice in chamber at top on a shelf, leaving space all round same with fillet about 1in. all round, and pipe from same leading melted ice-water to bottom. The top lid may be single, but must fit well. A small hole at top is desirable for ventilation. All sides and bottom may be matched lining, and filled in with any non-conducting material, as very dry sawdust, hair, felt, such as builders use, or powdered charcoal, the last being the best. There must also be an outlet at bottom for getting rid of condensed water; it must be trapped, to prevent the [illegible] running away also.—Arit.

[52455.]—**Shaft Journal.**—A rule given by Jno. Bourne is "Divide the number 70,000 by the velocity of the surface of the bearing in feet per minute. The quotient will be the number of pounds per square inch of section in the line of the axis, that may be put upon the bearing." The diameter multiplied by the length is the surface upon which the pressure is reckoned.—W. J.

[52458.]—**Electrophorus.**—The holes are evidently to blame, though I don't quite see how. Perhaps the electricity escapes through the holes in the [illegible] and [illegible] at the moment of lifting up.—F. A. R. Bennett.

[524..]—**Electric Lighting.**—It is quite possible to arrange a dynamo machine to work both arc and incandescent lamps from the same machine, but not in the same circuit satisfactorily. If [illegible] will address [illegible] me, I shall be pleased to help him to use his power to best advantage. [illegible] he has not constructed a dynamo [illegible] I fear that in attempting it he will cause [illegible]—F. M. Rogers.

[illegible]

[524..]—**Transmission in Cables.**—[illegible]

[524..]—**Casting Lead.**—[illegible]

[524..]—**Casting Lead.**—[illegible]

[524..]—**Transmission of Power by Electricity.**—[illegible]

[illegible] want a 20ft. [illegible] dynamo and [illegible] at the works [illegible]

[524..]—**Belt Working off Pulley.**—If your shafts are running true and parallel with each other and [illegible] and pulley square with shafting, the only thing left for you to do is to turn off a [illegible] from pulley, leaving the centre stand above the sides [illegible] the effect of shrinking, or rather [illegible] on pulley a [illegible] ring of small rope, [illegible] centre.—Wm. Hosken.

[52465.]—**Belt Working off Pulley.**—If this querist will see that both his shafts are quite parallel, and the drum and pulley in a line, and yet some leather strips about ½in. wide, carefully reduced in thickness on each edge: nail it on the centre of the pulley (if wood); if iron, he must drill holes for small bolts. We have no trouble at our works with 3in. belts; although we have no flanges, we always make the pulley faces convex.—Bad Vacuum.

[52465.]—**Belt Working off Pulley.**—As a machinist, you are just a trifle behind the times, since flanges have long since been abolished as a means of keeping belts on pulleys. Both your queries refer to the same defect—viz., the shafts are not fixed parallel to each other. The remedy is, first see that the shafts are level; if, after doing so, the belts still have a tendency to run off, move them further apart at that end which the belt has a tendency to run to.—W. J.

[52465.]—**Belt Working off Pulley.**—The pulleys may not be in line, or the shafts may be unlevel, or they may be nearer to each other at one end than the other. To prove if the pulleys are in line, take a string and hold one end at the side of the pulley so as to cross its diameter as near the centre as possible, while your assistant holds the other end across the other pulley. If the string is tight and the shafts are in line, the string ought to touch both wheels on their edges. If it only touches one edge of each wheel, it shows the shafts are not parallel. The same effect will be caused if the shafts are out of level. Try a spirit level on each shaft. Lastly, your pulley ought to be ⅛in. higher in the centre of the rim, rising gradually from each edge. Proved.—W. W.

[52466.]—**Cross Belts.**—Leather belts would be best.—Bad Vacuum.

[52466.]—**Cross Belts.**—To repeat an old saying, "There is nothing like leather," a 4½in. leather belt will do better than a 6in. cotton one, especially if crossed. Be careful not to have any lumps at fastening, but butt ends of belt, and do not allow points of fasteners to come through.—Wm. Hosken.

[52470.]—**Malting and Malt-Kilns.**—Please to understand that it is rather difficult to instruct you on paper how to make malt, but I will do my best. Take a tub holding more than the quantity of barley to be steeped, into which shoot the barley, and cover it about 4in. deep with water. Steep 60 hours, then drain the water off, and throw the barley out on the floor in a level heap, about 1ft. thick, more or less, according to the temperature of the air. Let it be till it begins to grow, then spread it out thinner (about 6in. thick). When the rootlets are about ½in. in length spread it out evenly, about 4in. thick: this is called turning the floor. If on taking a few grains up they hold together by their roots the floor must be turned again. When the acrospire or plumule has grown [illegible] the way up the grain it is ready for the kiln. Put the floor about [illegible] thick, the last time you turn it before placing on the kiln. Now as to kiln. The drying floors are usually constructed of tiles, wire, and sometimes iron plates pierced with holes. I suppose you will have the last, as kiln tiles may not be obtainable in [illegible] A kiln about [illegible] square will dry that quantity you name. Let the plates be [illegible] from the fire. Arrange a baffle plate over the fire, about [illegible] below the pierced plates, and you must be able to regulate the draught. [illegible] [illegible]

[524..]—**Sailing.**—[illegible]

[524..]—**Ferro-Manganese.**—[illegible] of iron and manganese [illegible] carbon [illegible] and manganese; but at present there is no direct evidence of such a combination. Spiegeleisen is a similar compound to ferro-manganese, only contains much less manganese, and may possibly be a double carbide of iron and manganese. Some chemists regard the combined carbon in white irons, ferro, &c., as a solution of the carbon in the iron—i.e., it is simply dissolved in the iron, and no chemical combination. In the Bessemer process, as conducted in this country, the whole of the carbon, as well as the Mn, is removed during the blow, and spiegel or ferro is added at end to give required amount of C to the steel, without which it would be unworkable. The carbon and manganese probably also act together to reduce any small amounts of oxide of iron formed to metallic iron again, which, if present, destroys the malleability of the steel. It is necessary to have some manganese in all good steel, as without it the metal becomes brittle; but how it acts, whether by forming an alloy, or by combining chemically with the carbon, is not determined. Manganese is also said to prevent honeycomb, and give sounder ingots. The action of ferro is same in Siemens as in Bessemer.—Ferro.

[52478.]—**Whitewashing.**—Common glue dissolved in water till of the consistence of jelly when cold; but being made by the glue manufacturer from refuse matter, can be bought cheaper than made on a small scale. About a bowlful is used to a bucketful of colour wash.—H. J. Sayer.

[52478.]—**Whitewashing.**—It is simply size, made by boiling cuttings of skins, &c., but you can use glue, if you prefer. The quantity depends on how thick you want the wash. To make that, steep whiting in plenty of water; pour off the water, and mash the whiting up to a smooth paste. Now put some size in a kettle over the fire, and when thoroughly melted stir into your whiting, add blue to taste, and there you are. About two pounds of size is sufficient for six balls of whiting. That is the common whitewash. For fine work some use rice flour in addition to the size or glue.—Nux. Dor.

[52479.]—**Electric Clock.**—The following hints may prove useful to you. You say your clock strikes: it cannot do this without a hammer. Now, what is easier than to connect the positive pole of the battery to the brass frame of the clock? Next, secure a piece of ¼in. flat ebonite to the clock, near to the hammer-stem; to this ebonite screw a thin but strong German-silver spring, this spring not touching the hammer-stem except when the clock is striking; connect this spring to the one end of the bell-coils; the other end of the bell-coils connect to the negative pole of the battery. Now, when the clock-hammer goes to strike, it rises and comes in contact with the German-silver spring, thus completing the electric circuit. As the hammer of the clock falls the armature of the bell also falls, only to rise again when the clock strikes. Two No. 2 Leclanché cells work admirably.—E. A. Barnes.

[52479.]—**Electric Clock.**—I have had a clock going for eighteen months that strikes the hours on its own bell, and on a single-stroke electric bell in another part of house. I also fitted my clock with alarm arrangement to ring vibrating electric bell in still another part of my house. The striking arrangement was accomplished by attaching a piece of brass wire at right angles to the hammer of clock bell, and bent so as to lightly touch a spring stub each time the clock struck, thus making contact. The spring stub is constructed so that it can be screwed either closer or further from the wire attached to clock hammer for adjustment. The alarm arrangement is similar to ordinary clock alarm [illegible] [illegible]

[illegible] suggestion, we then washed and dried the plate, and returned it to the dark slide. Next morning we exposed again for a [illegible] of a second to the view from [illegible] window [illegible] daylight, and redeveloped. [illegible] in two minutes the view was fully out, and a tolerably dense negative was the result. Not a trace could be seen of the room on it. Is it to be assumed from this that ten minutes' exposure with the [illegible] and a very rapid lens, leaves an instantaneous plate unaffected? It seems so, and yet is hard to believe. Have any of your readers had a similar experiment? It appears, also, that even prolonged treatment with the developer does not impair the sensitiveness of a plate [illegible] not been affected by light. Is this conclusion [illegible]—A. T. Hall.

[illegible]—**Laboratory for Ironworks.**—Will some correspondent kindly give a small sketch of above, suitable for works having four blast furnaces? Size [illegible] to be about 25ft. by [illegible]. Also, any hints [illegible] will much oblige.—[illegible]

[illegible]—**Pivot.**—I want to replace new balance, as [illegible] badly damaged. Will any reader kindly [illegible] without injury to [illegible] against top of [illegible]

[illegible]—**Sections of Ironwork.**—Will you or any [illegible] readers kindly favour me with [illegible] Example: How [illegible]

[illegible]—**Long Focus Telescopes.**—[illegible] power. [illegible]

[illegible]—**Photographic Rolling Machine.**—Can any of your readers [illegible] explain how to make the above, and also give a rough sketch of same [illegible]

[illegible]—**Micro-Photography.**—Will some kind [illegible] which [illegible] I have [illegible] myself [illegible] to make a photographic [illegible] dry plates [illegible] I [illegible] Micro-Photography [illegible] better.—[illegible]

Measurement of Curvature of Lenses.—At a recent meeting of the Physical Society, Professor [illegible] read a paper on "The Measurement of the Curvature of Lenses." [illegible] the spherometer cannot be [illegible] the method is based on the Newton's rings formed between the lens and a plain surface, or a curved surface of known radius. From the wave-length of the light employed in observing and the diameter of a ring, the radius of curvature can be determined. He places the lens on a plane or curved surface under a micro-scope, and lights it by the sodium flame—wave-length [illegible]—he measures the approximate diameters of two rings a distance apart—in practice the tenth and twentieth rings are found convenient—takes the difference of their squares, and divides [illegible] the wave-length and the number of rings in the gap between to find the radius of the lens. The formula is—

[illegible]

where [illegible] and [illegible] are the diameters of the [illegible] and [illegible] rings, [illegible] the wave-length of the light and [illegible] the radius of curvature of the lens. The method with proper care gives accurate results. Professor [illegible] has also used it to determine the refractive index of liquids in small quantities. Mr. [illegible] having found it for water = [illegible] by this method, which is usually correct to two places of decimals. It can also be used to determine if the lens is uniformly curved and spherical.

Twin Steamer for the Gaboon.—At the [illegible] trial of the little twin steamship [illegible] the Mersey, a speed of 8 knots was attained with [illegible] draught of [illegible]. The vessel, which is built of steel, is [illegible] long, [illegible] beam, and [illegible] deep, with raised forecastle, and deck-house amidships. She is fitted with [illegible] engines, having cylinders [illegible] fitted with a wrought iron [illegible] separate engine for air and circulating pumps. The [illegible] throughout. The vessel and machinery were built for service on the [illegible] of the West Coast of Africa.

Notes.

(a) [illegible] a novelty, but its soundness is questionable.

[illegible] K sq is more to the purpose.

White might also have played P-K 5.

[illegible] P-Q 3 would be better.

[illegible] White has now a fine game, helped [illegible] by Black's [illegible] move.

[illegible] White's game. R-K B sq is stronger.

[illegible] after combination, which the [illegible] to have seen through.

[illegible] have taken with the Q, as it is [illegible] in the way of the double [illegible]

[illegible] played.

[illegible] number two game.

A very pretty game, with a charming ending.

Top Dressing for Lawn.—Instead of top dressing a lawn with stable manure every fall, and then raking it off in the spring, as in the usual custom, [illegible] correspondent, try sowing broadcast in the fall [illegible] pounds to the acre of finely ground raw bone meal and an equal weight of refuse salt from the [illegible] packing establishments, and [illegible] gypsum (land plaster). Then scatter on the surface at least half an inch of good, rich [illegible] sow at the rate of two bushels of blue grass seed to the acre, and give it a thorough raking and then roll it, and you will have no further trouble with your lawn, no matter how dry the season may be.

such shoulder as that of a tenon that may need to be so pared, and, of course, the same is true of the mortise, of which the ends (across the grain) are always cut with a chisel. If proof is further needed, let such mortise be carefully marked on both sides, but cut right through from one side only. The chances are that it will be found to have been cut too long on the further side of the stuff from this drawing in of the chisel. The section will be that of A, Fig. 14. Of course, therefore, the safe plan when a mortise *must* be cut only from one side is to cut it more like B, and to pare it back carefully at the finish. Whenever possible, however, a mortise should always be cut from both sides—half through from each; but the same tendency of course prevails, the result being shown in C, and here the faulty work will not be visible in the least when the tenon is in its place. The joint will appear quite close fitting and neat, but it is evident that it will have little strength, as the component parts are only in contact just at the two surfaces, the rest being quite hollow. The best way to begin a mortise is shown at D. It should be commenced by cutting out wedge-shaped chips from the middle, cutting each side by turns, and it will be found in many cases easier to take out the main part of the chips with the bevel of the chisel downwards. Each chip is thus heaved by pressing on the bevel as the fulcrum, and the mortise is gradually lengthened each way. After the main part of the wood has been removed, the back of the chisel is used next the shoulders, as already stated, care being taken, as the work approaches completion, that the hole is not undercut, but that the mortise, when finished, shall have four perfectly flat walls, the sides as free, also, as possible, from loose fibres.

Only one more cause of failure need be mentioned, and that is the bruising of the fibres on the surface of the board at the ends of the mortise by using a blunt chisel. It is mainly avoided by commencing in the middle, as just explained, but chiefly by using a keen chisel to finish with. It is true that the work may be, and very generally is, planed over again after the mortise has been cut; but that is an operation quite as well avoided, as it is seldom allowed for in squaring up the piece at the commencement. In soft wood, especially where the fibres are loosely compacted, they will bruise, and start up considerably if struck with a blunt tool, and often come completely away, leaving a depression that cannot be effaced without deeply planing the surface. All such accidents are fatal to close joints, and betoken either want of skill, or, which is even more common, want of care on the part of the workman. The surface of the bench, too, is often terribly knocked about and untrue; and when a bit of clean soft wood is laid upon it, and then mortised or otherwise worked upon by a chisel struck by a mallet, it takes the impression of these bruises and inequalities. But chips, and possibly unnoticed tacks, are the main enemies to neatness which are to be dreaded. By way of an example of more difficult fitting, it sometimes happens that the mortise is cut in a piece of hexagonal form, or other section of that nature, and that a rail has to be fitted in which the shoulders of the tenon must be so made as to embrace the parts about the mortise. Fig. 15, A and B, represents such. The shoulders *a*, *b* are specially difficult to pare, owing to the angular direction of the grain, as the natural way of cutting such a surface smoothly would be to work from *x* to *y* of C, and this cannot be done in this case. It may be pared with a chisel more readily when laid down on its side, as at D, the chisel cutting perpendicularly; but the angles frequently prohibit the chisel from cutting into them closely. Still, there is no help for it, and there is no job which requires a sharper tool deftly managed. When the work is small, the finest saw, used carefully, may suffice without any subsequent paring, and is the safer tool to use. When however, the parts are to be constructed of wood of more than usually curled grain, it may suffice to cut a recess into what I may call the standard, to receive the hexagonal rail itself beyond its tenon, Fig. 16, A, B, and C, where the mortise is shown quite black, and the recess is shaded. Neatly done, the effect is the same as when the shoulders are cut, as in the previous case; but allowance must be made in the length of the rail, or it will, of course, be too short when fitted into its place. The first plan, even if well done, is not so strong as the second, and in an out-door job where exposed the latter would be far less liable to admit rain to injure the tenon; but there are many cases in which the same kind of fitting is needed where a plan similar to that first described is essential. Of all simple jobs a half-lap joint again is apparently one of the simplest, yet is one very often badly made. Each of the pieces has three surfaces in contact—viz., the broad face A of Fig. 17, the side *a d*, the front *a b*, corresponding to similar ones on B, to which it is supposed to be necessary to attach it at right angles. As a joint it has no strength, however well made; but it is of very frequent use in stuff of all sizes, and is used not only to join one piece at right angles (or at some intermediate angle) to another, but also to join them lengthwise. The line *a b* must be accurately scribed with the help of a square, and, with the same appliance, the line answering to *c d* of B must be marked round three sides of each piece. Then, with a marking gauge, *e f* and its counterpart, which, together, determine the plane of the part A, is set off, and this line is carried along the end *g h*. On white wood, a finely-pointed (or finely *edged*) pencil will make a better line. Now, it is here that amateurs are apt to be lazy. They mark perhaps *a b*, saw down a shoulder, with no further guide line, and holding a broad chisel at the end, hit it with a mallet, and off goes the whole cheek piece, leaving possibly a fairly true face, and more generally a very *untrue* one—so untrue frequently that no subsequent paring will correct it. But as it will be much concealed from view it is allowed to pass muster, and a nice botched job it makes.

Now, supposing this, intended as it often is, to be a glued joint, the great object to be aimed at is to make each face as level and true as possible, so as to provide plenty of surface contact. We may, in this way even make the half-lap joint strong enough. Hence it is essentially necessary to scribe all lines with accuracy, and then to cut precisely up to them. The cutting across the grain will, of course, be done by the tenon saw, which will be carried down to the line *gauged* to show the line *e f* marking the position of the half-thickness of the stuff. Then the work should be stood end up in the vice, and the cheek-piece carefully removed, leaving the surface, if possible, so flat and true as not to need subsequent dressing with the chisel. A *small* hand saw will do this best, its teeth set out only just so far as to prevent the blade from binding in the cut. A saw known as a panel saw will do this nicely; a large hand-saw with much set is far more difficult to use. Every tendency to encroach on the guide-lines, so as to undercut the work like D of this Fig., must be avoided and resisted to the utmost, because if the cut once takes that direction it will end too deep, making a misfit that cannot be rectified. The main secrets, it will be seen, of making close joints are, first, to mark every line with care; secondly, to cut accurately up to them, but not to efface them; and, have saws and chisels in perfect does not take long to learn to do but the second and third require good deal of practice, but a patien mination to succeed, and never account to slur over or hurry the ever unimportant it may appear to

O. J.

ELECTRO-MAGNETS.

By J. T. SPRAGUE.

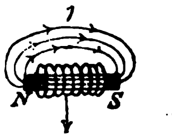
THERE is still some confusion meaning of the "strength of a and the various terms, "magnet ment," "free magnetism," "magnet and "lifting power." It is not deal with these subjects here, except as is necessary to explain the electro-magnets, but it is essential clear the distinction between strength and lifting power.

1. The *strength of a pole* is measured the field it can set up; by the repellent force it can exert upon magnet, and the unit strength of which at one centimetre distance similar and equal pole with a force dyne.

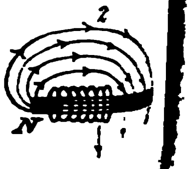
2. Now the essential feature of is its equal opposite dualism: magnet there are equal N. and present; in every magnet there N. and S. end, and in some sense S. pole; but it by no means the two ends of, say, a bar magnet stitute *two poles of equal stren* pole may be stronger than the withstanding the equal opposite netism.

3. Taking a bar magnet, netised throughout, and having opposite N. and S. poles, either capable of lifting a fixed weight— let the bar be turned into a horse- it will no longer lift only the its two poles, but several times Lifting power, therefore, depends thing besides "magnetic depends upon the arrangement or really upon how much of magnetic force is concentrated armature by which the lifting exerted. Figs. 1 and 2 will

1

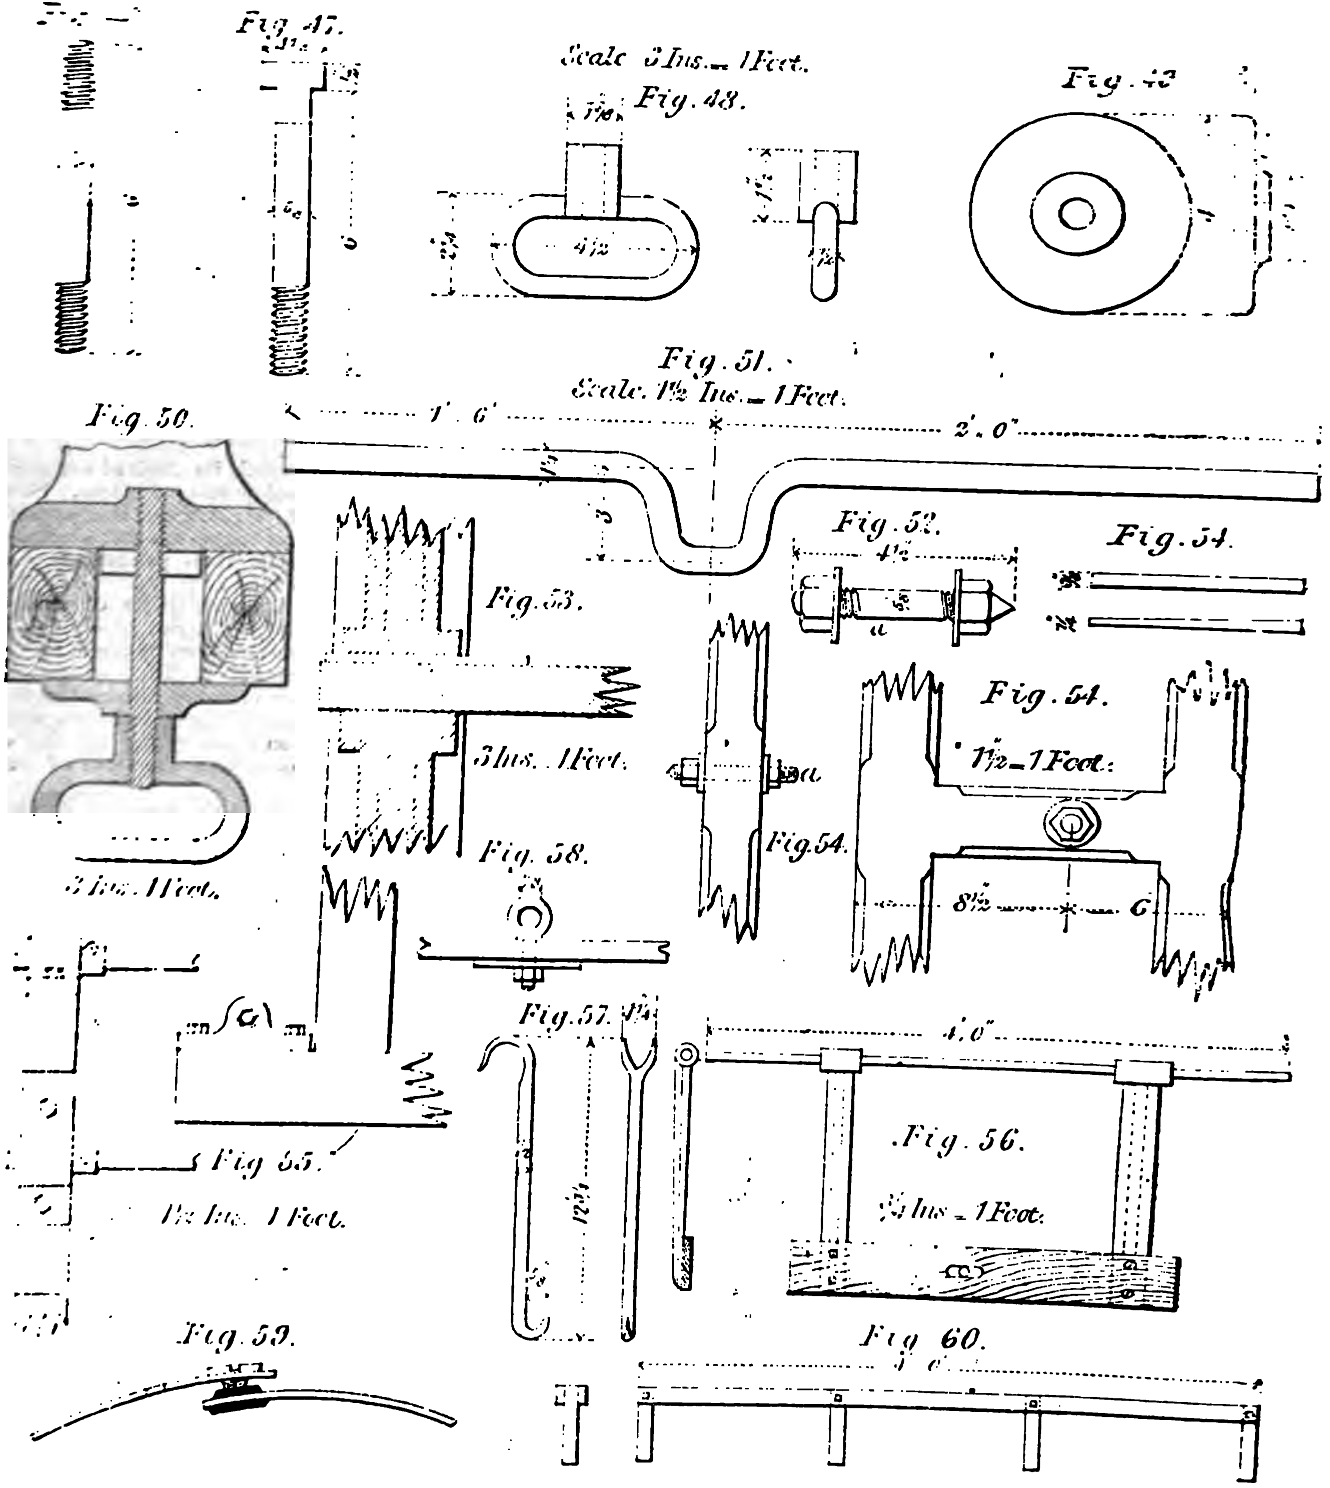


2



relations. Fig. 1 is a bar of helix over its whole length, magnetism throughout, and equal N. and S. poles. Now, that pole N. can hold up 1oz. such a current passes as satur §§ 15, we can make it hold a with the same current by adding iron to the S. end. We can we have increased the *magnetic* the system. Fig. 2 represents attained in a different way, that is longer core to the same helix. have no longer equal magnetism the core; we have equal N. and S. truly; but the middle or neutral magnet would no longer be at the the bar, but brought considerably the N. end; therefore, the N. pole stronger than the S. pole, and would greater weight, because the lines of netic force are of necessity more trated at that end.

4. The action of the horseshoe that of the straight bar, so far as its



[illegible] for the key. To turn the portion of the crank, round which the loop of the connecting rod fits would be a troublesome job for an amateur, requiring a couple of chucking [illegible] plates on the ends to bring the [illegible] in line with the lathe centres. The [illegible] method, therefore, will be to file this portion approximately circular, checking with a [illegible] metal templet from time to time.

[illegible] fit on the turned end of the [illegible] too large for your lathe, get it [illegible] way ⅝in. by ¼in. A turned rim [illegible] appearance, but is not an essential, so [illegible] for the work, or the [illegible], may influence your decision [illegible] Fig. 52, and key wheel on axle, [illegible]

[illegible] for the crank-axle, Fig. 54, [illegible] Two pieces of ⅝in. rod, 4¼in. [illegible] down at one end as shown, [illegible] for chucking, as was the [illegible] turning. Screw with stock [illegible] each end, and have the [illegible] nuts and washers. [illegible] in the middle rail [illegible] somewhat out of centre, Fig. [illegible] and screw them up moderately tight into the countersunk ends of the crank axle.

For the treadle bar get a piece of ¾in. gas tubing 4ft. long, and either skim in the lathe, or file the ends to a fairly decent fit into the bearings cast for their reception; grinding both bar and bearing together with a little fine emery and oil at the finish will facilitate the easy motion of the bar. We want to keep the bar in position endways. A couple of collars furnish the readiest method of doing so. Turn two metal rings, 1in. in the hole, 1in. long by ¼in. thick, or simply two pieces 1in. long, cut from 1in. gaspipe, will answer the purpose sufficiently well. Into each of these collars tap a ¼in. set screw, by which to hold them in position on the bar. Drill two holes in each bearing for wood screws, slip the bearings over the ends of the bar, and screw in position on standards, Fig. 55.

Now, temporarily slipping one of the end bearings off, take out the bar again, and fit to it the carriers for the treadle board. Cast an inch hole through the bosses of these, and they ought to fit just tight over the ¾in. gas tube without much filing. We must cut a key-way in each boss ¼in. wide by $\frac{3}{16}$in deep, and make keys to correspond; also flats on the treadle-bar. Drill besides a couple of holes for wood scr for fixing the treadle board; then key up, a replace bar permanently in bearings. Prepar piece of board 2ft. 6in. by 4in. by 1in., a screw in place. The treadle, now complete, h the appearance of Fig. 56.

Have the connecting rod forged to dimensio (Fig. 57). Rig up a chain and wheel if yo prefer it; but the rod is easier made, and answe well enough. Loop the rod into a ⅜in. eye bo let into the treadle board, having a washe between the nut and the wood (Fig. 58).

We may now consider the actual lathe a finished. The chucks we prefer to regard a accessories, and to discuss in a chapter devote specially to them.

For driving, get a piece of leather belting at a saddler's, ⅞in. or 1in. wide, by 8ft. 9in. long, an fasten at the ends with a common band screw No. 1 or 2. In a foot lathe, the removal of th strap from one speed to another is not so ofte necessary as in one driven by steam power, be cause the speed can be regulated within a wi range by the foot of the individual who treading. Hence, our driving wheel of one spe only will seldom put us to the inconvenience having to alter the length of strap. Then, ho

Fig. 1.

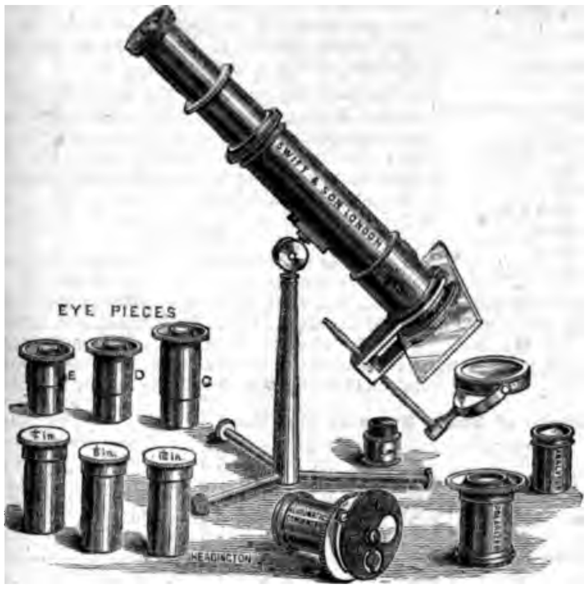


Fig. 2.

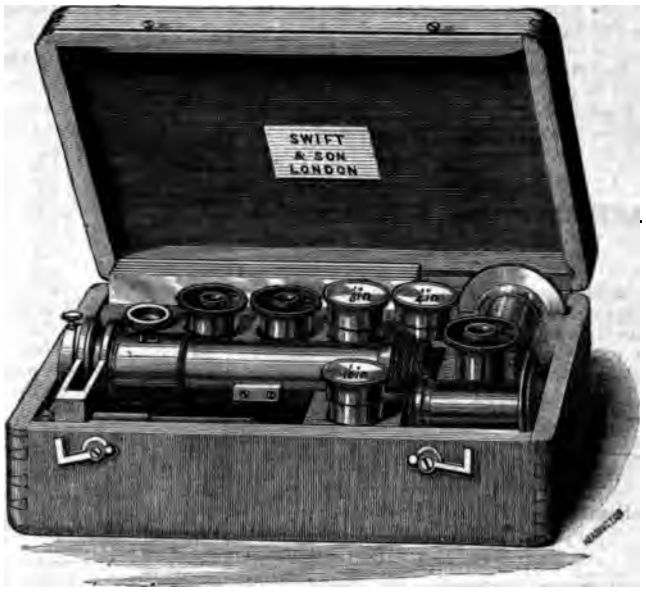

ever, the adjustment can be effected in a few seconds by removing the screw from one pair of holes to the other (Fig. 59).

A tool rack is a convenient accessory to a lathe. Prepare two strips of wood 4ft. long by 1in. by ⅜in., and screw them to four vertical strips 6in. by 1in. by ⅛in., the lower ends of which are to be screwed to the bar at the back (Fig. 60). A tool board also 4ft. by 9 by ½in. screwed on the top edges of the standards receives the tools and odds and ends of material which we have in use when working at the lathe.

In counting the cost, let it be noted that prices will vary, and the experience of no two persons will be exactly alike. But the figures we state will be found approximately correct.

The crank is the most expensive item. A piece of 1¼in. round bar iron, 4ft. long, will weigh 16½lb., which, at 1½d. per lb., will cost a couple of shillings. A smith will forge it for 3s. Then poppet, mandrels, screws, bolts, dead centres for crank, nuts, should not cost more than 5s. Another 1s. 6d. will pay for the three cast-iron washers and tightening nuts, and the strap at 3d. per foot will run to 2s. 3d. The bit of timber for tool board, rack, and treadle, about a shilling. Gas tubing at 4d. per foot, 1s. 4d.; total 16s. 1d.

This supposes that every little bit of wood and metal has to be bought; but odds and ends of wrought bar and strips of wood may often be had for the asking, and waste material may often be utilised, so that if we put the cost of these miscellaneous items at 15s., we shall not be out of pocket by our estimate.

SWIFT AND SON'S POCKET MICROSCOPE.*

MESSRS. SWIFT AND SON have added a stand to their (Brown's) Pocket Microscope (Figs. 1 and 2), which is one of the smallest microscopes made having any pretensions to be a serviceable instrument, and not a mere toy. As now modified, it appears to be the most complete really "Pocket" microscope yet issued. It is furnished with 1in., ¼in., and ⅛in. dry objectives, and $\frac{1}{16}$in. immersion, three eye-pieces, achromatic condenser with rotating disc having three diaphragms, central stop, and radial slots, together with polariser, analyser, adjustable concave mirror in gimbal fitting; the whole (with glass slips), packing in a mahogany box 4¾in. by 3¾in. by 1¼in.

The standard consists of a conical pillar, to the lower end of which three rods are screwed radially, having milled heads at the outer ends, and forming a tripod foot; the upper end has a cradle-joint carrying a dovetail slide-socket, in which fits a corresponding slide at the back of the body-tube. The microscope can be inclined on the cradle-joint as required. The slides, which can be of the usual size, are held on the stage by a spring cylinder-clip, having two lateral projecting pins, which slide in right and left bayonet slots; the clip can be raised by the pins and keyed in the bayonet slots by a slight lateral turn when the slides are being put in or removed. The coarse adjustment is effected by sliding the body-tube; the fine adjustment by moving the draw-tube in or out—a plan which is far more convenient in practice than we should have anticipated. We have found no difficulty in focussing the ⅛th objective in this manner, either with the microscope on its tripod and the light reflected from the mirror, or by pointing the body-tube directly to the sky; and, doubtless, with a little practice, the $\frac{1}{16}$th could be used with the like facility. By the addition of adapters, the objectives could, of course, be used on full-size microscopes. The three high powers are provided with correction-adjustment. We understand that the microscope was constructed wholly by Mr. Mansel Swift. (Fig. 1, half-scale; Fig. 2, two-fifths scale.)

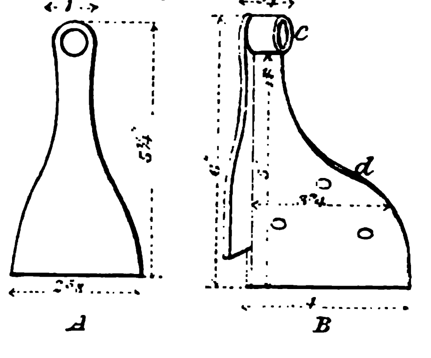
THE DYNAMO: HOW MADE AND HOW USED—X.*

By SELIMO R. BOTTONE.

§ 21. THE next pattern to be made is that of the *standard*, which supports the driving wheel. This should be made out of ¼in. stuff, a piece of which 5¼in. long by 2⅝in. wide must be cut to the shape shown at A, Fig. 17 (one quarter the real size). In order not to split the top while boring the hole, it is as well to bore the hole (which should be ½in. in diameter) before shaping the piece. For the same reason, the piece marked C, which should be ½in. thick and 1in. diameter when finished, should be glued to the centre of the top end of the piece A, and the whole bored (by means of a brace and sharp ½in. centre bit) before trimming up to shape. From the same ¼in. stuff, another piece, figured at B, is cut out, being ½in. wide at the top, sloping gradually, and becoming wider to about half its length (*d*) when it should sharply curve to a width of 4in. The length of this piece should be 5in., and it is to be glued and dowelled to the centre of the piece A, close against the boss C, as shown at B. A small piece *e* must now be glued and dowelled to the edge of the curved flange, so as to make it flush with the front A. When this has been smoothed and polished with paraffin, the patterns are ready for the foundry. The three holes shown at *d* may be bored in the castings.

Fig. 17



The Castings.

§ 22. The patterns may now be sent to the foundry, with the following instructions: First, the armature should be carefully annealed, so as to constitute a *malleable iron casting*; second, two legs should be cast from the pattern shown at Fig. 15, and these also must be carefully annealed, and be made as soft as possible; third, the standard (Fig. 17, B) will be better if left pretty hard, as in this way it will retain sufficient magnetism to start the machine without adventitious aid. Particular stress must be laid on the importance of the iron in the armature and legs being *very soft*, since much of the efficiency of the dynamo will depend on this point (see § 9). When the castings return from the foundry, their degree of hardness may be tested by trying with a rather coarse file. If the file bites easily, the iron is fairly soft; if it slips over without filing, it is altogether too hard. (This does not apply to the standard, which may be left quite hard without any detriment to the machine.) The armature must now be cleaned and trued up. If the student be the happy possessor of a lathe, this will not prove a difficult job; if otherwise, he may, by careful filing, remove any irregularities, and square up the ends. These must be made quite true; otherwise it will be impossible to centre the armature so as to rotate it between the poles of magnet. The thin central portion shown at *a*, Fig. 14, and there marked 2½, must have its edges rounded, so as not to cut the wire, which will have to be wound round it. No trouble should be spared to get the armature as truly cylindrical as possible; as care expended at this portion of the process will render the remainder of the work very much easier, and more satisfactory. The armature having been thus rendered true, the legs will demand our attention. Having gone over the surface with a bastard file to remove any irregularities, the curved channels, shown at A and B, Fig. 15, must be carefully cleaned out. Perhaps the quickest way to do this, and to clean the armature at the same time, is to lay the two pieces, channels uppermost, on a table, putting a little fine sand and water in the channels, and then to work the armature up and down the channels, first in one and then in the other, alternating also the sides of the armature, until the channels, as well as the external surfaces armature, are rendered quite smooth and bright. The sharp corners of the legs of the magnets around which the wire has to be coiled must also be rounded, and the top semicircular [illegible]

Ec Eclipse; **Oc** Occultation; **Tr** Transit of Satellite; **Sh** Transit of Shadow; **D** Disappearance; **R** Reappearance; **I** Ingress; **E** Egress. The printing of a phenomenon in *italics* indicates that its visibility is rendered doubtful, either by the brightness of the twilight or by Jupiter's proximity to the horizon.

is about as favourably placed for the observer as he well can be. His great angular diameter (42·6″ on January 1st, increasing by the 17th to 43″) renders him an easy object, even in the most moderate telescope.

The retrograde path thus indicated lies wholly in that void region of Cancer to the West of the Præsepe and the cluster of principal stars in that Constellation.

Saturn

Is visible during all the working hours of the night, and continues to present an all-repaying spectacle to the observer. He is now slowly receding, though, from the Earth, and his diameter diminishes from 18″ on January 1st to 17·2″ by the end of the month.

Day of Month.	Right Ascension.		Declination North.		Souths.	
	h.	m.	°	′	h.	m.
1	4	10·3	19	5·9	9	26·5 p.m.
6	4	9·1	19	4·1	9	5·7 ,,
11	4	8·2	19	2·7	8	45·1 ,,
16	4	7·4	19	1·9	8	24·7 ,,
21	4	6·8	19	1·5	8	4·4 ,,
26	4	6·4	19	1·7	7	44·3 ,,
31	4	6·1	19	2·4	7	24·4 ,,

Hence it will be seen that Saturn starts from a point about 3° to the west of ε Tauri, and describes a short retrograde arc in the Constellation to which that star belongs.

Venus

Is an Evening Star during the whole of January, and may be discerned with the naked eye close to the horizon immediately after sunset, on clear *evenings, towards the end of the Month. At the beginning of it she is but poorly placed,* indeed, for the observer. Her angular diameter increases very slowly from 11·2″ on January 1st to 12·4″ by the 31st. She is perceptibly gibbous in the telescope.

Day of Month.	Right Ascension.		Declination South.		Souths.	
	h.	m.	°	′	h.	m.
1	20	34·5	20	26·2	1	51·9 p.m.
6	21	0·0	18	48·6	1	57·7 ,,
11	21	24·9	16	57·9	2	2·9 ,,
16	21	49·2	14	55·7	2	7·5 ,,
21	22	13·1	12	43·5	2	11·6 ,,
26	22	36·4	10	23·1	2	15·2 ,,
31	22	59·2	7	56·0	2	18·4 ,,

Hence it will seen that Venus will start from Capricornus, across which constellation she will travel until the 16th, when she will enter Aquarius. She will not have entirely crossed Aquarius by the 31st. She will be rather more than 1° South of the 4th mag. Star λ Aquarii on the 28th.

Ceres,

Shining as a 7—8th mag. Star, is practically visible all night long. An ephemeris for intervals of 10 days will suffice for the comparatively small number of observers who will care to scrutinise such an object.

Day of Month.	Right Ascension.		Declination North.		Souths.	
	h.	m.	°	′	h.	m.
1	4	31·9	21	51·3	9	48·1 p.m.
11	4	26·3	22	16·1	9	3·2 ,,
21	4	23·6	22	43·5	8	21·2 ,,
31	4	23·9	23	13·9	7	42·2 ,,

From which it will be seen that Ceres is in Taurus, to the North of the Hyades, in a part of the sky destitute of stars visible to the naked eye.

Juno

Comes into Opposition to the Sun on January 4th, shining as a reddish 8th mag. Star, and may be seen during the chief working hours of the night.

Day of Month.	Right Ascension.		Declination North.		Souths.	
	h.	m.	°	′	h.	m.
1	6	55·0	0	40·6	12	10·7 p.m.
11	6	46·2	1	41·5	11	22·7 ,,
21	6	38·9	3	4·7	10	36·1 ,,
31	6	34·0	4	41·6	9	51·9 ,,

Juno thus travels backwards in the Constellation Monoceros, across part of the Milky Way.

Uranus

Is only above the horizon during the morning hours, so that we shall defer our Ephemeris of him until next month; but

Neptune

Is still visible during the working part of the night. As we have, however, said, upon more than one occasion, he shines only as a 7—8th mag. Star, and is singularly destitute of interest as a telescopic object: only the largest instruments being competent to raise a perceptible disc on him.

Day of Month.	Right Ascension.		Declination North.		Souths.	
	h.	m.	°	′	h.	m.
1	3	6·2	15	36·8	8	22·6 p.m.
6	3	5·9	15	36·0	8	2·6 ,,
11	3	5·7	15	35·4	7	42·7 ,,
16	3	5·5	15	35·0	7	22·9 ,,
21	3	5·4	15	34·8	7	3·1 ,,
26	3	5·3	15	34·9	6	43·4 ,,
31	3	5·3	15	35·2	6	23·7 ,,

This short path lies in that very barren region in the Eastern part of Aries.

Shooting Stars

May be especially looked out for on the Nights from the 1st to the 3rd, and again on those included between the 15th and the 19th.

Greenwich Mean Time of Southing of Eighteen of the Principal Fixed Stars on the Night of January 1st, 1884.

Star.	Souths. h.	m.	s.	
α Andromedæ	5	19	18·24	p.m.
α Cassiopeiæ	5	50	46·03	,,
β Ceti	5	54	34·57	,,
Polaris	6	33	51·54	,,
α Arietis	7	17	14·10	,,
α Ceti	8	12	39·88	,,
α Persei	8	32	27·53	,,
γ′ Eridani	9	8	54·85	,,
Aldebaran	9	45	28·10	,,
Capella	10	24	13·90	,,
Rigel	10	25	3·39	,,
α Leporis	10	43	39·42	,,
α Orionis	11	4	52·72	,,
γ Geminorum	11·46		53·02	,,
Sirius	11	55	52·95	,,
Castor	12	42	55·19	,,
Procyon	12	48	56·40	,,
Pollux	12	53	54·42	,,

Were the Stars absolutely and rigidly "fixed," any given one would South 3m. 55·91s. (or 235·91 seconds) sooner every day. This is so very approximately true with a large proportion of them, that we may assume it to be accurately so; and to find the time of the Meridian Passage at Greenwich of either of the Stars in the above List for any other night in January we have only to multiply 235·91 seconds by the number of days which have elapsed since the beginning the month (*i.e.*, by the day of the month − 1), and subtract the result from the time given in our table. For example: At what hour will Sirius South at Greenwich on the night of January 11th? Here 11 − 1 = 10, and 235·91 × 10 = 2359·10s., or 39m. 19·10s. If, then, from 11h. 55m. 52·95s. we take 39m. 19·10s. we shall obtain 11h. 16m. 33·8 as the Greenwich Mean Time of Southing of Sirius on January 11th. This really errs ·05s. from the actual instant of Transit—a quantity which no mean-time clock is able to indicate. In the case of Polaris, or any tolerably close circumpolar star, the error would be slightly greater; although even in that case abundantly sufficient accuracy would be attained for obtain- Mean Time from the Star's transit.

We may, however, further wish to ascertain the Local Mean Time of Transit of one of the above stars, and this we may do by subtracting 9·8565s. from the time given in our table for every hour of Longitude (and proportional parts for minutes and seconds when our Station is to the West of Greenwich, and adding that quantity when our Longitude is East). Thus: At what time will Capella South at Penzance on the night of January 1st? Penzance is 22m. 12s. West of Greenwich; so we say 60m. : 22·2m. : : 9·8565 : what we shall find to be 3·65s. Penzance being West of Greenwich, we must, according to the precept, subtract this from the given time, and say 10h. 24m. 13·90s. – 3·65s. = 10h. 24m. 10·25s.,—the instant a clock set to Penzance Mean Time should mark when Capella is on the Meridian of that place.

PRACTICAL NOTES ON PLUMBING.—LXXXVIII.—LXXXIX.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from p.* 335.)

Gutters with Springing.

THIS kind of gutter is shown at diagram 411, and is simply a piece of feathered edge stuff nailed on, as shown at S F, an enlarged view of which is shown at diagram 422. The use of this is to tilt the bottom course of slates, and is generally about 2½in. to 3½in. wide and ⅜in. thick at the thickest part, feathered off to nothing. It should be nailed about 4in. from the bottom of the gutter, and carried straight past the drip, then sloped down to meet the springing for the gutter below. The angles should be properly mitred, and left quite smooth and even.

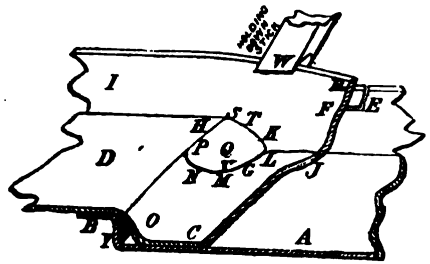

Fig. 421.

When such gutters are to be put in, take the bevel of the roof from D to E, diagram 411, and work your lead to this angle, which of course is not half the work as a square corner. Having worked the lead to the shape, put the gutter into its place. Now take a piece of quartering, and place it on the side of the lead and the bottom of the springing, as from Q to S; then kneel upon it, and break it into the springing, which is done by pulling the lead square up against the quartering, and pushing it back fair over the springing. After this is done with the hard (boxwood) dresser, dress the lead well into the bottom of the springing, and middling sharp over the arris. If the springing is properly nailed on, this will hold the lead down.

Sometimes it happens that the gutter has to be made with a square side, and the springing nailed on at the edge, as at S T, diagram 422. When such is the case, the end of the gutter is worked up square, and then on the splay, as at F E. I may here remark that in nearly all cases, when slating over the ends of curves and sides of lead gutters eaves, that springing, as illustrated at diagram, is required for tilting the bottom course of slates: and this should always be looked after by the plumber, because as a rule he is always on the job *before the slater, who cannot make good work unless* the springing is fixed. Speaking of springing, I may say that it should always be fixed under the slates by the side of walls where stop flashings are used (of course the thick part C goes against the wall), as this throws the slates towards the middle of the roof, and the water out from the wall, and so keeps the walls dry; but when soakers are used, then such springing is not required.

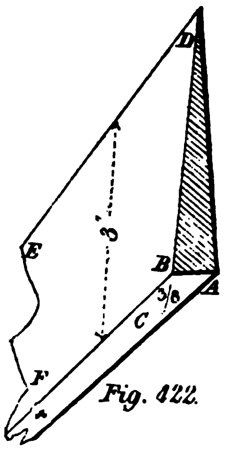

Fig. 422.

Secret Gutters.

These are illustrated at diagram 424. It is simply a gutter formed up the roof by the side of the wall, as at A B, and diagram 424. The general plan is to make them about 2½in. wide, and in such a manner that a welt may be formed on the lead as at F, diagram 424. This prevents water from running back under the slates; but care must be taken that the under lead of the gutter is not too wide, otherwise the slater will drive his nails through the lead, and here will be a chance of leakage. Of course the secret gutter slates should go up to the wall; but in this diagram they are kept back to show the lead. I have laid secret gutters exactly as shown in this diagram; but such gutters were 12in. wide, and, therefore, could hardly be called secret gutters. The gutters referred to were made for the sweeps to walk up when their attention was required to the chimneys.

Breaks.

For this, turn back to diagram 415. Here is a break suitable for a square 12in. ventilating or air shaft. On examining this it will be found to be useless to attempt to work up the sides, simply because you have not sufficient stuff to do so. For example, from X to Y, diagram 415, is 6in., and also from 1 to 2. From 1 to Y is 12in., so that the two sides alone will take all the stuff, leaving nothing for the ends. When such is the case, or anything approaching such, do not attempt to work it, but cut the two sides or two ends and solder a piece in and up the angle. But suppose your break to be, say, 3ft. long by, say, 14in. wide, or something of this sort, as illustrated at M V, &c., diagram 422. Here you have plenty of stuff, and to spare. For the marking out, turn to diagrams 407 and 408. Suppose that you have lined out the side B A, and the end R Q (Fig. 408), also the side C D.

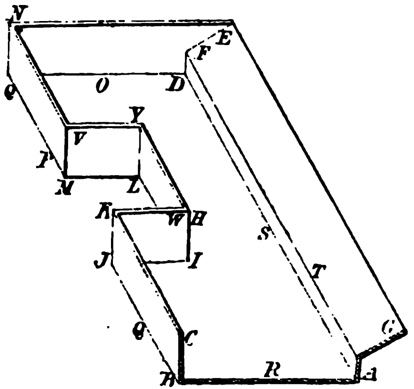

Fig. 423.

Next measure your distance from the end of the gutter at Q, to the corner I J of the break, and strike the line I J. Next measure the length of the break, as at K L, and strike this line, but allow room for the gutter to go in easily. The leadwork of the break or opening should be ¼in. larger than the break. Next measure the width of the break as from R to E and L to F (Fig. 407), or as from M to L, and J to I (Fig. 423), and set these lines out upon the lead, as at O P L M (Fig. 408), but see that they are put to the same angle on the lead as they are in the work.

Here are the lines of your break. Now measure the stand-up lines as at P O, M N, and H G, diagram 408, and shape the line in the lead as shown. Then chalk *outward* from these lines the corner lines, S J and T L, as shown by the dotted lines. Be sure and mark them rounded, as though with the compasses struck from the intersecting line at E I and K F, so that you may have enough stuff to drive back into the corners, so that the corner may be its proper thickness. A good plumber will work a lot of the stuff from the corners into the break, that is if the break is not too wide. Having marked it out as shown, now cut the piece out as indicated by the dotted lines J S T L, then pull up the back or side R A and the end C B, and work these two corners up; that is A and B diagram 407. Having these corners worked up, now pull up the sides of the break; but in doing so do not strain the lead at any point. Now take a sharpish box dresser, and well mark all round the lines L K, F E, and I J. I generally do this with a sharp chace wedge. The principal object of this is to get a line, as the chalk line is apt to get rubbed out. Having this done, and the sides pulled up as far as it will allow, turn the gutter on its side as at diagram 416, and put in a stiffener all round the edges of the break. Now (see that it does not tumble over) get your dummy and bossing stick and work away at the corner L Z, at the same time driving your extra lead into the break angle and towards the point K F or E I. Keep working away very evenly, keeping your corners nice and round, and by degrees the corner and break [illegible] the sides. When done, [illegible]

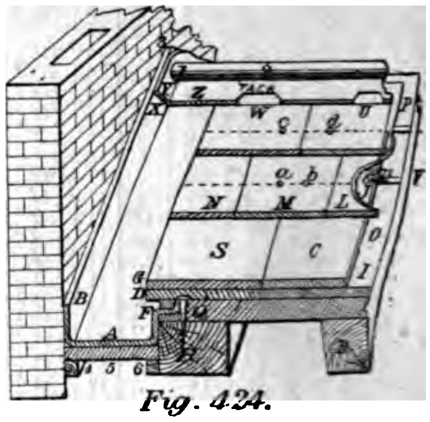

Fig. 424.

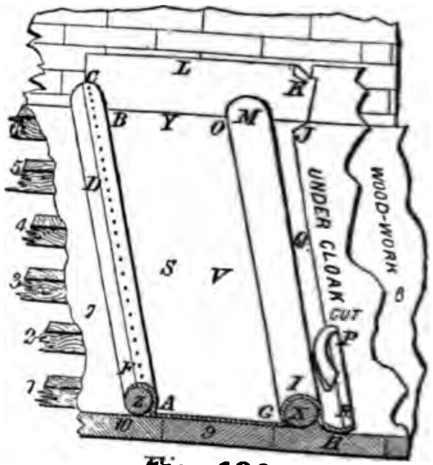

Fig. 426.

---

* *From the Building News. All rights reserved.*

[illegible] When [illegible] taken as unity, we get the following [illegible]:

Objective focus, F = 1·000
Aperture, A = ·066
Focus of each corrector, f = ·074
Aperture, a = ·022

A[illegible] case the ratio of apertures may be taken as 4 to 1: we should then have—

Objective focus, F = 1·000
Aperture, A = ·066
Focus of each corrector, f = ·041
Aperture, a = ·016

With the use of correctors of very short focus, their difference in focal length with the same curves is considerable. Thus in the second of the above combinations, the focus of an equi-concave flint would be about ·036, giving a difference of ·005 or $\frac{1}{200}$ of the whole focal length. It is also very desirable that the correctors should be cemented; but this seems scarcely possible when minute differences of aberration have to be compensated. Probably the triplet form has some advantages for a short-focus corrector.

The problem of correcting a single lens by a smaller combination at some distance from it seems to have formed the subject of some correspondence between Sir John Herschel and Mr. Rogers, as the letter from which I have quoted concludes thus: "This construction appears shorter than Mr. Barlow's with an account of which you favoured me, there being no extension of the original focus of the object glass; but where a high magnifying power is required, this extension of the focus and focal power is certainly a great advantage, and might be easily adopted in this construction by allowing the interposed lens to act as a concave in the manner you suggest. And if such an alteration destroys or materially reduces the secondary spectrum, it must be an immense improvement of the construction I have described; for in it the magnitude of this spectrum appears to be the same as in the ordinary achromatic. At all events, I hope that the reduction of the size of the flint lens and the facilities of destroying the aberrations will prove conducive to the practical perfection of the telescope."

There is a wide field for experiment with this method of obtaining achromatism. It does not seem likely that it ever can equal or surpass the ordinary plan because the coloured rays must become considerably separated by the time they reach the correctors, and it is difficult to see how they can be entirely reunited. But no purely theoretical deductions can be safely relied on in matters of this kind, for the compensatory influence of many rays in their passage through several lenses may give rise to results which it would be difficult to account for. The different practical accounts which have been related, and in which various arrangements of lenses have been used, seem to show that as regards central rays the dialyte is not inferior to the ordinary achromatic. Whether anything can be gained in reduction of the secondary spectrum, by permitting the negative refraction to lengthen the original focus, seems doubtful. But setting aside minute matters, it is well to remember that it is not every observer who needs a telescope of the highest excellence. The question is not so much whether the dialyte can be made equal to the ordinary achromatic, as to whether it will furnish a good and useful instrument. The practical accounts which have been given by Messrs. Rogers, Wray, [illegible], and Smith, are sufficient to show that with patience and perseverance and care in its adjustment and use, the dialyte will form a very efficient substitute for the ordinary achromatic telescope.

ALUMINIUM AND ALUMINIUM ALLOYS.

Not much has been heard lately of the new [illegible] of obtaining aluminium which [illegible] commercial world [illegible] the raw material [illegible] the metal would be as useful [illegible] at a low price, that it [illegible] to be taken [illegible] to render the [illegible] One of [illegible] is a method of obtaining [illegible] alumina from alum, patented by W. H. Thompson, [illegible] In the [illegible] the patentee takes a given quantity of aluminium sulphate or ammonium alum, potash alum, sodium alum, or other salts or compounds of alum, and dissolves it in a sufficient quantity of water to form a concentrated solution. To this he adds an excess of alkali; by this means all the alumina contained in the solution is precipitated as a gelatinous hydrated precipitate of alumina mingled with impurities. This precipate should be collected on a filter, and drained and dried. It is then subjected to a red heat, or any higher heat, long enough to reduce it to a calcined oxide. The calcined oxide is then washed with water, which will within a very short time, in comparison with the old process, remove enough of the impurities to leave the alumina sufficiently pure to be manufactured into aluminium by the present well-known processes. The patentee, however, recommends that ammonium alum, or aluminium sulphate be used, and the following process employed. In producing the gelatinous hydrated precipitate from ammonium alum, or from aluminium sulphate, use as an alkali ammonia, either in the form of concentrated liquor ammoniæ or by passing ammonia gas through the solution. The precipitate is reduced to a calcined oxide, so as to drive off the sulphate of ammonia, which will generally require from fifteen minutes to half an hour. The calcined oxide thus produced from ammonium alum or from aluminium sulphate is alumina sufficiently pure to be manufactured into aluminium by the present well-known processes. The process of obtaining aluminium patented last year by J. Morris, of Uddington, consists in mixing a solution of aluminium chloride with powdered wood charcoal and lampblack, then evaporating until it forms a viscous mass, which is shaped into balls. During the evaporation, hydrochloric acid is given off. The residue consists of alumina intimately mixed with charcoal. The balls are dried, then treated with steam in appropriate vessels for the purpose of driving off all the chlorine, care being taken to keep the temperature so high that the steam is not condensed. Then the temperature is raised, so that in the dark the tubes are seen to be at low red, and dry carbon dioxide is passed through. This is said to be reduced by the charcoal to carbon monoxide, which then reduces the alumina to aluminium. Although the quantity of the escaping carbon monoxide is in general a good indication of the progress of the reduction, it is nevertheless advisable not to continue the heating of the tubes or vessels until the evolution of this gas has ceased or even nearly ceased, as, in consequence of slight differences in the consistence of the balls, some of them give up all their carbon sooner than the others. The treatment of the balls with carbon dioxide for the purpose of the reduction lasts about 30 hours, when the substances are mixed in the proportions of 5 parts carbon to 4 parts alumina. As Morris states, the metal appears as a porous, spongy mass. It is freed from the residual alumina and particles of charcoal by fusion and mechanical treatment, and is then poured into moulds.

AN EASY METHOD OF PRODUCING NEGATIVES FROM PRINTS.*

HAVING had a little leisure time on my hands during the last few days, I thought that I could amuse myself by making some enlargements from very small negatives.

The first method tried was that of magnifying an enlarged transparency from the small negative, and then making from the transparency a paper negative, which was waxed. This method, I believe, was introduced by Mr. Valentine Blanchard.

However, I was not satisfied with the result obtained, as I could not entirely prevent the grain of the paper showing in the finished proof. I next tried the ordinary method of making a small transparency and enlarging from that; but the result did not satisfy me. Finally I hit on an idea which I believe to be novel, and which is the object of this communication.

I first of all take a print from the small negative on albumenised paper, in the ordinary way, which is toned and fixed as usual. I then mount this print on glass, face downwards, with gelatine. This mounted print is then placed in front of the copying or enlarging camera, and an enlarged negative is taken from it. Owing to the print being in such close contact with the glass, the enlarged negative does not show the grain of the paper, and I find this way of enlarging to be by far the most satisfactory of any I have tried.

At present, I have only made a few enlargements in this manner, and I have sent two negatives, [illegible] the prints from which they were made, for your in[illegible]spection, as from this experiment I think it a ve[illegible] satisfactory way of enlarging.

One thing I have already discovered, and that [illegible] that it is necessary to avoid, as far as possi[illegible] having air-bells intervening between the print an[illegible] glass; for if they come on the sky of the mou[illegible] print, they will show on the enlarged negative.

---

* By C. E. ABNEY, a paper read before the London and Provincial Photographic Association.

NEW DEVICE IN PHOTOMETRY.

A NEW method of measuring the intensity [illegible] very powerful lights is described in [illegible] *Zeitschrift für Instrumentenkunde.* If any stro[illegible] light, like the electric light, for example, is to b[illegible] compared with a normal candle, the distance [illegible] which the former must be removed is inconveniently great. Dr. H. Hammerl has devised a very ingenious method of reducing the intensity of any light by purely mechanical means, cutting of one-half, three-fourths, or even nineteen-twentieths of the light, so that what remains is easily measured. It consists in placing in the path of the rays that fall upon the screen a revolving metallic disc from which are cut sectors that allow a portion of the light to pass through, but cut off and absorb the remainder. If the sum of the angles of all the sectors taken together equal 180 degrees, one-half of the light will be intercepted while the other half passes through. Experiments show that three sectors will suffice to give a uniform illumination with a moderate speed of [revolution. The size of these sectors will, of course, depend upon the amount of light to be cut off. When it is desired to reduce the light to one-third, each sector must has an angle of 40°. If each sector have an angle of 12°, the light will be reduced to one-tenth, and so on.

When two discs are employed, each having three sectors of 60° degrees each, they can be so arranged on the axis as to give any desired result.

If a single disc is employed, the openings should not be true sectors, having a definite angle at the centre, but cut so that the angle increases from the centre towards the circumference in a definite ratio. This may be so chosen that the weakening shall regularly increase from centre to circumference just as the distance from the centre increases. When this form of disc is employed, the usual greased spot on the screen must be elongated instead of round, and as long as this opening. One end of this spot will be dark, the other light, and it must be noticed where this change occurs, and the amount of weakening read by a scale on the disc itself.

THE E.M.F. AND RESISTANCE OF BUNSEN CELLS.

AT a time when the work and constancy of battery cells are subjects of dispute and interested advertisement, any details of carefully conducted experiments are of considerable value. We therefore abstract the chief points of a short paper contributed by Mr. G. G. Grower to *Van Nostrand's Engineering Magazine.* The electromotive force of cells, as given in various books, seems very irregular; different figures being given by different authorities. This may be partly due to the fact that the electromotive force is constantly changing while the cell is working, being highest at first, and falling more or less rapidly according to the work the cell is doing. The density of the acids or solutions used also affects the electromotive force, and as experimenters use different densities, this may also account for part of the irregularities mentioned. The resistance of the cells keeps changing also, and very few books give any figures in regard to it. The electromotive force of cells is usually given in volts, and although the volt has an absolute value theoretically, it is practically a very uncertain unit.

The Daniell cell, charged with solution of zinc sulphate, is frequently used as a standard of electromotive force; it is taken as 1·079 volt by many experimenters, but some regard it as ·955 volt, and still others as one volt. This shows how uncertain the volt is as a practical unit of electromotive force. The Bunsen cell is charged in a number of different ways, each of which has it advantages and disadvantages. The two commonest ways of charging is to fill the porous cup with nitric acid, or a solution of bichromate of potash in sulphuric acid. The zinc is put in dilute sulphuric acid.

To compare the merits of the two ways, one cell was set up charged each way, and they were left to run down on a resistance of about 1 ohm. The electomotive force, resistance, and current were taken at intervals. The method of obtaining the electromotive force, etc., was as follows:—

The cells were left short-circuited on a resistance of 1·05 ohm, except when deflections were taken. A key was inserted in line, which kept the circuit closed, except when depressed, when it threw the cell direct on the galvanometer. By [illegible] switch the galvanometer could be connected to the terminals of 1 ohm in the line. The galvanometer used was a high-resistance reflector shunted so that a suitable portion of the current would go through it. A high resistance was also inserted in the galvanometer line. The steady deflections are proportional to the current; but as it takes time to bring the spot to rest, the battery may have changed considerably when the deflection is obtained. The electromotive of the cells begins to increase the moment the current is stopped. The various swings or impulses are also proportional to the current, so to make the observations rapidly, before changes can occur in the cell, the first swings were taken.

For a standard cell I used a Daniell containing a saturated solution of copper-sulphate and a solution of zinc sulphate, prepared by dissolving 1 part of zinc sulphate in 10 of water. Pure chemicals were used in this cell. The zinc was not amalgamated. The galvanometer was set so that the standard cell gave a first swing of 100, therefere each deflection meant ·01 of the standard cell.

It will be seen from the above that the deflection of the cell equals the electromotive force, that of the ohm equals the current. The electromotive force divided by the current equals the total resistance; subtracting from this the external resistance 1·05, we have left the resistance of the cell in ohms. The dimensions of the cells were: glass jar, 4in. diameter, 5in. high; porous cups, 2in. diameter, and zincs, 2½in. diameter. The carbons were about ¾in. by ½in.

Each jar contained 25 cubic inches of dilute sulphuric acid (1 to 12 by volume). No. 1 contained 6 cubic inches of nitric acid (spr. gr. 1·35) in the porous cup; No. 2, 6 cubic inches of chromic solution, prepared by dissolving nearly 1oz. of bichromate of potash in 15 cubic inches of water, and then adding 3 cubic inches of sulphuric acid. The zincs were amalgamated the day before using; they were also weighed, so that the amount of local action could be ascertained. The cells were left charged 1½ hour before using. External resistance was 1·05 ohm.

The electromotive force is given in terms of the Daniell cell; the resistance in ohms. The current answers the formula $\frac{E}{R}$

After working 5 minutes the E. M. F. with the nitric acid cell was 1·70, the current 1·20, and the resistance ·35; with the chromic solution the E. M. F. was 1·40, current ·90, resistance ·50. At the expiration of one hour, the nitric acid cell gave E. M. F. 1·69; C. 1·23, R ·32; the chromic cell, E. M. F. 1·17; C. ·79; R. ·43. At the end of five hours the nitric acid cell gave E. M. F. 1·65; C. 1·23, R. ·28; the chromic E. M. F. ·76; C. ·49, R. ·50. At the end of 25 hours the nitric acid had still E. M. F. 1·02; C. ·63, R ·56: but the chromic cell had only E. M. F. ·31; C. ·17, R. ·77. The current here taken will dissolve in 1 hour 1·32 grain of zinc.

Zinc wasted in nitric acid cell is about 30 per cent. as much as utilised.

Zinc wasted in chromic cell is about 19 per cent. as much as utilised.

The figures show that although the electromotive force of the cell with the chromic solution is at first higher than with nitric acid, it immediately falls far below it.

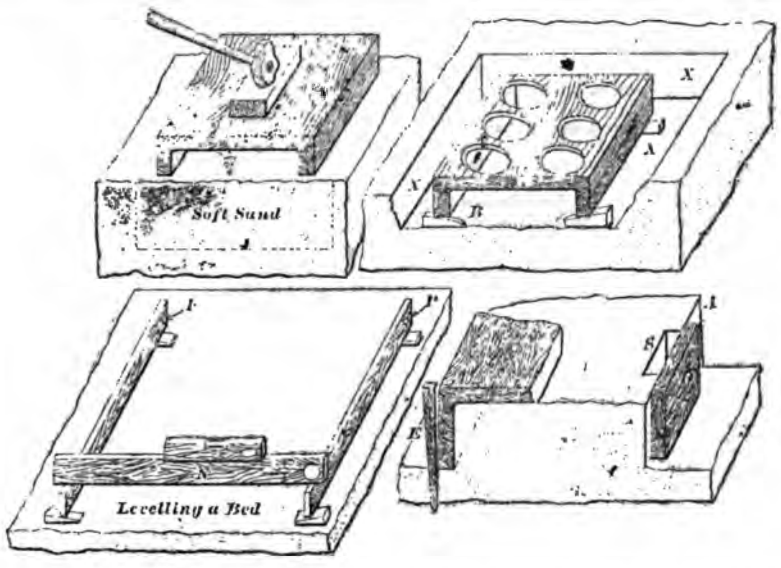
The nitric acid cell holds its electromotive force well until nearly exhausted. With nitric acid the resistance is less and the current stronger and steadier than with chromic solution.

The nitric acid cell is far superior to the chromic as far as the work is concerned, and if it were not for the disagreeable and unhealthy fumes it gives off, would be used in nearly every case.

BEDDING IN AND ROLLING OVER.*

BEDDING in and rolling over patterns in moulding have each their special advantage. As a general thing, rolled over moulds produce the smoothest castings, and are the simplest to construct, the reverse being the case with bedded-in castings. A moulder that cannot successfully turn out a good general run of casting by rolling over never need attempt it by bedding in. The writer is well aware that there are castings that cannot be as reliably made by rolling over as by bedding in, but this fact does not change the truth of the statement made. It will be acknowledged by all practical moulders who have had experience in both rolling over and bedding in, that to do general bedding in requires higher skill than rolling over. Any shop that does most of its moulding by rolling over can get along with less skilled mechanics than where the patterns, as a general thing, are bedded in.

When a moulder is furnished with nice patterns and flasks, the requirements are like those of machine labour; the physical and not the mental powers are the ones most required. Were there more bedding in practised, we would have more and better-skilled tradesmen. A novice, in travelling through the foundries of the country, would be at a loss to reason why shops, in making similar castings, do not adopt similar methods. He sees one bedding in almost everything. Another he finds rolling over everything. In many cases this puzzles even practical men to reasonably explain. One can go into many shops and there see patterns being bedded in that, all points considered, could be better rolled over. Then, again he will find the reverse, there being large expensive flasks used for moulds that could be made in less time, and with far less risk by being bedded in. There is no doubt that upon this point there are shops that are working in error. Almost every machinery foundry has some jobs that would be better were they bedded in, and some that would be better rolled over.



Sometimes circumstances may be such as to call for a pattern being bedded in, when properly it should be rolled over. This, however, is no excuse for the wide difference in shop practice.

I have seen practical men who, when questioned why they did not have certain jobs bedded in, would say they knew it was the proper way to mould them; but having so little of that class of work to do they, did not like to have their shop floors all dug up. This is, no doubt, in many cases a good reason for not bedding-in work. Shops in which most of the work is bedded in are, as a class, the dirtiest and ugliest to be found. It is pratically impossible to keep them as clean and orderly as a shop that does all rolling over. A foreman that loves order hates to see his shop a jumble of holes, sand heaps, and foundry tools. He may to some extent control and keep order, but to this there is a limit. It can be carried so far as to be a source of expense, rather than of profit. My lot has been chiefly to be employed with the dirty class of shops. It has often made me feel envious of my brother tradesmen who work in the clean shops, to think with what comfort they can work; and I would long ago have been one of their number were it not for the charm that bedded in and heavy work has for me. There is a fascination about bedding in that many moulders enjoy, whether because it is so dirty or that it makes them exercise their brains more, is for them to say.

The advantage that bedding in has over rolling over, is, in the first place, the saving of flask making; second, the rigidness with which sides and bottoms of moulds can be supported against the strains of high and heavy heads of metal: third, the assurance it presents of making a casting the duplicate of the pattern in shape. The twisting and wrenching that is given large flasks in being turned over often makes it impossible to make a casting as true as its pattern.

It is amusing to see how some moulders who have never done bedding-in go about such jobs. Not very long ago a moulder who thought himself a first-class man started to work under my supervision. I gave him a pattern, with instructions to bed it in. He said if he had a flask to roll it over he could make it in half the time. My answer was, that we did not make a practice of making expensive flasks that could be saved by bedding in; especially so where there was only one or two of a piece to make. He started at the job, and at the end of about two hours he put on his coat, remarking to a moulder, that he was not going to work in a shop where they had to lay upon their bellies to make a mould. The trouble was, he did not know how to bed in, and would willingly have kept that position all day if it would have given him the knowledge which his conceit prevented others from giving him.

Among moulders who bed in, there are two plans that are often adopted. One is to pound down a pattern, and the other to tuck it up. This pounding down business I do not approve of. In the first place, it causes a mould to be the reverse of what its condition should be (a point which I have previously written upon); in the second place it abuses a pattern, and in the third place, although it may often be a quick process, it is not by any means a mechanical one.

Any bull head can sledge down, but it requires skill to tuck up.

There are a large number of patterns that can be either sledged down or tucked up; the one shown in the sketch being of that class. In sledging down such patterns, the process is generally to first dig out a hole and fill it up with sand riddled through the shovel, then sift on about ½in. thickness of facing sand on top of which set the pattern, and on top of this the block, without any regard to which way the grain of pattern timber runs.

Then sledge down the pattern until about level with the sand bed, that is providing the patterns hold together.

To tuck up such a pattern, the hole is generally dug out about 3in. deeper than the pattern, and the pattern is rested upon four blocks or wedges, as at B; or, the four bearings may be sand mounds; with the hand sand is tucked under the pattern, after which the pattern is drawn and the surface of the mould felt all over, and any soft spots found filled up. A thickness of about ¼in. facing sand is then sifted on the bed, and the pattern returned. A sledge is then used to knock it down about ¼in., after which the sides X X, are rammed up, the joint scraped off and the pattern sighted to see if it is out of wind. This completes the bedding in.

While this in substance is one proper way to bed in, I will dwell upon a few details showing different ways of handling such jobs. Some, in tucking up such jobs, especially if the boss is not looking, will use all facing sand for the inside. Others will use all common heap sand, and when the pattern is drawn they will press facing sand against the sides; and after sifting ½in. thickness, or such a matter, over the surface, the pattern is knocked down to its bed. Some, again, will draw the pattern up to examine if all places are firm and of an even hardness. There is a great difference in the ability of moulders to make a firm bed the first time. Some will have to draw out a pattern three or four times before they can get as firm and reliable tuck as others can obtain by once drawing out.

Before going any further there are two points which I would call especial attention to. The first is the rapping down of tucked up patterns. Before a pattern is first drawn the guiding stakes should be driven so as to be a guide in showing how much the pattern is to be knocked down. At E, the stake is shown driven, having its top even with the top of pattern, there being one of these stakes at each corner. When the pattern is returned it is readily shown how much it should be pounded down. I doubt if one-fourth of the moulders ever make any calculation upon knocking down a pattern. Some of them pound until the pattern will go no farther, and others won't impress it enough. Every piece that is bedded in should have a limit to its impression into the bed, and the moulder should use his judgment as to what that limit is. The majority of moulders can tell by feeling a mould whether it is too hard or too soft. This is certainly an accomplishment, but it would be a better one to know how and when they were making it hard or soft. The second point I would like to call up is shown at D. This represents a plan which some moulders have of filling the sides of tucked up mould is a very good plan too. It is simply cutting out a piece of the side of the mould, and then by means of a board, D, running up the cut-out place at S with facing sand. After this cut out another portion and ram it up, and so on until the whole side is rammed up. This plan for heavy work, where sides or flanges cannot be come at to ram solidly up with facing while the pattern is in place, is a good one to adopt, as it gives a chance to make a firm surface when the pattern is withdrawn. There are many patterns where level beds can be used to assist in bedding in, the plain surfaces of the patterns resting upon the beds, and the irregular parts being tucked up. Wherever a levelled bed can be used, it should be, as there is no way that a mould bottom can be controlled and made so reliable.

---

* By Thos. D. West in *American Machinist*.

Few moulders will make a level bed. In levelling a bed, one side, as F, should be first leveled up, after which set the opposite one, P. Then upon the top of each and at one end, as seen, set a parallel straightedge (by parallel I mean that it must be [illegible] the same width at each end, not 1in. at one end and ½in. at the other). The straight edges F and P do not require to be parallel, but N must be if a level bed is wanted. With the parallel straightedge, level across from F to P, then try the level on P; and if it should not be level, make it so by raising or lowering the end at P. Then test the straight edges by going over them all two or three times if necessary. Another point to be watched is the level, which in a foundry soon gets out of truth. The way to test a level is to turn it end for end. If it shows level one way and not another, it is out of truth. The only way to use such a level is to turn it end for end, and make the bulb stand the same distance from the centre mark each way.

Under the straightedges shown are four wedges, representing what should be sand mounds. The middle portion of the straight edges should be kept clear until they are levelled up, after which tuck under them. Levelling straightedges having a bearing their entire length causes a loss of time and extra labour. The holes seen in the straight edges are to hang them up by—something that is not always done.

The six holes seen in the pattern being bedded in, show a provision that ought to be allowed in many patterns to give the moulder a chance to tuck them up. A pattern to be used for rolling over work, and one for bedding in, should seldom be made upon the same plan, although they generally are. A pattern to be bedded in should be well braced, and made of good strong lumber, for the reason that bedded in patterns have to stand more or less sledge pounding, and where they are like a hollow box it is often impossible for the moulder to make the bottom of his mould as solid and reliable as it should be.

SCIENTIFIC SOCIETIES.

ROYAL METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this Society was held on Wednesday evening, Dec. 19th, at the Institution of Civil Engineers, Mr. J. K. Laughton, M.A., F.R.A.S., President, in the chair. The following were elected Fellows:—viz., E. Bentley, W. [illegible] T. H. [illegible] J. M. [illegible] W. B. Tripp, and [illegible]

The papers read were:—

[illegible] Weather Prognostics," by the Hon. Ralph Abercromby, F.R. Met. Soc. The author explains about 44 weather [illegible] relating to the following [illegible] moon, and stars [illegible] by referring them to the [illegible] in which they are observed. By [illegible]

"Preliminary Inquiry into the Causes of the [illegible] Black-bulb Thermometers [illegible] F.R. Met. Soc. [illegible] the author has made a comparison with a number of these thermometers, the results of which are given in the papers. It is shown [illegible] to raise the temperature, and that the size of the thermometer bulb is a most important factor in the case of this instrument.

[illegible] Phenological Observations for 1883," by the Rev. T. A. Preston, M.A., F.R. Met. Soc.

Mr. [illegible], F.R. Met. Soc., exhibited a series of [illegible] illustrating the recent atmospheric phenomena during November and December.

LIVERPOOL ASTRONOMICAL SOCIETY.

THE third meeting of the session was held on Monday, 17th Dec., the Rev. T. E. Espin, B.A. (vice-president), in the chair. A paper on the proper motion of sunspots was contributed by Miss E. Brown. The observations were made on 8th Nov. last, by projecting the sun's disc on a sheet of white paper. Two small spots were first visible near the E. limb, followed by a larger one, then just coming into view. By the time these spots had advanced fairly on the disc they formed a well-marked group, and it was plainly evident that the two first observed were much nearer to each other than to the third; but, on the 12th Nov. the relative position of the three spots was altered, the central one having gone backward till it was about half-way between the other two. This seemed clearly to show a retrograde motion in the central spot, and it may be as well to remark that, during this time, neither of the spots exhibited any changes of outline, as is so frequently the case. The positions and shapes of the spots were illustrated by carefully executed diagrams.

A paper by Mr. J. E. Gore, F.R.A.S., was read. The remarkable variable star χ Cygni had lately passed through a maximum. The period of its variation was not uniform; but, on the whole, the observations showed that it had been slowly increasing. At its brightest it seemed to vary from the 4th to the 6th mag.; but is usually about 5 mag. as at the recent maximum. The variable is Bayer's χ Cygni, and has been frequently confused with 17 (Fl.) Cygni, to which Flamsteed affixed the letter χ, by mistake; the variable, which is the true χ, having been faint at the time. Referring to the previous paper, Mr. Espin said, a request was received from Mr. Gore in September to observe the maximum. The systematic observation had been undertaken by Mr. Gage. The comparison stars were 17 Cygni of 5·2 mag., and 8 Cygni of 4·6 mag.; but most of the estimations were made from 17 Cygni. The value of different stations, widely apart, was shown from the fact that, while during a fortnight the weather was unfavourable at Ballisodare, four nights' observations were secured at West Kirby. There were some discrepancies in the resulting magnitudes; but these were probably due to the plan they adopted of placing the opera glass out of focus, which, in a great degree, eliminated the colour. The variable is a fine orange, and he found the difference between the brightness in and out of focus, was about half a magnitude for orange stars.

A paper was read by the Rev. S. J. Johnson, F.R.A.S., on the "Afterglow and Auroræ." The extraordinary character of the dawn and sunset for some ten days previous to the 6th December had attracted much attention. The rule had lately been that, for an hour after sunset and an hour before sunrise, the heavens had been suffused with an intensely ruddy vapour, the illumination being often grand, yet no actual aurora had been witnessed, at any rate in Dorset. The nearest approach to an aurora was on Saturday, 1st Dec., when at 5h. 15m., a very fine semicircular auroral cloud stretched across the sky from a point due N. to the S.W., ending in a mass of cloud at a low altitude. After a few minutes the cloud passed towards the E. and died away. In the W. there was at the time a ruddy cloud indented with dark finger-shaped rifts; the whole thing had probably been an edition of what is termed the "afterglow" referred to by Sir J. Herschel. That it had not been auroral was clearly shown by the absence of flickering or streamers.

Mr. W. E. Jackson wrote that in Constantinople they had had the most glorious sunsets imaginable. On the 1st Dec., the crescent moon, then a little more than 1½ days old, was, in his 4in. refractor, of a pale green, and the bright limb seemed to extend to an extraordinary distance round the dark body. On the 4th, the moon, Fomalhaut, and Vega seemed to float in a rose-coloured sea, and the thin fleecy clouds, which slowly drifted across the moon's face, were of a beautiful pale green.

Mr. Gemmill, in a short paper on 95 Herculis, directed attention to the estimates of the colours of its components. He said that, as these colours had been put upon record by different observers, they seemed to differ greatly, and, as a consequence, it has been suspected that the colour of one, or both, is variable. He thought, however, that many of the apparent discrepancies were due to the want of a reliable standard of colour.

In a communication to the Society, Mr. A. Stanley Williams called attention to the effect of mist in altering the relative brightness of lunar objects. He had lately been giving some attention to the determination of the brightness of different objects on the moon, basing his estimations on the standard objects photometrically measured by Prof. Pickering at Harvard. To take what was perhaps an extreme instance, a slight mist or haze would spread over the sky, and the standard objects, Plato and Mercator, and 4·5 and 4·4 mags. respectively, would be scarcely distinguishable in brightness from Billy and Grimaldi of 5·4 and 5·2 mags. Again on a to all appearance similar night, while the two first-named objects would be of their normal brightness, the two latter would appear almost perfectly black, and much darker than they should. Even in the pure sky of Brighton, these curious changes were a great inconvenience and source of possible error: but, on coming to London, the whole phenomenon was greatly intensified, and the standard objects were in a state of almost constant change, sometimes altering from one extreme to the other in the course of a few minutes.

SCIENTIFIC NEWS.

THE Comet Pons-Brooks passed very near Zeta Cygni last night, and is now entering the constellation Pegasus, being near Zeta Pegasi on January 8. It is getting very low down, and shortly after that date will be invisible in these latitudes: but the calculated intensity of its light will be at a maximum about the middle of January. The comet, though not conspicuous, is visible to the naked eye, and it appears was first so seen by MM. Henry, of Paris, on Nov. 27. Its position at Greenwich midnight on Jan. 2, 1884, will be R.A., 21h. 53m. 26s.; N. Dec. 20° 45·2′. The comet will be nearest to the earth on Jan. 9.

It is stated that Admiral Mouchez has drawn up a memorial praying for the removal of the Paris Observatory, but it has not yet been presented.

At the meeting of the Paris Academy of Sciences on Dec. 3, M. Faye gave in his report as representative at the Geodetic Conference. He supports the proposal for making the universal time that of Greenwich, but thinks that the civil hour ought to be the point of departure. For counting longitude, he thinks it ought to be 12 hours to the east and 12 to the west. It is probable that astronomical time will be adopted, and that longitudes will be reckoned consecutively over the 360°.

Considerable doubt exists as to who will succeed Prof. Owen as Superintendent of the Natural History collections of the British Museum at South Kensington. It is stated that there is a desire on the part of the official community that Dr. Günther should be appointed; but in other quarters it is asserted that the post will be offered to Prof. Flower.

Some idea of the industry of Prof. Owen may be gathered from the fact that he published, between 1830 and 1873, no fewer than 355 papers, the titles of which are given in the Royal Society's list, and since then he has contributed several others to the *Transactions* of the Royal and the Geological Society.

Amongst the lectures to be delivered before Easter at the Royal Institution, there will be a series of five by Prof. M'Kendrick on "Animal Heat," and six by Prof. Tyndall on the "Older Electricity, its Phenomena, and Investigators." Amongst the discourses announced for the Friday evening meetings, there will be one by Mr. J. N. Langley on the "Physiological Aspect of Mesmerism," and another by Prof. Osborne Reynolds on the "Two Manners of Motion of Water," shown by experiment. One of the most important discourses is that promised for Feb. 29 by Prof. D. E. Hughes, in which he will elucidate the "Theory of Magnetism," and illustrate his views by experiment.

A Mr. C. C. Hinsdale, of Cleveland, Ohio, whence several notable electric inventions have emanated, has obtained a patent for a new insulator, which is said to consist of paper pulp impregnated with liquid silica, which produces a covering having all the advantages of glass, without its brittleness.

An alarming accident happened the other day in Baltimore to a foreman of telephone line-men. He was holding one end of a wire which one of the gang was endeavouring to fix to a pole. The man unfortunately dropped the wire, which fell on to a line conveying a current from the Brush Electric Light Co.'s works, and the result was that the foreman received a shock which felled him to the ground, paralysed his arm, and bruised and blistered his body in several parts.

Mr. L. Daft's electric train, which we mentioned on p. 238, met with an accident during an experimental trip through taking a sharp curve at too high a speed. The gradient of the experimental line is 70ft. to the mile, and the accident occurred on the return journey. Mr. Daft uses a central insulated rail as the conductor, and a distance of a mile and a furlong was covered in eleven minutes.

The largest locomotive in the world is being built at Sacramento for the Central Pacific Railroad. The engine and tender will weigh 165 tons, and be 65ft. 5in. long.

At the Whitebank Engine Works, Kirkcaldy, Messrs. John Key and Sons have succeeded in making the largest casting known in that town—a low-pressure cylinder 100in. diameter by 6ft. 6in. stroke, measuring 12ft. 3½in. across the trunnions. The weight of the metal run down was over 25 tons.

A Mr. J. F. Schultz, of New York, proposes to tackle tornadoes by placing a barrel of powder at the limit of the town, firing it by means of a priming tube and a cord 100 yards along just as the tornado arrives over it. Probably, if the charge were large enough, the tornado would be checked; but the difficulty is to have the watchman always ready.

M. Dupuy de Lome, at the instance of M. Zédé has been making experiments on the Rhone with a system of towage by endless chains, in which a heavy chain rests on the bottom of the river, and is carried over pulleys on the tug. A tugboat is provided fore and aft on each side with an endless chain, sufficiently heavy, and plunging into the water so as to rest on the bottom for a space, the part on board being sustained by pulleys. These pulleys being turned by hand or by an engine, the chain moves with them propelling the boat against the stream. The chain on each side is actuated by a separate motor, the craft is steered by making one chain move faster or slower than the other. The chains are disposed in such a way that for the greatest depths the weights resting on the bottom produce an adhesion to the latter still greater than the drag of the tug and its convoy.

It is stated that the great volcanic mountain, Popocateptl, has been sold to an American company, who will mine the sulphur, and set up vitriol works in the neighbourhood. It is proposed to drive a tunnel into the crater, and to connect it by means of a railway with the Interoceanic line. If that is carried out, Popocateptl will probably have as many tourist visitors as Vesuvius.

Copies of the new rules for obtaining patents can now be purchased at the Patent Office Sale Department, Cursitor-street, Chancery-lane, W.C., price 6d., by post 7d. No applications under the New Patents Act will be accepted if they bear an earlier date than Jan. 1, 1884; but as the forms of application may not be ready at the Post Offices until the 29th inst., MS. applications will be received if prepared in conformity with the rules.

Imitating Expensive Leather.—The leather which it is desired to imitate is thoroughly cleaned and carefully coated with graphite, the work being similar to that necessary in preparing a smaller article for electroplating. It is then placed in a copper bath, the tank of which is large enough to easily receive a skin of any size. A dynamo-electric machine, generating a powerful current, furnishes the electricity. The copper is deposited upon the coated surface of the hide to a thickness of from one-sixteenth to one-eighth of an inch. The plate thus formed reproduces, but reversed, every mark and minute vein of the leather, so that a print taken from it is an exact copy of the original in every detail. A hide of cheap leather is laid upon the bed of a machine much resembling the ordinary iron planer. Extending across the bed is a large iron roll journaled at either end in boxes which slide between two vertical standards. Strong screw bolts regulate the distance between the bed and the bottom of the roll. The copper plate is laid upon the leather, and two or three thicknesses of felt cloth placed on the copper. By the aid of long levers the bolts are screwed down until the iron roll bears upon the copper and leather with a pressure of many tons. The bed being moved forward until all the plate has passed under the roll, the hide is removed, and is found to have been raised, in looks, to grain leather of the finest grade, or to alligator, as the case may be. The copper plate, being extremely hard, will print many hides. In some instances the plates are engraved, but as this method is more expensive and the reproduction not so faultless, it is but seldom resorted to.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

LIGHTNESS OF WINTER NIGHTS.

[22168.]—I have for a long time, like your correspondent "M. A.," noticed an unusual degree of light on certain cloudy and starlight nights: last night (Dec. 19) was an instance. During former seasons, when the aurora was prevalent, I have been ready to suppose that when clouds were present it might be explained on that ground; but I think it is equally perceptible at other times. It would be interesting if simultaneous observations of this phenomenon were made at distant stations. I am glad that attention has been drawn to it, and hope that some of your readers may be more capable of assigning a cause for it than myself.

Hardwick Vicarage. **T. W. Webb.**

SATURN.

[22169.]—I am obliged to "F.R.A.S." and Mr. Franks for their courteous reference to my letter upon the above subject. Might I remind the former that in his letter in the "E.M." for November 23 he did not give the exact time at which his drawing was taken, but simply said "which I made on the night of November 9th"? Mr. Ranyard's paper before the R.A.S., reported in this week's number, shows exactly the species of phenomena the watch for which I urge. "F.R.A.S.'s" observation of the uniformity of the polar shading is both interesting and valuable.

I am obliged to Mr. Denning for his note. If my recommendation *re* drawings of Saturn "staggers" him, however, he must excuse me saying, to employ his own not *very* happy phrase, that his criticism "staggers" me. I did no such thing as *advocate* such representations of Saturn. I *suggested* that drawings of the *ball alone* might be published, so that space and expense might be saved—if you, Sir, should object to the expenditure of either. My reason was plain enough—that *ordinary sketches* are not fitted to advance our knowledge of the Ring System. Is Mr. Denning prepared to say that such sketches could throw any light upon the difficult and delicate phenomena mentioned in the letter of Prebendary Webb referred to? Yet these are the points upon which we require information. The general aspect of the Ring System we know well enough. "Cousin, thou wert not wont to be so dull!" (to quote Shakespeare).

"Stella" (query "Standard Stars," 52516) will perhaps kindly excuse my replying in *this* communication. I mean to deal with the subject later, and will do my best to help "Stella."

S. Maitland Baird Gemmill.

Glasgow, December 21.

SOLAR PHYSICS—AFTERGLOW.

[22170.]—Those of your readers who are interested in the question of "Endowment of Research" should beg, buy, or borrow a copy of the *Glasgow Herald* for Dec. 14th, as it contains a capital article on "Solar Physics." Through the kindness of a brother correspondent in Scotland, I have been enabled to peruse the said article, which occupies two and a half newspaper columns of closely-printed matter; and I venture to say that its calm and sensible review of the whole question will carry conviction to any unprejudiced mind.

It is strange that in the pages of the English Mechanic no reference has been made to Piazzi Smyth's explanation of the "afterglow." He appears to ascribe it to purely atmospheric conditions; yet it is curious that these conditions should so seldom prevail, and when they do, to manifest themselves all over the globe at nearly the same time. The meteoric theory is more plausible; but, again, this rain of meteoric dust is no new thing, and this beautiful phenomenon ought to have been seen on many previous occasions if that hypothesis be the correct one. Cannot our veteran observers give us the benefit of their long experience as to whether they recollect its previous occurrence, and when?

W. S. Franks.

THE SUNSET GLOW.

[22171.]—Whatever may be the cause of the unusual atmospheric effects we have experienced, they are apparently world-wide. The following is taken from the *Melbourne Argus* of Nov. 7th:—

"A peculiarly rich glow, which has appeared in the western sky for a considerable time after sunset, has been popularly ascribed to the Aurora Australis. The Government astronomer, Mr. Ellery, however, attributes the phenomenon to a different cause. The spectrum, Mr. Ellery points out, exhibits great breadth in the telluric or atmospheric lines, and especially of those shown by M. Janssen to be due to aqueous vapour in certain conditions in the higher strata of the atmosphere. He is satisfied that the cause of the gorgeous sunsets is simply a peculiar hygrometric condition of those regions. He predicted wet and broken weather, and, as a matter of fact, the peculiar sunsets have been followed by copious rains all over the Australian continent, and unsettled weather still prevails. The season, in fact, has been almost as remarkable as the sunsets, nothing like it having been experienced for many years."

It does not appear to have affected our weather here, unless the circumstance that we have had a few fine days recently can be traced to it.

In considering cosmic causes as acting, we must take into account the difference of time, and also the opposite season, as compared with Australia. As to the Java volcano, of course the distance to Australia is trifling compared with ours: but it is in just the opposite direction. **Sigma.**

THE EARTHS OF THE HEAVENS ("LES TERRES DU CIEL." PARIS: MARPON ET FLAMMARION, EDITORS).

[22172.]—Those of our readers who are acquainted with the French language will, no doubt, welcome the new edition of Flammarion's "Terres du Ciel." The work is wholly consecrated to planetary astronomy, and is quite *au courant*. Readers of the English Mechanic will find there the most recent observations and drawings by Schiaparelli, Trouvelot, Denning, &c. The ideal views of the universe, as seen from the different planets, are well calculated to give to the non-geometrical reader an exact idea of the movements of our solar system. The historical part of the work is certainly very interesting, especially as many fine and curious old engravings have been reproduced. **C. Detaille.**

MICROSCOPIC MOUNTING.—V.

The Use of Reagents

[22173.]—1. *The Use of Reagents in General.*—At the close of my last letter I gave a recipe for the use of extract of logwood or crude hæmatoxylin, in order, as I said, that any reader who happened to be new to the subject might have something to stain with. But to use staining and hardening fluids and preservative media to the best advantage, it is necessary to be acquainted with the action of the reagents which compose them. In fact, the stains, fluids, and media, *are* reagents. About the use of reagents, then, the following general directions may be given:—

I. They must, as procured, be of determinate strength. With most solids there is no difficulty about this: a grain of bichloride of mercury, for example, is a grain of bichloride of mercury all the world over. But with liquid, such as glycerine or spirit, ammonia or hydrochloric acid, and with some solids, such as caustic alkali in sticks, it may not be easy to ascertain how strong they are. The means of discovering this are their obvious physical properties, their specific gravity (the chemist ought to know, or should be able to ascertain, the specific gravities of liquid chemicals as supplied to him by the wholesale house with which he deals), and the amount of chemical action which a given quantity is able to exercise. Many reagents, as ammonia, become weaker in time through evaporation; this should be taken into account, and prevented as far as possible. 2. No glass rod or anything else should ever be put into the bottles containing them (which ought to be kept in a dark, dry, clean, dustless cupboard, liquids beneath, for fear of accidents), as dust would thus be introduced. To withdraw a few drops, tilt the bottle till the liquid covers the stopper or cork; pull it out, but not altogether; and on slowly returning it a drop or more will escape. More than five drops or so should not be measured in this way, as drops differ in size according to the thickness of the fluid. 3. No acids or alkalis should be allowed to touch the glasses of the microscope; acids, moreover, spoil the brasswork. Strong volatile acids are especially dangerous, more particularly hydrochloric and nitric acids; they should not be used in the same room, or when the microscope is exposed where the contaminated air can reach it; and their vapour should be killed by ammonia Care, indeed, should be taken as to all volatile substances, which, though otherwise innocuous, may condense on the glasses and dull them. Let from it, or may be seen apparently unconnected with it. It moves with a rolling or streaming motion in a living and active cell; contains granules in its substance or on its edges, and looks like syrup floating in water or the splash of a raindrop on glass. To see it, cut a transverse section through the soft stem of an actively living plant where the colouring matter is not abundant: use as little water as possible, and after a few minutes examine with a quarter, or, much better, an eighth. Now acetic acid especially possesses the power (·5 to 5 per cent. or so) of rendering cell walls transparent and showing up the nucleus, the stronger solutions destroying the cell wall after a while, and setting the contents free; it also, like hydrochloric acid ·1 per cent., renders muscular tissue very transparent; the latter is apt to break striped muscle up into plates, while chromic acid resolves it into fibres. The action of alkalis on cells depends on their degree of concentration. They clear tissues and, like acids, coagulate the nuclear or internal bioplasm. As strong as they can be made (e.g., a saturated solution of soda), they at first do little more than this; but the tissue rapidly becomes a homogeneous transparent mass by their continued action. Weaker, about 20—35 per cent. for soda, or 26—40 per cent. for potash, they act on the tissue cement. Weaker still (say 15 per cent.) they dissolve the cell wall; and they also, even when stronger, produce in the cell a condition in which it absorbs water with great avidity, swelling or bursting when water is added. Weaker still they have the same effects, but act more slowly and manageably (say 5 per cent. for soda), and when the strength is yet further diminished, they seem to fail to coagulate the internal protoplasm, which very dilute solutions appear even to dissolve. **F. Grant.**

P.S.—I am only too glad to receive a hint. The wash-leather answers as well as the handkerchief for cleaning covers, and better for very thin covers, of which, however, I was not speaking. Disadvantage of leather, dust; of handkerchief, threads.

THEORY OF THE EYEPIECE.—DISPERSION OF LIGHT.—II.

[22174.]—IT may be well to mention that this only professes to be an elementary theory—that is to say, one in which we only proceed to first approximations, and so it may be said once for all, that all such quantities as are usually neglected for the purpose will be neglected here, such as products of aberration, thickness of lenses, &c.

Let two lenses be placed at A and B, and let a ray R P, which, if produced, would meet the common axis in C, be incident at P, and after the first refraction let it meet the axis in D, and after second refration in E. Let $PCA = \alpha$, $PDA = \alpha_1$, and $KEB = \theta$, $AC = b$, $AD = c$, $BD = b_2$, $BE = c_2$, $AB = d$. Then—

$$\frac{\tan. \alpha_1}{\tan. \alpha} = \frac{b}{c} \text{ and } \frac{\tan. \theta}{\tan. \alpha_1} = \frac{b_2}{c_2} \therefore \frac{\tan. \theta}{\tan. \alpha} = \frac{b\, b_2}{c\, c_2}$$

Now, by the formulæ for lenses, $\frac{b_2}{c_2} = 1 + \frac{b_2}{f_2} = 1 + \frac{c - d}{f_2}$, whence—

$$\frac{\tan. \theta}{\tan. \alpha} = \frac{b}{c}\left(1 + \frac{c - d}{f_2}\right) = \frac{b}{c} - \frac{b}{c}\frac{d}{f_2} + \frac{b}{f_2}$$

Also, $\frac{b}{c}\ 1 + \frac{b}{f_1}$, by means of which the last formula becomes—

$$\frac{\tan. \theta}{\tan. \alpha} = 1 + \frac{b}{f_1} + \frac{b}{f_2} - \frac{bd}{f_1 f_2} - \frac{d}{f_2}$$

This gives the course of the ray after the second refraction corresponding to the values $f_1 f_2$ which are the focal lengths belonging to any given colour.

Suppose that for any other colour f becomes $f + \partial f$, and θ becomes $\theta + \partial \theta$, we have, if we take the variations by the rules of the differential calculus—

$$\frac{\sec.^2 \theta\, \partial \theta}{\tan. \alpha} = -\frac{b}{f_1}\frac{\partial f}{f_1} - \frac{b_1 \partial f_2}{f_2 f_2} - \frac{bd}{f_1 f_2}\left(\frac{\partial f_1}{f_1} + \frac{\partial f_2}{f_2}\right) + \frac{d}{f_2}\frac{\partial f_2}{f_2}$$

But when the lenses are of the same material, $\frac{\partial f_1}{f_1} = \frac{\partial f_2}{f_2}$, and the above becomes—

$$\frac{\sec.^2 \theta\, \partial \theta}{\tan. \alpha} = \left(\frac{b}{f_1 f_2}(2d - f_1 - f_2) + \frac{d}{f_2}\right)\frac{\partial f_1}{f_1} \text{........(A);}$$

which is, therefore, the general expression for the dispersion which a ray undergoes after excentrical refraction through two lenses.

To determine the condition of achromatism, we must put the right side = 0, which gives—

$$2d - f_1 - f_2 + \frac{d f_1}{b} = 0 \text{........(B),}$$

which agrees with the formula usually given.

One advantage, however, of finding the general formula for dispersion is this: that it enables us without fail to determine the actual dispersion for any value of d, which is supposed to make the pair either actually or approximately achromatic. But since all things are only great or small by comparison, let us first establish a standard wherewith to compare it. The most convenient will be a single lens, so placed that the rays which fall upon it may come from its focus. The dispersion in such a case we may name the "focal dispersion."

The general formula, then, when f_2 becomes infinite, reduces itself to—

$$\frac{\sec.^2 \theta_1 s\, \partial \theta_1}{\tan. a} = -\frac{b}{f}\frac{\partial f}{f}$$

If, moreover, we suppose the above lens to be the equivalent one to the pair that is, the one which produces the same deviation, i.e., that which gives $\sec.^2 \theta_1 = \sec.^2 \theta$—and observing that for the focal dispersion $b = f_1$, and that $\partial f / f$ is the same for all lenses, we shall have—

$$\frac{\partial \theta}{\partial \theta_1} = \frac{b}{f_1 f_2}(f_1 + f_2 - 2d) - \frac{d}{f_2} \text{........(C),}$$

which gives the ratio of the dispersion of the pair to that of the equivalent single lens.

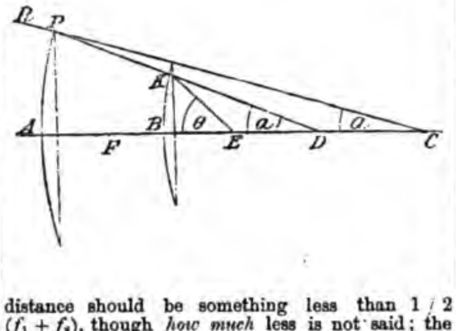
We may now apply this to some particular cases. The first will be that in which we have the so-called "achromatic combination," i.e., that in which $2d = f_1 + f_2$. In this case the formula reduces itself to $\partial\theta / \partial\theta_1 = -d / f_2$ where b disappears altogether. In the usual form of Huyghenian $d = 2f_2$, so that the dispersion is double that of the equivalent single lens.

To apply it to other cases we must first assign some value to b, and must again repeat that the necessary value which it must have is that which will cause its conjugate quantity c to terminate in that focus of the eye-lens which lies furthest from the eye, in order that the image may be in the proper position for distinct vision. This will give, by means of the formulæ for lenses—

$$b = \frac{f_2(d - f_1)}{f_1 + f_2 - d} \text{.................. (D)}$$

In the case of a Ramsden, where the lenses are equal, and $d = 2/3 f$, b becomes $= -1/4 f$, and the dispersion becomes $5/6 f$.

Again, in a Huyghenian, it is said that the *correct* distance should be something less than $1/2 (f_1 + f_2)$, though *how much* less is not said; the artist seems to be left to go by the "rule of thumb." Let us suppose it, instead of being $= 2f_2$ to be $3/2 f_2$, the value of b will become $1/5 f_1$, and the dispersion will be 13/10, which is better than the other, but still greater than that of the single lens.



Equation B will always suffice for the problem of finding a value of d, which will cause achromatism, provided only that b is a *known quantity*, whether it be great or small; but it is far otherwise when we have to take into account the consideration that the image must lie in the focus of the eyelens; or, in other words, that the ray, after first refraction, must pass through that focus. In order that it may do so, the value of b, as has been shown, must be that given in equation C, and it involves d; so that to give B as a complete solution, would be the same thing as finding the unknown quantity in terms of that unknown quantity itself; we must, therefore, look upon B, not as a complete solution, but only as a step towards it; and the next step must be to eliminate b between B and C. This will give, after a little reduction

$$(d - f_2)^2 + f_1 f_2 = 0,$$

$$\text{or} \quad d = f_2 \pm \sqrt{-f_1 f_2} \text{ .... (E).}$$

This is the value of d, which must be used when we take into account the condition as to the situation of the image. It involves only known quantities, and will only give possible values of d, when one of the lenses is convex and the other concave.

Also, there are *two* values of d, each of which will give a different e.p. We may also have cases where one or both the values of d will be negative; but these seem to be inadmissible, or, at least, to have a difficulty about them which will make it advisable to restrict ourselves to positive values. I may, at some future time have something to say about the case of parallel rays, in which, as far as I see at present, strange as it may seem, we can only have achromatism when the convex lens is of longer focal length than the other.

W. G. Penny.

[22175.]—ALL articles on light and lenses I read and study just now with a practical interest, having a bit of optical work on hand, which I wish to make as good as I can. I can assure the author of the paper on "The Eyepiece," p. 283, that his was no exception. I gave it the best attention, and for the very reason he anticipated it might get no notice. His results certainly are at variance with the views hitherto held by mathematicians, and I must say they do not agree with experiment in so far as I have made it.

When "trying," a short time ago, with a three-quarter inch o.g., slightly over-corrected I think, I found that by using different lenses in the eyepiece and placing them at different distances, I could indeed exaggerate or reduce colour to a minimum. With an uncorrected o.g. I found that while a single eye lens gave any amount of colour, I could greatly reduce it by using two, and when I put in two lenses, both uncorrected, for an o.g., and used a stop, I got a very fair correction.

So much for my own experiment. Now to turn to Mr. Penny's article, p. 283.

A ray falls upon the lens P, is refracted and resolved into two coloured rays, and passes through another lens Q. The rays after the second refraction "will be either convergent, divergent, or parallel." They are first supposed to converge and to meet in some point F. If they do so meet, and I think they must, will not an eye placed at F see the ray in the same condition as before it entered P, and if so, is not the combination achromatic? The achromatism may be what Deschanel calls "in a manner spurious," as the rays will not unite, but overlap.

But while the rays are supposed to converge after the second refraction, it seems to me they must converge. Before they could emerge parallel the second lens Q would require to be an achromatic combination if not over-achromatised. Before they could diverge the second lens Q would require to be at a less distance from the lens P than P's focal length. There is a point, though not a very material one, save for correctness of supposition. The ray Pq is supposed the red ray. It is on the diagram the ray of greater refrangibility, whereas in experiment the red ray is the least refrangible of all.

Again in paragraph 10, it seems to me that the supposition is, in the circumstances, an impossible one. A ray P q is supposed to proceed as a ray of *common light*, and to be resolved by the second lens into a red and a blue one. Now, from the last words of the paragraph, "the dispersion of *the pair*," &c., this ray is supposed to pass through the lens P, and if it does it could not emerge and proceed to the lens Q as a ray of common light—*i.e.*, an unresolved ray. Unless the lens P were an achromatic combination itself, it would resolve the ray before it got to Q. The conclusion following from Mr. Penny's reasoning is not then, I think, reliable when it proceeds upon an impossible supposition. All we could say is that in an eyepiece both the lenses must be uncorrected, or both must be corrected. I beg to assure Mr. Penny that I am not examining his paper in any hostile spirit, but am anxious for present practical purposes to know the truth about eyepieces and object-glasses. If I am wrong in my ideas, I shall be glad to have them corrected, and I await coming articles with as much interest as ever. I have been examining—theoretically—eyepieces with concave lenses, but I shall not anticipate what may be coming.

7th December. **J. A. C.**

ON THE RELATION OF APERTURE TO POWER IN MICROSCOPE OBJECT-GLASSES.

[22176.]—As a great deal of attention is now being devoted to this most important subject by the brass-and-glass section of microscopists, permit me to lay before your readers a few suggestions for their consideration.

In approaching this question we must first fix values to two factors. 1st. The smallest visual angle for definition with a normal eye. 2nd. The multiplication of the initial magnifying power that high-class objectives will bear, without fogging the picture. In answering the 1st we must remember it is not the visual angle of the smallest thing we can see that is required, but of the smallest thing we can define. In determining this angle, I have made use of finely ruled lines, and find that 250 lines to the inch can be separated at a distance of 10in. This gives a visual angle of 1′ 23′. My own eyesight can do rather more than this, but I think that it will be found a fair average to adopt. I may mention, in passing on, that a larger angle than the above will be required to split stars. This, I imagine, is due to a certain amount of flare being present, even with the keenest vision, and also to there being only one interspace.

It is a far easier business to fix a value to our [illegible]. No microscopist would rate an object glass as a high class that would in the slightest degree fog a picture with at least a 1in. eyepiece on the standard [illegible] tube.

This will be enough for us, as eyepieces deeper than 1in., while useful for adjusting and testing a lens, are admitted to be of questionable utility for work. Now, the question simply resolves itself into this: What aperture must be given to an object-glass to enable it to define anything that would be brought to a visual angle of of 1'23 by an amplification of [illegible] times the initial power of the lens?

A simple rule for finding the initial power of a lens.—Divide its focal length by 10. Produce the fraction to unity for the numerator. The denominator then expresses the initial power.

Example.—The initial power of a 2in. ?
— [illegible] = [illegible].—Ans. 5.

The initial power of a [illegible]?
— [illegible] = [illegible].—Ans. 15.

The initial power of a [illegible]?
— [illegible] = [illegible].—Ans. [illegible], &c.

The following are the apertures for object-glasses that would fulfil the above conditions:—

[illegible] N.A.	[illegible]	air angle	10°.
[illegible] ..	[illegible]	.. ..	15°.
[illegible] ..	[illegible]	.. ..	20°.
[illegible] ..	[illegible]	.. ..	30°.
[illegible] ..	[illegible]	,, ...	40°.
[illegible] ..	[illegible]	,, ...	65°.
[illegible] ..	[illegible]	,, ...	81°.
[illegible] ..	[illegible]	,, water angle	[illegible]°.
[illegible] ..	[illegible]	crown glass angle ..	[illegible]°.
[illegible] ..	[illegible],	which has yet to be constructed.	

In giving this table far be it from me to insinuate that objectives with less aperture are to be despised. The eye is so slow to recognise any new feature, unless it is very prominently put before it, that magnifying power with far less aperture is most useful. But, if ideal perfection is to be reached, the values given in the above table must be aimed at.

Dec. [illegible]. **Edward M. Nelson.**

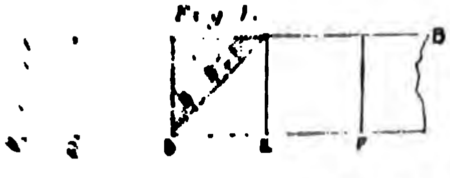
EQUATORIAL STANDS.—III.

[22177.]—*There are two or three misprints in my last letter, which it may be as well to notice. In the third paragraph, on page* 304, "sometimes as" should be "*sometimes a*"; and in the P.S., "I have *formed*," should read "I have *found*."

The next matter to be dealt with is the mode of constructing and applying verniers. It is evident that any attempt to directly subdivide a short length of arc or of a straight line into a great number of parts must render the divisions too minute to be readily distinguishable, and we therefore adopt the principle of the vernier, in which we have two adjacent portions of arcs or straight lines, one on the fixed and the other on the movable part of the instrument, such divisions differing in number for an equal length of arc or line, while neither set of divisions need necessarily be small as compared to the amount of motion to be measured.

It may, however, be as well to describe first other modes of measuring small amounts of motion before entering on the details of the actual vernier. In Fig. 1, let A B be any given length of a straight

Fig. 1.



[illegible] divided by the lines C, D, E, F, &c., [illegible] this the triangle shown by [illegible] that the base of the [illegible] the upper line B of [illegible] with the [illegible] of this triangle ex- [illegible] of one of the division [illegible] from the bottom of [illegible] this hypothenuse be [illegible] as it is desired to [illegible] divisions on the [illegible] is divided into [illegible]

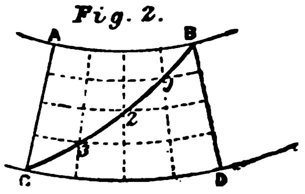
[illegible] left to right; then [illegible] coincides with the [illegible] the triangle [illegible] one-fourth [illegible] when the divi- [illegible] will have [illegible] divisions; [illegible] brings the lower corner of the triangle into coincidence with E, and the top corner with F, completing one division of the scale, whence the process can of course be repeated.

Thus one short inclined scale, equal in length in this instance to about 1¼ times one of the main divisions of the long scale, serves to subdivide the latter's divisions each into four; and to do this, however many of the main divisions the long scale may have—moreover, each of the divisions on the inclined (sliding) scale will be nearly 1¼ times as long as one of the subdivisions of the main scale would be were the number equal—that is, were the main divisions such as to measure equal amounts of motion of one scale over the other.

If we attempt to apply this system to curved scales we meet with a difficulty, because the inner and outer radii will necessarily differ, and the lengths of arc on the inner and outer curves will therefore differ in length, as is evident from the nature of the case. To obviate this difficulty it becomes necessary to make the sliding (which has now become a rotating) scale with a curved edge, the curve being such as to measure equal angular motion by the intersection of the curve with one or more radii of the curved scale.

Fig. 2 shows such an arrangement with the means of obtaining a certain number of points through which to draw (approximately) the curve required. A B is the inner and C D the outer arc bounding the principal division to be subdivided, and let the required number of such subdivisions be (as in the former case) four.

Fig. 2.



Divide the arc C D into four equal parts, and draw lines as radii to the centre of the circle as shown. Divide also A C or B D into the same number of equal parts, and describe the arcs concentric with A B or C D. Through the points of intersection B, 1, 2, 3, C, draw the curve, then this curve and the points 1, 2, 3 will correspond in the case of the circular scale to the straight line, and the points 1, 2, 3 in the case of the straight scale of Fig. 1.

On a large scale it is possible to obtain a sucession of radii of varying length (whose centres themselves lie in a curve), and with these radii to strike out the curve B to C; but for so small an arc the method would scarcely exceed in accuracy the one described, being in fact only an approximation itself, as the curve is really a portion of a spiral, and therefore impossible to be described from centres.

The same end might be attained with a straight line as in Fig. 1, by having it divided into unequal divisions so as to compensate for the difference in the lengths of the arcs, but it is not necessary to go specially into this, as the advantage would be somewhat doubtful.

We now come to the regular Vernier (or Nonius, as it was formerly called), of which the principle may be thus stated.

If two equal straight lines or circular arcs A and B are so divided that the number of equal divisions in B is one less than the number of equal divisions of A, then will the excess of one division of B above one division of A be compounded of the ratios of one of A's divisions to A and one of B's divisions to B.

Let A contain 11 parts or divisions, then one of A's to A is as 1 to 11 or $\frac{1}{11}$. Let B contain 10 parts, then one of B's to B is as 1 to 10 or $\frac{1}{10}$.

But $\frac{1}{10} - \frac{1}{11} = \frac{11-10}{10 \times 11} = \frac{1}{10 \times 11} = \frac{1}{10} \times \frac{1}{11}$.

Or, generally, if B contain n parts and A contain $n + 1$ parts, then $\frac{1}{n}$ is one part of B and $\frac{1}{n+1}$ is one part of A.

And $\frac{1}{n} - \frac{1}{n+1} = \frac{n+1-n}{n \times n+1} = \frac{1}{n} \times \frac{1}{n \times 1}$

This may be easily tried with two ordinary drawing scales; say, one with the inch divided into 3 and the other with the inch divided into 4. Place them alongside so that the 1 of the ¼ scale coincides with the 1 of the ⅓ scale, and then slide the former till the two 2's coincides. It will be found that the 1's will now be separated by an interval of $\frac{1}{12}$ of an inch, or ¼ × ⅓.

Similarly, if the scales are respectively 2 and 3 divisions to the inch, the difference, after sliding the one on the other will be found to be ⅙ of an inch or ½ × ⅓.

It is i

other the number of divisions in the vernier be one more or one less than the number of divisions in a corresponding length of the scale. Take a slip of card and divide it into inches, numbering them from left to right 0, 1, 2, 3, &c., to 6 or 7. Take another slip of card for the vernier, mark off 3in., which divide into four equal parts, also numbered from left to right 0, 1, 2, 3, &c. Then, when the two 0's correspond, the 4 of the vernier comes to 3 on the scale of inches, and by successively making coincide the two 1's, the two 2's, and the two 3's, the 0 of the vernier will show ¼, ½, ¾, of the first inch between 0 and 1 of the scale.

Make a second vernier 5in. long and divide it into four equal parts, numbered as before; on sliding this along the scale, it will equally divide the inch into four parts, but it will be the inch extending to the left of the zero of the scale, instead of the inch from 0 to 1, as in the former case.

The simple rule to remember is that the vernier has as many divisions as we require subdivisions of each inch (or other length to be divided), and that it must extend over either one less or one more than this number of inches (or other main divisions) of the scale. In the above we have in one case ¼ × ⅓ = $\frac{1}{12}$ of 3in., and in the other ¼ × ⅕ of 5in., each being equal to ¼ of an inch.

For an Hour Circle divided into degrees we may use either the ¾ or the $\frac{5}{4}$ division of the vernier in order to read to one minute of time, remembering that one will read forwards and the other backwards.

For a Declination Circle divided into degrees, if we wish to read to five minutes of arc, since 5' = $\frac{1}{12}$ of 60', we must make vernier with twelve divisions, extending over either 11° or 13°.

If we wish to read to single minutes, the vernier would have 60 divisions, and extend over 61: but as this would make it inconveniently large, it is better to have the circle divided into ½ degrees, in which case the vernier would only extend over 31°, and be divided into 30 parts.

It may be useful next to show *how to divide a line into an odd number of parts for the purpose of graduating a vernier.* Let us say we wish to divide a line into nine parts. To do this by trial and error is a tedious and inaccurate way, whereas it can be done with ease as follows:—Let A B, Fig. 3, be the given line. Divide it into eight parts (an even number) and lay off one of such divisions on A B extended as to C. At B erect an indefinite perpendicular line B K, and with radius A C and centre A intersect the perpendicular in point D, and draw A D, then A D obviously equals $\frac{9}{8}$ of A B. From centre A, and with radii A1, A2, A3, &c., draw arcs intersecting A D, then A D will be divided into nine equal parts. Parallel to the perpendicular line B K draw the verticals through the division points in A D, intersecting the given line A B, then A B will likewise be divided into nine equal parts, as required; or a line may be drawn from B parallel to A D, and similarly divided; then, joining the points of division in these two parallel lines, the line A B will be divided into the same number of parts.

Fig. 3.

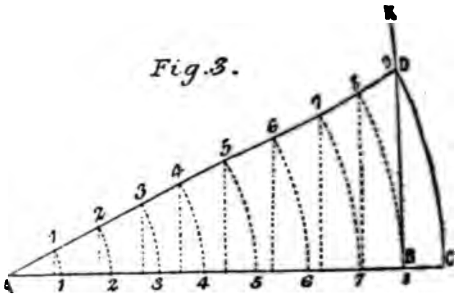


Fig. 4.

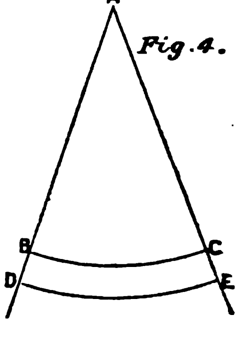

As a practical application of this geometrical method, we may take an ordinary drawing divided into eighths, and making the 0 coincide with the point A, and the 9 coincide with some point on B K may find at once the point D, and divide A D by the scale. Simple as this method is, it does not seem by any means generally known.

The same principle is also applicable to the division of arcs. In Fig. 4, let A B and A C be two radii, including the arc B C, which we may assume to be already divided into eight equal parts, but which we wish to divide into nine equal parts. Produce A B and A C indefinitely, and with a radius A D or A E equal to $\frac{9}{8}$ths of A B or A C describe the arc D E; then the length of D E will be $\frac{9}{8}$ the length of B C, and one of the divisions of B C stepped along D E will divide the latter into nine equal parts with all needful accuracy. Therefore, by drawing radii to the several divisions of D E, the original arc B C will also be divided into nine equal parts, as required.

There are certain practical details to be attended to in arranging the size of the vernier, and the most convenient number of divisions to be adopted, having regard to the sizes of the hour and declination circles; but as this letter is already a long one, I had better leave them for a future occasion.

A. S. L.

COMPOUND ENGINES OF TWO CYLINDERS.

[22178.]—I HAVE read letter 22136 from "Engineer, Dewsbury," and I must say I cannot follow his arguments. The letter states, on page 325, "The exhaust valve in the high pressure being now open, the steam will now pass into the low-pressure cylinder, whose volume to point of cut-off = whole volume of high-pressure cylinder. The volume of steam not being increased, but only removed, its pressure will remain the same, &c." Now this is the point. In this case, the point of cut-off in low pressure is $\frac{1}{3}$ stroke. Now, while the low-pressure piston travels $\frac{1}{3}$ stroke, the high pressures does the same, I imagine, ∴ $\frac{2}{3}$ of high-pressure cylinder is full of steam, and also $\frac{1}{3}$ of low pressure, and $\frac{1}{3}$ of low pressure = the whole of high pressnre. ∴ the steam that formerly occupied high pressure now occupies $\frac{2}{3}$ high pressure and $\frac{1}{3}$ low pressure, which is equivalent to $\frac{5}{3}$ high pressure, or has expanded $1\frac{2}{3}$ time the volumes.

This is as the case appears to me; but I should feel much obliged if "Engineer, Dewsbury," would inform me on this point. **A Beginner.**

[22179.]—HAVING read "Engineer's" letter (22136) in the ENGLISH MECHANIC of the 14th inst., I beg to differ from him as to the back pressure in the high-pressure cylinder; he takes 72lb. as the pressure at the point of cut-off in $\frac{1}{3}$rd of stroke; the terminal pressure will be 24lb. This steam exhausted into the low-pressure cylinder for one-third of the stroke, which is equal in capacity (at that point) to the whole capacity of the high-pressure cylinder. We shall now have 3,600 cubic inches of steam in the low-pressure cylinder, and 2,400 cubic inches at the exhaust side of the high-pressure cylinder. At this point the steam will occupy a space of 1,666—the space it did in the high pressur at the cut-off—with a corresponding reduction of pressure, and instead of a pressure of 24lb., as stated by "Engineer," at the cut-off, there will only be $14\frac{1}{2}$lb.; or to "ignore" decimals, say, 15lb., giving an average pressure throughout the stroke of $10\frac{1}{4}$lb., if we allow a two-pound back pressure from the condenser, the average effective pressure of $8\frac{1}{4}$lb., and not 14·79lb., as stated by "Engineer," which will be equal to 37 horse-power, and not 53·8, as he states. I will now deal with the back pressure in high-pressure cylinder. As before stated, we have a back pressure of 15lb. in that cylinder, when the low-pressure valve closes for steam; consequently the steam on the exhaust side of the high-pressure piston will have to be compressed for two-thirds of the stroke, and at the termination of the stroke the pressure will be something like 360lb. I should not be surprised if the cylinder cover gave way. The average back pressure throughout the stroke would be 62lb., or 12lb. more in back pressure than the average pressure on steam side of piston.

I will now draw "Engineer's" attention to a few disadvantages in connection with compound engines working. There is the loss of pressure from the point of exhaust in high-pressure cylinder to the steam line in the low-pressure one, in some cases as much as 20lb., without giving out any duty; in fact, I have a pair of diagrams before me taken from one of Hick's compound engines, where the steam was taken on for nine-tenths of the stroke in high pressure, at a pressure of 59lb., and exhausted at that pressure, and only gets 26lb. at the admission of steam in the low pressure. A loss of 33 betwixt the two cylinders. There is also the loss from leakage from two valves and pistons, power required to work the two valves, radiation from the two cylinders and valve-box and connections. In

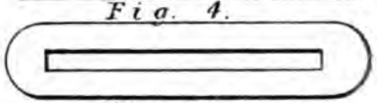

Fig. 2.

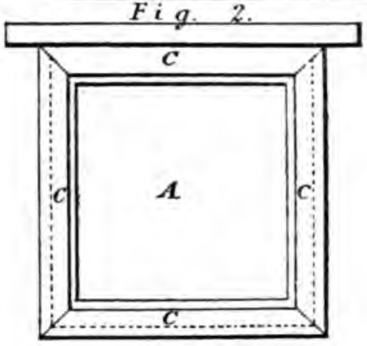


A CHEAP AND EFFICIENT DOUBLE DARK SLIDE.

[22180.]—I THINK the following will serve many of our amateur photographers. The wood I used consists of the thin boards placed as a backing to pictures. They are about 4ft. 6in. long by 11in. wide and 3-32in. thick, and should be procured as free from knots as possible. I gave 3d. each for mine. They will have to be sandpapered until a smooth surface is obtained. Cut two pieces the size the slide is intended to be to fit the camera, and out of these two pieces cut openings slightly smaller than the size of plate used—say $\frac{1}{8}$in., each way (A). Glue three strips of wood on the face of one of these pieces round three of its sides (B, Fig. 1), and then fasten another of the pieces of wood, with the openings over all; this will be the groove for the shutter to work in. Four more strips of wood are now to be glued on to the face of this last piece forming a rebate to contain the sensitive plate (C, Fig. 2): it should be slightly larger each way than the plate. This will complete one-half of the double book, the other is made in exactly the same manner, and the two halves are neatly hinged together. The top consists of a piece of wood about $\frac{1}{4}$in. thick, slightly longer than the body of the slide. It has two slits cut down its length for the shutters to pass through (Fig. 3), and care must be taken in fixing the top that these slits correspond with the openings in the slide. I have screwed this top piece on to one half of the slide, leaving the other half free to open. When the plates are in position the two halves are kept together by closing them and inserting the shutters.

I use cigar-box wood for the shutters planed down to make it work easily in the grooves, as I find light gets through those thin pine boards. A strip of wood is glued on to the top of each shutter (D, Fig. 4), which projects over the grooves which makes it light-tight. I find by gluing a piece of velvet over the slits in the top piece, then nicked with a knife to let in the shutters, makes it quite light-tight when the shutters are drawn out for exposure. The parts which enter the camera, as also the inner face of the shutters, should be stained black, and some opaque material interposed between the sensitive plates. Care should be taken that the plates occupy the same position as the focussing screen. This should br accurately measured from the front of the camera. With regard to tools, I find a fret saw and vice to answer every purpose. I trust I have made my description clear, and should anyone feel inclined to make a dark slide and be in donbt upon any point, I shall be pleased to help them through the query columns. I have given few dimensions, as these must necessarily vary in each individual case. **William Holmes**, Heanor.

TRICYCLES.

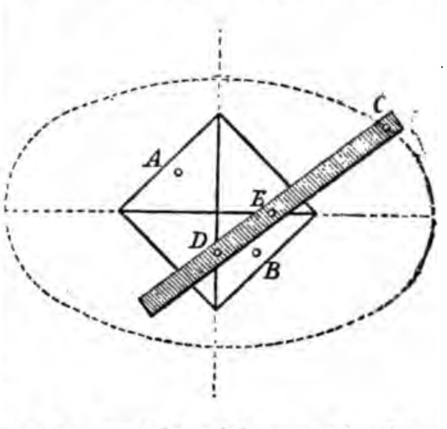
[22181.]—I HAVE been looking for some answer to your correspondent's inquiry about the Burdess Sterling Tricycle; but unfortunately there has been very little notice taken of it. I saw one in Glasgow recently, and was much pleased with the simplicity of its direct driving, doing away, as it does, with all cranks, chains, and wheels, which, in my estimation, are to be avoided.

I should like very much to hear how the machine works in actual practice, as I am wanting a machine on which I could do a run of twenty miles in the morning, and have a day's fishing, returning again may add that I have not yet arrived at the prime of life, and feel quite sound in wind and limb, but have not time to learn the Otto. My first attempt will most likely be for a run of 40 or 50 miles.

J. K.

SIMPLE TRAMMEL.

[22182.]—IF the following simple method of constructing a trammel for describing ellipses on a blackboard or any other surface is likely to interest your readers, I should be glad if you would insert it in your next. Choose a hard bit of wood about 6in. square and 1in. thick; make two clean saw cuts about $\frac{1}{2}$in. deep along the diagonals; bore two holes, A B, by which to fasten it to the blackboard. Cut a straight bit of wood 18in. or 2ft. long, $1\frac{1}{4}$in. broad and about $\frac{1}{4}$in. thick. Fasten a block, 1in. thick, under one end, and through it drill a hole (C) for chalk or pencil. Fix two French wire nails, chosen so as just to move easily in the saw cuts at D E, so that C D equal semi-major axis and C E semi-minor axis of required ellipse. It is wonderful with what ease and certainly the curve is described with this rough and easily-made instrument.



Leonard Marshall, M.A.

A FIRST LESSON ON THE PIANO WITHOUT THE INSTRUMENT.

[22183.]—MANY persons cannot read music because they learnt by the ear first, instead of the eye and touch or feel. This is so. Now for the remedy. Take two pieces of stiff cardboard and a penny slate; rule five lines across each, $\frac{1}{8}$in. apart, with pen and ruler, and bradawl for the slate. On the first card make a full dot between the lines, which read as F A C E upwards; on the second card make a full dot on all the lines, which read E G B D F, call this F the upper F. Number the first 1 2 3 4 space, and the second card 1 2 3 4 5 on the lines. Learn the space card first, and get anyone to hear you, dodging backwards, forwards, and in and out, then set different arrangements of these letter notes on the slate, as A E C F, &c., and with the pencil dot them off in their places, which can be corrected by the card; this is capable of many changes, and more so when the second card through the other's persistence. Now, get any printed piece of music and read off the notes in the treble sign. The extra note above all the lines will be upper G, and the extra note below will be lower D. Don't tire, for there is only one more note to learn this lesson, it is really lower than D, having a short line drawn through it, and looks like the planet Saturn: this is middle C on the piano. All you have to do now is to draw on cardboard a copy or diagram of part of the keyboard, commencing at middle C and upwards. This C has a line on its left side, and is followed by two black keys; then comes F, with a line on its left side and three black keys. Whatever you do, make the drawing yourself, and so have the image of the keyboard impressed on the mind. Draw the five lines as on the cards, on the diagram, and as low down as where the fingers should play; then dot the notes and learn their position, dodging, putting your finger over the dot till you can go to the real piano and read the notes off. Czerny's "Fifty Studies," op. 481, price 1s. 3d., at Enoch's, Holles-street, is the best for beginners.

Fiddler.

KEY CHARACTERISTICS IN MUSIC.

[22184.]—I AM not quite sure that I understand the remarks of Mr. G. Templeton, p. 345, for I am unable to see what "bird crumbs" (sic) and the injury to his forefinger have to do with key characteristics. Mr. Templeton "demurs" to my illustration, as he calls it, founded on Colin Brown's voice harmonium, and says that instrument does not give perfect intonation. I suppose we all know that reed instruments are very touchy affairs, and that the amount of fall of the key and the pressure of the wind both exercise some effect on the pitch of the reed; but my reference to the voice harmonium meant that the instrument was to be played properly or naturally, and without any conjuring, and if that be so, I say that it gives practically perfect intonation—so perfect that the human ear has not yet been made which can detect any unjust intonation. If Mr. Templeton will explain in definite language what it is he really means, I shall be happy to assist him in any way I can. I presume he knows what he means; but I confess I do not.

N. E. Child.

GLACIERS AND THEIR MOVEMENT.

[22185.]—IT would be difficult to find anything in nature of more curious interest and fuller of wonders than the great ranges of mountains which break up the surface of the level earth in every country, more or less, and the more especially in those vast continents wherein alone it is possible that they should exist—such as Asia and the Southern America and the Arctic land. So many are the wonders to be found in mountain forms and "influences"—to adopt a general expression—that it would be difficult to give any one of them any priority; but there is most surely not one of them more full of mystery and wonder than that of glaciers—their formation and their downward movement from the mountain tops to the valleys beneath. This difficult subject has been the study of many who have spent very much of their time on mountain travelling and observation—thus with their own eyes to watch from day to day, and from hour to hour, what goes on and what changes take place in, and with, the vast masses of snow which fall on the mountain tops, and then to finally fall, as in Greenland, into the sea in the form of icebergs, into which it has been changed. This is a scientific question of no small interest, and a few words on it in the ENGLISH MECHANIC may, therefore, be of some interest to a reader here and there—the more especially in these days of travelling.

It is certainly not the least of the many curious things which Nature offers us, and which at times we make note and record of, that however far advanced a science may be, there is most surely an infinity of details in it and about it to be yet inquired into. No theory is quite complete in illustration, and no analysis quite exhausted. Nature is inexhaustible and infinite, and all inquiries which depend on observation and eyesight for a record of the facts of them, are always being added to, and so are never complete. We see the facts, but cannot explain their cause or causes, and it is only by such facts passing through a succession of minds that the true explanation of the phenomenon is at last found. I would, therefore, but venture to hint at a somewhat new explanation of a not a little curious natural fact worth careful looking at, viz., the movement of glaciers. Glaciers have been seen and wondered at for a long time, indeed, for they are as old as the world itself, and the wonder of them is, as with so many other curious things, that all the mystery in them, and in their mode of motion down the sides of huge mountains, is, and must needs be, the result of forces ever and always in full operation, and as *ready to operate ages* before the glacier itself came into being. *What a glacier is* admits of no doubt; says *M. Rendu, the first of glacier students,* [illegible] matter is their mode of motion: but how this is (he continues) is entirely unknown. I would but attempt here to help to solve this knotty problem.

It is sufficiently well known that all vapour from the moisture-saturated air on and about the tops of snow-capped mountains, as in the Alps and Andes, is eventually precipitated in the form of snow. Snow is always falling and heaping up; but there are limits to the vertical increase of it: it cannot grow in thickness to an indefinite extent on the mountain summits. The mountain tops are being perpetually relieved of their snow coverings, partly by evaporation and partly by huge masses of this mantle of snow suddenly falling away in the form of huge snowfalls or avalanches. But neither evaporation nor snowfalls are sufficient of themselves to drain the mountains of their vast reservoirs of snow. This is accomplished by a series of snow and ice rivers, or glaciers. These have been described in a well-nigh endless series of volumes and papers, which alone show the degree of importance attached to a more correct knowledge of their formation and movement. Many a hot fight have these ice rivers occasioned, and the battle still goes on. How do the ice rivers move? and why do they move? is one of the momenteous questions involved in the very work of the world itself.

It is one of the properties of snow, full enough of mystery, to consolidate into ice on becoming subjected to pressure. A severely-pressed cube or mass of snow is converted by this pressure into ice. It is this fact which renders a glacier possible. The pressure of the snow, as it accumutates, presses on the mass beneath, and converts it into true ice. In addition to this mere pressure, there is, to a limited extent, the alternate thawings and freezings on the surface of the snow. Water also percolates downwards into the body of the snow. But it is mainly by pressure that the snow becomes ice. This being so, it would naturally be thought that this solid ice mass would remain absolutely immovable, and would form, indeed, a part of the very rock mountain itself. But not so; hard and solid and immovable as it seems, it is found to move *slowly* down, the mountain sides as a huge ice river or "glacier," at times of enormous length and thickness, and to eventually, as in Greenland, fall into the sea, there to form icebergs. It is found also to move not only down steep inclines, but along slopes barely appreciable by the eye, so slight is the incline; and the question then is, and it is yet an unsolved problem, *how* and *why* does this huge mass move as it does, and what and where is the propelling force? Right curious mechanical problems. I would here but venture to hint at a solution.

But before doing so it may be as well to advert to some of the solutions which eminent observers have already propounded. It will serve to show how hard a problem it is to solve, and it will also serve to illustrate and to explain more fully the precise nature of glacier motion.

There was first the theory of Scheuchzer and M. de Charpentier, commonly known as the "dilatation theory." It was supported by M. Agassiz. This theory supposes that the motion of a glacier down its bed or valley is caused by the conversion of the water within the glacier into ice, the irresistible expansion which takes place in the freezing of it furnishing the force which urges the glacier downward, and thus squeezing it out. It may here be noted, as opposed to this theory, there is this startling fact—that, as in Greenland, and the farther North, where the glaciers are from one to two thousand, and even five thousand, feet in thickness, no evidence is to be found of this squeezing out of any portion of the ice mass. All moves together. The pressure at the bottom of such a huge mass must be enormous. The Swiss glaciers are but as pigmies to such, and yet do the Greenland glaciers come down to the sea as pure ice in blocks, and, breaking off in huge masses, fall into the sea and float on it as icebergs. Had ice been but a fraction heavier than water, this world of ours could not have been habitable, it is curious to note.

2. In 1760, another conjecture was started by Altmann and Gruner, by which it was supposed that the glacier *slid* along its bed. This theory was adopted by the great Alpine traveller De Saussure. It has been called the "sliding theory." It may be thus defined: currents of water are found to flow between the ice of a glacier and the mountain bed which supports it. The frozen mass of the glacier being thus disengaged by the water from all adhesion to the stony bed beneath, and sometimes even being raised by the water, must, it was thought, glide down slowly, and well-nigh imperceptibly by its mere weight—i.e., by the force of gravity. It must here be noted, and it is strenuously contended for by many, and was considered proved by Canon Moseley, that the action of gravity alone is not sufficient of itself to move the glacier down the bed on which it is supported. The glacier does not slide down its bed as a plate of glass or slab material whether down the roof of a house with [illegible] ight to urge it downward. [illegible] least [illegible] would seem to be needed to account for the movement. What is it, and where does it originate?

3. The late Professor J. P. Forbes, an eminent authority on this subject of glacial action, came, after long observation, to the conclusion that the motion of a glacier was due to the "viscous" or plastic nature of the ice itself; that the ice moved down the slope of the mountain much in the same way as a viscous substance, such as tar, might do, and that its weight was alone sufficient to urge it forward. And this at first sight might seem indeed to fully solve this puzzling problem, as nothing more would appear to be needed to do it. But it is not so: mere gravity acting alone downwards will not do the work.

4. Professor Tyndall has proposed a different solution of the problem. When two pieces of moistened ice are brought into contact it is found, as Faraday proved, that they immediately freeze together. Broken pieces of ice, as they break in a glacier, reunite, and form thus a solid mass. Dr. Tyndall, therefore, concludes that the motion of a glacier is due to "fracture" and "regelation." Its own weight, therefore, drags forward the ice, which seems to flow with a viscous motion, owing simply to the "fracture and regelation" of all its particles.

Canon Moseley has "proved" that the mere weight of a mass of ice is not sufficient to cause the ice to move down a moderate slope. There must, therefore, be some other force urging the ice forward and downward. Again, therefore, we may ask, What is that force which compels the ice to move?

5. One more attempted explanation may be described. Mr. J. Croll says:—"Water, in the act of freezing, gives out heat, and while passing into the solid state expands. Ice, therefore, occupies, weight for weight, a greater space than water. Ice, in the act of melting, absorbs heat. The sun's action, when shining on the surface of a glacier, does not raise the temperature of it, which it cannot do, but converts a portion of it into water. This action, if continued, would in time cause the glacier to melt away altogether, as it, in fact, does when the ice of it reaches the warm valleys to form a river." Mr. Croll, therefore, supposes that the heat thus finding its way into one portion of the glacier is rapidly conveyed to another portion, and in the doing so compels the icy mass to change its position. It is not, therefore, the ice, as ice, of a glacier that is moved downward by the force of gravity—as supposed by this ingenious theory—but the water, particle by particle. This water is again converted into ice. It is difficult to see here why the water, thus permeating, by supposition, the mass of the ice everywhere, should not act as a river full of ice does flowing downwards. But where, it may well be here asked, does enough of water come from to do the work of floating, or even of "oiling," such enormous masses as go to make up a thick and wide glacier? This, therefore, cannot account for the movement of a glacier down the slopes and across the levels of a mountain incline. Is there nothing else in nature which is found to move in the like way, it may be here asked, thus to help us to a solution of this difficult problem? I hope to be able to show that there is, or at least that there is yet another theory tending to a solution of this problem.

C. B. A.

LIGHTNING CONDUCTORS.

[22186.]—IN reply to "F.R.A.S.," p. 339, it appears to me that the lightning conductor of Chichester Cathedral, which he very truly describes as an elaborate arrangement, was put up with very small regard to sound principles. A woven copper ribbon is a very good thing—for the makers, because it is expensive, and glass insulators, &c., come under the same category. With such accompaniments I should expect to find a very bad earth, because that makes no show. Nothing can well be simpler than a good lightning-conductor, which only needs a sufficient mass of metal, either as rod, rope or strip, the rope being handiest for fitting up, and the strip less likely to be fused, but more exposed to injury otherwise. But a cathedral spire ought to have at least an inch section of metal, and here economy, so-called, is always unwise, seeing that the mere addition of mass of metal, while vastly increasing security, adds little proportionately to total cost.

The insulators are mischievous, and it would be better to insert strips of metal in the edifice, and connect them to the conductor, especially where bells and other metallic masses are contained in the structure which ought to be connected to the conductor, provided the prime condition of all is duly attended to. This, of course, is "good earth." This ought not in such a case to exceed 1 ohm resistance; but I understand some of our cathedral conductors have been found in the 800, the effect of which may be to make the conductor a source of danger instead of protection. It may increase conduction in the upper strata, and invite a discharge which, failing to be carried off, may then distribute itself into the buildi
had anything to do with protecting an i

structure, I should insist upon two or three distinct good earths at different parts, and lead the conductors to all of them, making the ridge cap of the edifice a part of the system of conductor if possible. Above all, I would put the money in solid metal and honest work, not in fancy tips and insulators.

Sigma.

SOCIETY FOR PSYCHICAL RESEARCH.

[22187.]—What a funny letter 22152, p. 341, is! The idea of collecting negative evidence! Why a single positive evidence upon any subject outweighs millions of negations. Asking, too, of all the world, if they have ever had "hallucinations." Of course they have. I take it I am myself a singularly unsusceptible subject, and I often have the "impressions" inquired about. Occasionally, I have to move about my house in the dark, and at times I have the impression of some presence walking behind me, and even taking the liberty of putting an arm over my shoulder. It has been so strong at times that I have actually been reluctant to move in the dark, and have taken the trouble to get a light. When it comes to that pitch, I always consider a few drops of tincture of podophyllin desirable as an exorcism.

I know perfectly well why I have this impression. I have a distant remembrance of being twice frightened—once as a small child by some stupid servant in the dark. I was also subjected to an extreme nervous impression, when I was ten years of age, by my father and uncle, who ought to have known better. They took me without a word of warning into a strange house, and showed me, in his coffin, an uncle of whom I had been very fond, and had seen a few days before in good health, and made me kiss him. I have a very distinct remembrance of the following night, and how little peace there was in the house. I also understand perfectly well that this nervous impression will never be removed. It has had one singular effect which proves its cause. I have had all my life an intense repugnance to approaching a dead body—but only of a white person; a dead Hindoo or negro—and I have been a good deal among them—never sets up the same action, any more than any other animal.

Now, such incidents act on the majority of mankind, and they are subject to the effects, though few may be able to trace the actual cause, as I can. Of what conceivable consequence can any record of such transient nervous reactions be, except so far as to render doubtful other things which may be natural, and actual facts of an entirely different order? The attempt to collect them seems to me a ridiculous absurdity, which can only result in throwing contempt on the whole proceedings of the society.

The collection of *positive* evidence, and the careful testing of the conditions and trustworthiness of the testimony, would be legitimate and useful; but the other course is reducing the society to the level of a set of old charwomen chattering horrors over gin and tea. To those who have examined these subjects it is well known that only a few, and those of special constitution, are capable of receiving impressions worth examining, and there is quite work enough before any society proposing to carefully examine the reality of these cases, without taking up those which are certainly unreal.

Sigma.

Fish-Balls.—Prepare a pint of cold salt fish, after it is freshened and boiled, and chop it fine. For this have not quite a quart of fresh-boiled potatoes, mashed fine, a cupful of broken butter, and two even teaspoonfuls of made mustard, with salt to taste. Beat up an egg light and mix with these last-named ingredients, adding a little cream or sweet milk; then add the chopped fish, mixing all thoroughly together. Make into balls on a floured board, and fry in boiling lard like doughnuts. When uniformly browned, remove from the fat with a skimmer, drain, put on a hot dish and serve. Carefully prepared these fish-balls are exceedingly appetising and nutritious.

To Ebonise Wood.—1. One pound of logwood, three quarts of water; boil three hours. Apply hot. When dry, brush over with a hot solution of 2oz. sulphate of iron in 1 quart of water. Repeat if not black enough as soon as dry. It will be better if 1oz. of powdered gall nuts is added to the latter solution, though it is not strictly necessary. 2. Wash the wood with a boiling decoction of logwood three or four times, allowing it to dry between each application. Then wash it with a solution of acetate of iron, which is made by dissolving iron filings in vinegar. This stain is very black, and penetrates to a considerable depth in the wood, so that ordinary scratching or chipping does not show the original colour. 3. Mix a strong stain of copperas and logwood, to which add powdered nut galls. With this solution stain your wood, dry, rub down well, then use French polish made quite dark with indigo or finely-powdered stone-blue.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[52131.]—**Boiler Query.**—"Machina" asks whether the method I gave for testing a model boiler would not strain it severely. It would strain it, certainly; but if it is not capable of standing that strain, it would be quite unfitted to be used for working a model engine, because pressure is apt to rise very quickly in such boilers, and they are not always well made. For models, the factor of safety should, I think, always be 4, and the method of testing I gave is simple and trustworthy. If the boiler is to have a valve permanently loaded to 50lb., say, it ought to be tested to 200lb. by the expansion-of-water plan. It is practically impossible to calculate the bursting strain of such small boilers by the usual formulæ based on the strength of metals.—Essar.

[52147.]—**Chilled Roll Turning.**—In reply to "Mechanic," I wish to know how many revolutions per minute a roll 15in. diameter should make? what steel is used? and how tempered? what kind of emery wheel? how many revolutions it should go at? also the speed of lathe and the traverse? Any other information regarding the above I shall feel grateful for.—A. R. Wilkinson.

[52216.]—**Storage Battery.**—If "F. H." will refer to a goodly number of back Nos. he will find a variety of storage or secondary batteries described, and can take his choice. Kabath's is about the best he can make; but the simple Faure is the easiest: see p. 442, No. 851, and the volumes since XXXIII.—Nun. Dor.

[52225.]—**Raising Steam by Gas.**—I do not think gas can be made at a cost of 1¼d. per thousand cubic feet to give a profit; but there is not much doubt that it might be used in boiler furnaces with advantage. On p. 49, Vol. XXXIV., there is an article on the Gasifaction of Fuel, in which it is stated that Dr. Siemens had proposed to gasify the fuel used on board steamships, by adapting a modification of his regenerative furnace and using the fuel as what is called "producer gas." I believe the late Sir W. Siemens had intended to bring this matter prominently before the Society of Arts—not so much with the idea of preventing smoke, as with increasing the economy of the coal. There need be no smoke from those long chimneys which "K. M. G." mentions, and would not be if their owners knew what's what.—Nun. Dor.

[52229.]—**Induction Coil.**—Impossible to answer this query. The "Y. E." should try without the condenser.—E. L. M.

[52232.]—**Brass Polish in Liquid.**—Rather a peculiar title this. Why not dip the brass in dipping acid? If that won't do, try the effect of oxalic acid, and a bit of leather to bring up the gloss.—Nun. Dor.

[52234.]—**Electrical Measurements.**—I hope some one will kindly help with an answer to my query. If anyone has a dynamo that gives good results, will he kindly give the dimensions and weight of wires on armature and field magnets, and show how they were arrived at by calculating? One example would suffice to explain the system.—A Private in Electricity.

[52235.]—**Manganese Battery.**—"Herne Hill" must not expect to find the information in books, for many writers do not know, and when they do are too learned to trouble themselves with such details. The quantity required should be sufficient to make a saturated solution.—P. G. T.

[52239.]—**H.P. of Engine.**—This query is always cropping up. Why cannot the querist do the sum himself? The area of the piston is 3·14in., the length of stroke ⅓rd of a foot; the revolutions are 25, and the pressure of the steam 10lb. For convenience, multiply 25 × 10 = 250 × ⅓ = 83 × 3·14 = 260. That number divided by 33,000 would give the h.p.—in this case, 13-1650ths of one horse-power, or say 1-126th.—Essar.

[52240.]—**Stone Polishing.**—"Lapis" can find much information in back volumes; but if he wishes for a definite reply to his query, he must say more definitely what he means by stone, and also by the "saw."—Mason.

[52246.]—**Payne's Battery.**—The querist can scarcely expect an answer to his query. The proper way would be to purchase a cell, and see how it is made.—C. Ker.

[52255.]—**Parian Cement.**—I am not sure about this; but Parian, like Keene's cement, is made from plaster of Paris mixed with some solution, allowed to set, then recalcined and ground to powder. In the case of Keene's, the solution is, I think, a saturated one of alum; in the case of Parian cement, a solution of borax.—Nun. Dor.

[52256.]—**Brush Dynamo.**—I am unable to give the resistance of my machine either in A. or F.M.'s, not having a resistance galvanometer. The weight of wire on the four pole pieces is 40lb. The commutator is formed of six copper segments, each one being ⅙ of the circle, with a small air space between each one of 1/16 wide. Will he kindly say how I can increase the E.M.F. without rewinding, and I will try it and report result.—Williams.

[52281.]—**Whitening Silver.**—I think it better to explain to the "Plateman" or "Young Jeweller" the rationale of the process, and then he will be in a position to try for himself, with some idea of what he is doing. He had better leave cyanide alone until he is compelled to use it. I don't mean to say there is anything very objectionable about it, but it is poison, and should not be used when the work can be done better without. The principle of the process of whitening silver and colouring gold is to work out the alloy on the face of the article, and leave the outer surface pure metal. In the case of silver, provided it is not of too low a grade, heat the work to a good red, and boil in a mixture of sulphuric acid and water (one part to 40). For fine silver, once boiling will be enough; for inferior grades repeat the process until the desired whiteness is obtained. If the articles are very delicate, heat with a gas blowpipe until thoroughly hot all over. The advice to boil in sulphuric acid and water 1 to 8 may be correct, but if you did so at a factory you would get the sack. For plated articles, the cyanide is useful, but even then tartar and other things will do as well; but if the "silver" is of so low a quality that it ought with as much reason to be called copper, you must plate with a battery or by rubbing on a mixture of chloride of silver and cream of tartar equal parts, made into a paste with water and applied with a clean piece of good cork. Further information if required, but not privately.—Nun. Dor.

[52296.]—**Nearest Fixed Star.**—I am much obliged to those correspondents who have kindly answered my query. The journal (I call it a serial) may be, as Mr. Arthur Mee says, an "excellent" one, and "does not pretend to be scientific." That is just the mischief of it; it pretends to be a great deal more than scientific. I have had something more than a quarter of a century's experience in printing, and though I am tolerably conversant with the capabilities of printers to make muddles, I really should like to get a glimpse of how such a muddle could have been managed by the most ingenious compositor; for not only was "Alpha" omitted, but the whole thing was inverted and bungled besides. Mr. Mee is no doubt correct in saying the passage I quoted was a "slip"; but I submit that however excellent the medium through which they convey their teaching, "teachers" have no justification if they slip in that fashion.—Stellarius.

[52302.]—**The Cheapest Food.**—Thanks to those correspondents who have recommended me to read certain publications, including one on "How to Exist [no, Live] on 6d. a day." The information may be useful to some of my fellow-readers, if not to me; because I am getting quite an old reader of the "E.M.," and know that the pith of all those books can possibly contain is to be found in my back volumes. By the way, I saw a rather pertinent complaint the other day—in the *Echo*, I think. A working man went to the place where one of these wonderful books is issued, and after paying 11d. for his dinner, he didn't feel satisfied. He very reasonably asked "Where is the 6d. a day?" There is, unfortunately, a great deal of quackery in connection with food nowadays, as if some wonderful discovery had been made since the days when the Roman legions invaded Gaul. I have just been reading in an American paper a most instructive article by Dr. A. T. Cuzner, of New York, who has been making an elaborate analysis of certain flours and "foods" which are offered for the acceptance of the American people. I suppose most of your readers have heard of the celebrated Pillsbury Mills at Minneapolis, where they claim to have introduced the most perfect and scientific method of making flour. Well, Dr. Cuzner took as a standard white flour, a sample of Pillsbury "Best"; as a whole wheat flour a sample of the Franklin mills; and also a sample of the Health Food Co.'s cold blast gluten flour. This is what he found:—

	Bran. gr.	Gluten. gr.	Starch. gr.
Pillsbury Best	—	265	1,600
Franklin Mills Entire Wheat Flour	50	315	1,000
Health Food Co.'s..........	150	150	900

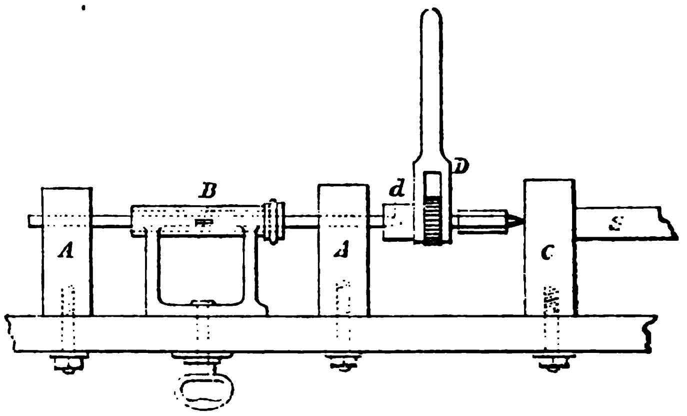
The microscope is not a complete test of the value of any flour, so Dr. Cuzner adopted the washing process as well, and the result was as above. The white flour contained a large per cent. of gluten and no bran residue; but as gluten cells stick to bran, the Franklin Mills' sample showed the highest amount of granular gluten ever found in fine flour—viz., 315gr., or allowing half the bran residue as gluten, 340gr. Here, however, is the curiosity: The

Health Food Co.'s sample contained actually a larger quantity of bran than is natural, indicating pretty clearly that bran had been added! It seems that I have been guilty of "flying in the face" of an answer (sic) sent to my query by Mr. Mee. I remember the "reply" sent by that gentleman, which I characterised as absurd, because, as an answer to my question for the "cheapest" food, it recommended something just double the price of Scotch oatmeal; but I am at a loss to know how I performed the gymnastic feat of flying in its face. It seems, too, that I have "very properly" admitted something—Mr. Mee being the judge of what is proper; also that I "wax so wroth" at some cereals which Mr. Mee has taken under his special protection, but which, strange to say, he does not describe in any definite manner. I should be very sorry indeed if I could believe it possible that the poorer inhabitants of the Principality cannot get the best Scotch oatmeal, or find a roller mill or a couple of stones to crush wheat, both of which, I believe, are "cereals," though Mr. Mee seems to hint that they are not. I spoke of them, because I know that they are the best and cheapest of the cereal foods, and as to the side-issue about dyspepsia, I can only say that doctors cannot provide a new stomach to order; but, if boiled crushed wheat cannot be digested, I am afraid that the stomach is hopelessly ruined. Dr. Edmunds, in his altogether excellent directions for making oatmeal porridge (Nos. 848 and 906), recommended a little heavy calcined magnesia to be taken where the porridge was not digested easily at first, and I presume that is a general remedy. If the inhabitants of Wales cannot afford a little roller mill, let them get two large flat stones, and just crush the wheat between them, not grind it. If Mr. Mee will condescend to inform us of the real character of his peculiar cereals, we may be in a position to judge whether they are such wonderful things as he seems to think; but I would beg of him to remember that my question has reference to food value, not to his or anybody else's personal tastes.—S. R.

[52383.]—**Crumpets.**—Take 2lb. of flour, make into dough with warm milk and water, adding a little salt, three eggs, well beaten, and three teaspoonfuls of yeast mixed to the consistence of thick batter. Stand before the fire to rise, pour into greased tins, and bake slowly until of a light yellow. If "S. B." wants a commercial recipe, he will, of course, omit the eggs, and I think he would find it more convenient to use baking powder than yeast; but the addition of even one egg to the quantity of flour above given will vastly improve the plain article.—B. M.

[52387.]—**Bending Brass.**—If "Jim" can make his brass soft by heating it to a red, he will be able to easily bend it, by getting some one to make him a moulding of the desired form. Thus the mould might be carved out of beech, and a block to fit other side. It would be advisable to have the under block a good length; the other may be any convenient size, and be hammered with a mallet. Brass, after being heated red, becomes very soft, but the hammering makes it hard again. Hence, if "Jim" has many to do, it would be advisable to have his "form" cast in iron longer than his plates; or get a proper set of rolls made at once. Two sets of shaping rolls and one in the centre, set a little out of line, will keep his plates quite straight, and he can bend as fast as he can get them through the machine.—J. T.

[52411.]—**Cheap Lathe.**—Although I have never adopted the following method, an acquaintance of mine made use of it with successful results. Having arrived at that stage where the headstocks are fitted to the bed, we proceed in this way. Get two blocks of hard wood, A A, and fasten down on the bed, with the article to be bored, say the poppet, between them. In these blocks, in a position corresponding exactly with the poppet centre, bore two holes with a centre-bit to take a cutter, or boring bar, fitting closely, but not so tight that it will not turn round when slight torsional leverage is imparted to it. Let this bar be ⅝in. or ¾in. in diam. (as large as the bore of the poppet will permit, for the sake of rigidity). A slot cut through at B will receive the boring tool. At the right-hand end, *d*, the bar is filed square, like the shank of a drill, in order to fit into a ratchet brace, D. Behind the ratchet brace, a third block of wood, C, is fixed; but this block, instead of being bored like the others, has a piece of metal plate screwed upon its face, with a countersunk hole corresponding in position with the poppet centres, which hole receives the point of the ratchet brace, and becomes its point of resistance. The strut S is carried from the back of the block C, to any convenient place of support—a wall, if available. To bore the hole, work the ratchet lever, tightening it at every third or fourth turn. When run out, carry the back block, C, forward, two or three such removes being sufficient. The sketch shows the cutter half-way through. It is rather a slow process, but one doesn't mind a little time in amateur work. In boring the headstock, the ¾in. hole for the back centre must be drilled first; then 2in. or 3in. of the end of the cutter bar turned down to slide in it, while the cutter bores through the mandrel brasses. J. H.



[52435.]—**Extraordinary Phenomenon.**—I will call it "achromatopsy" next time, and then I shan't be accused of "poking fun" (p. 349), because critics will dive into their books to discover the meaning of the term. "H. O'B." appears to think that the "colour-blind" see everything as either black or white.—Nun. Dor.

[52460.]—**Casting Lead.**—If the castings are light, and a number are required, I have tried plaster of Paris, and find it works well. See that it is properly dried, and if the mould is so that a little blacklead can be rubbed on the face with a piece of rag, the casting will look much better. Don't have the lead too hot, or it will cause the plaster to crack. With care, several hundred castings can be made off one mould.—Williams.

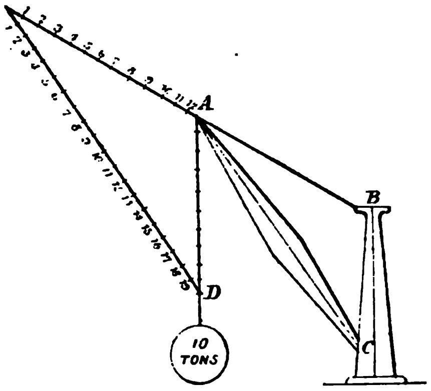
[52465.]—**Belt Working off Pulley.**—Your belt works off the pulley because your shafts are not parallel. Take off the flanges and adjust the shafts truly parallel. The belt will run off the pulley on the side at which the shafts are furthest apart. —R. R. N.

[52465.]—**Belt Working off Pulley.**—If "A. B. C." will have the face of pulley well rounded similar to a barrel, the belt will not work off unless it is stretched more on one side than another. See that the pulleys are in a straight line. —Williams.

[52466.]—**Cross Belts.**—Cotton belts are not suitable for cross running: the edges wear very fast. Try a good leather one, and order from the makers to run crossed; and if it is a double one, have it copper stitched. In working, castor-oil the edges.—Williams.

[52466.]—**Cross Belts.**—There is always more or less attrition in a crossed belt, and nothing but leather is suitable for this purpose. If a 4½in. belt gives enough power, a leather one would last a long time, though in the case you have given the attrition will always be considerable, and power is absorbed thereby. If circumstances admit of it, an open belt with the working side at the bottom (the shafts being horizontal) would be far preferable. This arrangement causes the slack side of the belt by its own weight to embrace the pulley, and admits the use of a comparatively slack belt.— R. R. N.

[52474.]—**Strain on Jib-Chain.**—If by "jib-chain" "Radnor" means the tie-bar (or chain) A B, then let him make A B = length of tie-bar;

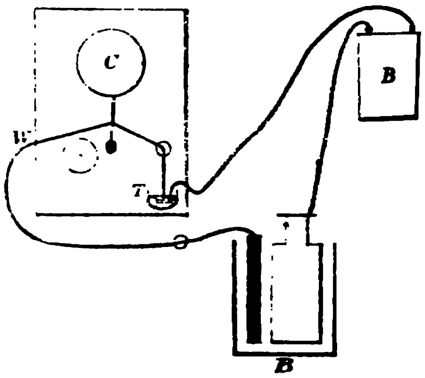


A C = length of jib; B C height of post. Draw A D vertical equals W = 10 tons, or 10 divisions of any scale. From D draw D E parallel to the jib until it cuts the line A B produced to E. The strains may be measured off by means of the scale as follows:—Strain on tie-bar = A E = 12¼, strain on jib = E D = 19½ tons.—J. S. B.

[52472.]—**Sailing.**—No glazing or smoothing of the sails of a ship would make any appreciable difference to its speed. The friction between particles of the air (their resistance to motion over or against each other I mean), is less than that between the same particles and the smoothest surface that could be produced on the sails. The result, therefore, whether the sails are smooth or comparatively rough, is the same: a film of air clings to the fabric, becoming, for the time as it were, a part of the sail, and the friction is between particles of air only a little distance away from the sail, and not between the surface of the sail itself and the air.—W. Wyatt.

[52479.]—**Electric Clock.**—Having read "Kiko's" reply to this query, I am much interested with it. I have made an arrangement so that my clock rings an electric bell for ten minutes: but should like if "Kiko" would send a sketch of his arrangement. I am sure he would oblige other readers besides.—A Rechabite.

[52479.]—**Electric Clock.**—If "Nomen" is satisfied to have his bell strike in the interval between each stroke of his clock, he can do so in the following manner:—One wire from the battery is to be connected direct with the bell. The other wire is to be connected with the hammer of the clock in such a manner that when the hammer rises it will drop the end of the wire into a small trough of mercury, or upon a small plate of clean copper, where the break in the circuit is made. The diagram will explain itself. C is the clock, B the bell, and B′ the battery, and T is the trough of mercury. The wire between the hammer and the trough passes through one or two small rings, which serve to guide it, and is slightly weighted near its end, in order to insure its dipping into the mercury when the clock hammer rises. The wire between the point W and the hammer should be twisted into a spiral, in order to allow the hammer to rise freely. I can testify to the working of this plan, as I have done it myself exactly as I have described it. The best battery for this work is the Leclanché.— W. B. M.



[52482.]—**Electric Bell.**—I have a similar bell hung in my bedroom, which, like the querist's, refused at times to work. On watching it closely, I found that the contact-spring stuck to the pillar-screw; therefore, the current was not broken at all, so I bent the hammer back away from the bell very slightly indeed, so that it would have to go farther to strike the bell, and it has not failed to work since.—F. B., Moseley.

[52484.]—**Dark Slides.**—Get a piece of mahogany, 2ft. long by ¾in. deep and 5/16in. wide [illegible] measurements. With circular saw, run ⅛in. width three grooves—one in the probable that a metal, otherwise so permanent, would lose its durability when so thin."—S. R.

[52530.]—**Engine v. Man Power.**—One man's-power is usually reckoned ⅙th of a horse-power, or = 5,500ft. lb. Therefore, a "two man-power" gas engine should give out 11,000ft. lb. But you will find it better and more economical to have a ½-h.p. gas engine, as the smaller sizes are not so reliable except when new and in first-rate condition.—Labor Omnia Vincit.

[52535.]—**Electro-Magnets.**—An article of mine is in type on this subject, and will be followed by another, in which I will see if I can meet the querist's wants without merely working out a particular case, which is a thing I never care to undertake, except as an example.—Sigma.

[52540.]—**Incrustations in Boilers.**—Your correspondent "Ferro" should visit the locomotive sheds of the London and North-Western Railway Company in London or Liverpool, or one of the many large manufacturing establishments to which the patentee of the Porter-Clark process would be willing to refer him, for a view of the "practical working" he desires information upon. The leading feature of the process is the precipitation of the carbonate of lime of the hardwater by the use of caustic lime in solution, the caustic lime becoming carbonate and being precipitated also. With soda ash the soda would remain in solution. Moreover, the price of the soda is ten times as great as that of the lime. Agitators are employed in the Porter-Clark process, which is carried out in closed vessels and pressure filters, whereby large quantities of water are treated, by continuous working, within a small space, and, being under pressure, the softened and filtered water at Camden re-ascends without pumping to the service tank. The larger the quantity treated, the smaller the cost per 1,000 gallons.—C. C.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Natural Gas for Manufacturing in Western Pennsylvania.—For nearly ten years past natural gas has been utilised for manufacturing and lighting purposes in only a few instances, although several abundantly-yielding wells, and a large territory from which it was known gas could be drawn, have been familiar topics among the manufacturers of Western Pennsylvania. Recently, however, attempts are being made to utilise this natural gas on a large scale by the iron and steel and glass manufacturers. All the window glass manufacturers of the Southside, Pittsburgh, Pa., have closed a contract with the Niagara Gas Company to supply their factories with natural gas. The company is now operating in Washington County, and representatives of each factory have been negotiating there for the drilling of gas wells and laying of pipe. The manufacturers have leased about twenty thousand acres of land in that county, in the neighbourhood of the McGugin well, the largest natural gas well in the world. They expect to arrange for the drilling of several wells on their territory, the work to begin at once. The Edgar Thomson Bessemer steel works, at Braddock, Pa., have also been completing arrangements to run their whole plant, in which 100 boilers are in use, by natural gas to be obtained from a gas well at Murraysville.

Raised Doughnuts.—Mix together one quart of flour, two cups of sugar, half a teaspoonful of grated nutmeg, a pinch of allspice, a teaspoonful of cinnamon and a teaspoonful of salt. Cream half a cup of butter and put in, stir half a cup of good strong yeast with a pint of warm sweet milk, and put in with the rest. Of these make a soft dough and let it rise over night. Next day stir in three eggs beaten separately, and a pint of flour with a half teaspoonful of soda mixed with it. Let this dough rise till it is light, then fry in hot fat.

QUERIES.

[52548.]—**Wharf Crane.**—Would any of your readers inform me what measurements I should take of a wharf crane to enable me to calculate its lifting capacity? Also, could any one recommend a good simple work going fully into this and similar matters?—Vaga.

[52549.]—**Unfermented Bread.**—I have for some time made the unfermented bread described by "J. F. E." and "A Physician" in the E. Mechanic two or three years ago, but lately find that the bread has an unpleasant smell. Can any of your correspondents kindly explain this? I much like the unfermented bread, and should regret having to give it up because of this smell.—C. E. L.

[52550.]—**Power of Engines.**—Will some readers tell me what power my engines are? I have a pair connected together. The cylinders are 18in. diam., 4ft. stroke, cut off steam at two-thirds of the stroke, and work at a pressure of steam in the boiler of 45lb.—Engineman.

[52551.]—**Small Steel Balls.**—Could any of our readers give particulars of tools, &c., for making?—R. G.

[52552.]—**Steel Reeds.**—Purposing to make four sets of steel reeds for my harmonium, the body of which I have just finished, I should feel obliged for information as to length and breadth of slit in brass frames for tongues for a 4, 8, 16 and 32ft. set of five octaves each, and what thickness should I make the brass frames for the different sets? What effect has the thickness of the frame on the tone of the tongue?—Brazier.

[52553.]—**Photographic.**—Will some subscriber kindly answer the following queries?—(1) We are told that the rapidity of a lens is equal to $\left(\frac{f}{a}\right)^2$ (f being focal length, a aperture). May this rule be applied equally to doublets and single-view lenses? I have seen the rule applied to both, but have also heard it stated that a photo. taken with one combination of a rapid rectilinear requires only twice the exposure (with the same aperture) that the whole lens would require. One of these statements is obviously incorrect. (2) Can the back combination of a portable symmetrical lens be used alone as a single-view lens? (3) Would a pair of portable symmetrical lenses answer well for general stereo work, and would 4in. or 6in. focal length be the most suitable?—Amateur.

[52554.]—**Travel of Gauge.**—What travel should a gauge (or inside calipers) have in a round hole from 1in. to 100in., to secure a good fit?—A. R. Wilkinson.

[52555.]—**Piano Keys.**—Would Mr. Davies oblige by informing me the best and handiest way to prevent keys from sticking down? The keys appear to have warped or twisted at the hopper end of key, and rub one against another. Surely good keys should not do so? The keys appear to be made of a very light wood to feel at; rather like colour of pitch pine. What kind of wood should they be made of?—Ivory.

[52556.]—**Geometrical Drawing.**—Can any of "ours" mention the title of the textbook or books used by students with a view to passing the examination in this subject of the Science and Art Department? Is "Payne's Projection" sufficient for the solid geometry in all three stages?—Stud.Inst.C.E.

[52557.]—**Ornamental Steelwork.**—Would any one kindly explain the manner French mechanics ornament bright steelwork, say the plates of locks, &c., with geometrical designs which are more or less elaborate, according to the quality of the articles ornamented (moirés)?—T. W. W.

[52558.]—**Food for Bees.**—Will some of the many readers of the "E. M." kindly give me a good recipe for making candy for bees? What sort of sugar should I use, what proportion of water, and should I use any cream of tartar in it? I have tried making it several times; but it gets quite grainy, something like the sugar being boiled, and if boiled less it is too soft and sticky. I can't make it like barley sugar—hard, but not grainy. The best way I succeed in doing it, though not well, is by boiling to syrup first, and then boil it until all the water gets evaporated. If it gets slightly burnt is it injurious to the bees? I was told putting lemon-juice in it makes it hard. Is it so?—O.

[52559.]—**Extracting Aniline Colours.**—Is there any acid (or other substance) that will extract aniline colours from papers, &c.?—Chemicus.

[52560.]—**Springs.**—As I have been unable to get any information respecting the music-turning machines referred to, will "S. M." kindly say if they are costly articles? I presume they can be obtained through music-sellers? With a little alteration one of them would perhaps suit my purpose.—Inexperienced.

[52561.]—**Waterproof.**—I have recently seen in the shops a new waterproof overcloak with a peculiar white glossy surface resembling plush. It is called the electric cloak. I should be very glad if any of your numerous readers could inform me the process by which this surface is obtained? From a cursory glance it appears to be from a surcharge of sulphur; but in this I may be wrong.—James T. Vincent.

[52562.]—**Terracotta.**—I have a terracotta statue which is broken at base. The fragments will not piece. Can any reader inform me how to make a new one—and how to get the desired colour? I have no knowledge how to mould one, and would be thankful for information.—Ercildoune.

[52563.]—**Harmonium.**—As Mr. Fryer seems to have overlooked my query on p. 269 (reply 52125), may I try to catch his eye through the query column, and ask him what size he would make the holes leading from the windtrunks and the reservoir to suit valves of the sizes given by him on p. 248? Will he also explain how he fits the escapements to those valves—that is if I am not asking him to disclose trade secrets?—Fliegen.

[52564.]—**Model Yacht.**—Can any of our friends give good lines for a model yacht (schooner preferred), and also say if pine, oak, or mahogany "planks" are the easiest to bend and work? The model is to be about 4ft. long, and to be built, as there is such a difficulty in getting suitable log.—V. P. Y. C.

[52565.]—**Spectroscope.**—It seems to me that amateurs might easily make a pocket spectroscope if some one would give similarly plain directions as were given by "Aldebaran" for telescopes. I mean an instrument something like the star spectroscope or the rainband spectroscope.—Latheman.

[52566.]—**Plaster Casts.**—Will any one tell me how to take plaster casts from clay models where there is a good deal of undercut work? The work I mean is done for the students of art classes, who now have to send in all their model work in the shape of plaster casts. The workman moulds up the clay to the desired form, and then the caster builds a frame round it, and pours over it the plaster—working the latter well down. When the plaster is dry, the clay is picked out a piece at a time, and as the work is thus destroyed it is of importance to make sure of getting the plaster mould all right. When that is obtained a plaster cast is taken from that. Now will some one help us in this, and give us such instruction as may enable us to take our own casts?—Seven Students of an Art School.

[52567.]—**Packing Screws.**—Could any of "ours" kindly inform querist if they are aware of any machine for making screws for the removal of old packing from stuffing boxes, &c.? If so, give the name of the maker; if the machine is a patent, and the probable cost of the screws. Also, is there any particular name given to such screws?—Johnstone.

[52568.]—**Oxidising Silver.**—I have tried the two methods recommended on p. 311, but neither makes the silver black enough, and it will not stand the scratch-brush. I want a jet black.—E. H.

[52569.]—**Steam Jacket.**—Having an engine cylinder steam jacketted, supplied with steam from steam chest through a 1in. pipe, and a stop tap in pipe to shut steam off, underneath cylinder is another pipe leading to a steam trap: will the trap keep the steam back, and let any water pass which may be in jacket? Also, is it necessary to keep the tap always open when the engine is at work? I have been told to close it after the engine has started. If so, I cannot see the use of the steam trap. Perhaps "L. O. V." or "Firer, Dewsbury," will explain the use of the steam trap to me, and oblige.—Cold Chisel.

[52570.]—**Hair.**—If any one can kindly tell me how to destroy the roots of superfluous hair, I should be much obliged.—X. X.

[52571.]—**Carmine.**—Can any of our readers who have a practical knowledge of the subject tell me how much pure ammonia it will take to dissolve 1oz. of chemically pure carmine?—F. H.

[52572.]—**Sunspot.**—Will any reader give me an approximate date for the large sunspot which not long ago was visible to the naked eye? From cloudy weather and other causes I regret to say that I missed it.—T. W. Webb.

[52573.]—**Dimensions of Boiler Plates.**—Will Mr. S. Nicholls, or some other reader, give the rule for finding the length of plates for dished and flanged ends of boilers?—Boiler.

[52574.]—**Torpedo Engine.**—Can any reader kindly furnish me with the size and power of engine used in propelling the Whitehead torpedo?—Gun Cotton.

[52575.]—**Grease.**—Will some reader of ours be good enough to give me a recipe for the manufacture of hot and cold neck grease suitable for use in mill and forge work, and the method of preparing same?—Grease.

[52576.]—**Boat Cloths.**—Please give me the correct size the deck cloth, cabin cloth, and wings should be for an ordinary canal boat, with an outline plan showing the exact position of the various holes for tying on. Also what length should the ropes be that are spliced in these holes?—Tarpaulin.

[52577.]—**Organette.**—I wish to make one of these instruments myself. Will any one kindly tell me a good selection of reeds (there are only 14 in the common instruments), and give any directions for cutting the music papers? How are the spaces marked off so as to find the exact position to give correct time?—T. J. P.

Making Black Leather.—It is not every sort of leather that will take the black colour equally well, says *Gerberzeitung*, the oak tanned taking the colour best, pine and birch bark leather taking it the worst. If the leather does not take the colour well, it should receive some previous preparation. A solution of the carbonate of soda is generally used for this purpose; although the use of caustic soda or ammonia is less injurious to the leather. The leather is then washed off with clean water and the ground colour laid on thinly with a brush and rubbed in until it is all taken up. A good preparation for this purpose is obtained by boiling Campeachy wood for half an hour in twice its weight of water, adding a sixth part of fustic to give a more intense black, pouring off the decoction, and boiling the wood in clean water for two hours. Some potash may be added to the second decoction to aid in the extraction. The dye is poured off clear or filtered and preserved in a closed vessel. The black colour is prepared by treating old iron with a decoction of barley, sour beer, or sweet tan liquor. It is left for a few days, the dirt removed from the surface, and the clear liquid drawn off. This black colour must not be applied until the ground colour is completely absorbed, or the leather will be sooty. After the black dye has been rubbed in with a brush, it will have a finer appearance if another light coat of Campeachy solution is applied, and then rinsed with water until it runs off clear.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, JANUARY 4, 1884.

THE PROGRESS OF ASTRONOMY IN 1883.

IF the year which has just drawn to a close can scarcely be regarded, in an astronomical point of view, as a very eventful one, yet it has seen an amount of good and enduring work done, and results achieved which may fairly entitle it to be regarded as marking a yet further advance in astronomical science.

The chief celestial phenomenon of the year has undoubtedly been the Total Eclipse of the Sun on May 6th, remarkable, inter alia, for the great length of totality. The sun, as probably a large proportion of our readers are aware, was hidden for nearly 6 minutes, and this is a duration which will be only once exceeded during the remainder of the century—viz., on Aug. 29th, 1886, when, in West Africa, the sun will be covered by the dark disc of the moon for 6m. 21s. The Eclipse observed in the May of the previous year (1882) lasted less than two minutes. The recent Eclipse was observed from Caroline Island in the South Pacific by observers sent out by Austria, France, Italy, the United States, and this country. The Corona was observed to extend visibly to some two diameters of the sun—i.e., to a height of 1,732,000 miles above his surface. The French photographs show that its real extension was greater than that observable either to the naked eye or in the telescope. Dr. Hastings found the line D of sodium dark in the Corona—a pretty conclusive proof of its consisting of matter which reflects sunlight (of which M. Janssen obtained independent evidence), and one affording a strong corroboration of the truth of the theory of the meteoric character of the outer part of the Corona. Moreover, in the largest of the Coronal streamers, M. Tacchini detected the spectral bands so familiar in the spectra of some of the recent comets; and there are but few people now, and assuredly no astronomers, who are ignorant of the very intimate connection which exists between comets and meteors. The form of the Corona remained absolutely unchanged during totality. MM. Palisa and Trouvelot occupied themselves in making a diligent search for the entirely mythical planet Vulcan. M. Palisa was supplied by Prof. Holden with a chart of that region of the sky in which the sun was situated, and while he succeeded in recognising nine stars in the Bonn "Durchmusterung," could not see the slightest trace of any fifth mag. star unmarked in his chart, between R.A. 2h. 52m. 14s. to 19° N., and R.A. 3h. 40m. 16s. to 22° N. In sweeping with his instrument, M. Trouvelot, while easily recognising 41 and ε Arietis, did come across a reddish star, which he was, for some time, disposed to imagine might be the intra-Mercurial planet. Professor Holden has since shown that this was simply α Arietis. We can scarcely conceive, after this, that any future observers of total solar eclipses will waste a single instant of their precious time in looking for Vulcan, whose non-existence may now be considered to be irrefragably established. The English observers were successful in getting photographs of the bright line spectrum which appears at the instant before and after totality. The red prominences, which have formed such a marked feature in former eclipses, were, on this occasion, conspicuous by their absence. Much coronal structure is shown in the French photographs.

Two Comets have been discovered during 1883. The first one on February 23, by Messrs. Brooks and Swift, in America; the second by Brooks alone on Sept. 2nd, which has since been identified with the one discovered by Pons on July 20th, 1812. The latter is visible as we write. The spectrum of the Brooks-Swift Comet, as observed by Dr. Von Konkoly, at O'Gyalla in Hungary, consisted of three bright lines superposed upon a very faint continuous spectrum. There can be little or no doubt that these lines belonged to hydrocarbon. This observation has since been repeated at the Royal Observatory at Greenwich.

Reverting to the Sun, we may recall the numerous and striking indications of activity afforded by the splendid spots and groups of spots which have appeared; some of them having been visible to the naked eye. Notably was there one at the beginning of April, covering an area of upwards of 484,000,000 square miles on the solar surface. All observers of solar prominences with the spectroscope are familiar with the line D_3 immediately following D_2, which, as every one knows, is one of the lines of sodium. So far, this line D_3 had never been identified with that of any known terrestrial object, and the unknown substance to which it is referable was called, for want of a better name, "Helium." During the past year, however, Professor Palmieri has discovered this line in the spectrum of certain Vesuvian lava; so that at last it would appear that we are in the way of identifying this hitherto unknown element in the solar atmosphere. We mentioned last year (Vol. XXXVI. p. 396), the invention by our greatest living English spectroscopist, Dr. Huggins, of a method of photographing the Corona of the uneclipsed sun. Grave doubts, however, have since been thrown on the validity of his mode of proceeding: in fact, it is now suspected that the pseudo-Coronal structure visible in his negatives may have its origin in reflection from the dark backing of his photographic plates; such backing being painted on in streaks with a brush.

In connection with Celestial Photography, nothing has hitherto ever been effected to equal the superb photograph of the great nebula in Orion obtained by Mr. Common, with his 3ft. reflector, on January 30th, 1883. This marks a very distinct advance, indeed, in the photographic reproduction of celestial objects. Dr. Huggins has also successfully photographed the spectrum of this nebula with an 18in. reflector.

Three new Minor Planets have been added to the already terribly overgrown list of these useless and uninteresting bodies; the known number of which now amounts to 234. This exaggerated meteor-ring (for it is very little better) between Mars and Jupiter is now becoming emphatically a nuisance, as much valuable time is wasted in certain observatories in efforts to identify and follow objects which are wholly unworthy of the labour bestowed on them. In the cases of the few which approach nearest to the earth, Juno, Flora, Victoria, Sappho, and one or two others, it is needless to say that they can scarcely be too sedulously observed, affording, as they do, one of the most promising and accurate methods of determining the Solar Parallax. As regards, though, by far the larger proportions of these bodies, we are indebted to German astronomers for following them at all. They might very well be let alone altogether.

In Physical Astronomy, one of the most important essays of the past year was made by Mr. E. J. Stone, F.R.S., the Radcliffe observer at Oxford, and P.R.A.S., in his investigation into the alleged retardation in the rate of the Earth's rotation (in other words, the lengthening of the terrestrial day) in connection with the amount of lunar acceleration, supposed to be otherwise unaccounted for. In his very remarkable paper, first read before the Royal Society on April 12th, of which he gave a *vivâ voce précis* on the succeeding evening at the Royal Astronomical Society, he advances the novel and somewhat startling hypothesis, that the strange discordance between the theoretical value of the secular acceleration of the moon's mean motion, as determined by Prof. Adams, and that required to reconcile Hansen's tables with the records of ancient eclipses, really had its origin in the fact of our having changed our unit of time! The Radcliffe observer contends that no proper distinction has been drawn between the longitude of the mean sun and the mean longitude of the sun, and that when consistent units are adopted, the observed acceleration of the Moon's mean motion agrees with that required by theory. Mr. Stone's paper was subsequently published in an extended form in the R.A.S. *Monthly Notices* for May. If we accept Mr. Stone's deductions, it follows that the whole question of the supposed increase in the length of the day must still be considered as sub judice, and without any practical or observable proof whatever.

M. Nyren has re-determined the Constant of Aberration, from many years' observations at Pulkowa: he finds it to be 20·492″. M. Folie, of Liége, has discovered what he believes to be observable proof of diurnal Nutation, whence he concludes that the earth must consist of a fluid nucleus surrounded by a crust scarcely exceeding 180 miles in thickness. A short account of M. Folie's investigation was given by one of our correspondents on p. 300.

A re-determination of the Mass of the planet Saturn has been made by Professor Asaph Hall, from observations of his satellite Iapetus during the years 1875, 1876, and 1877. Calling the sun's mass unity, Professor Hall finds that of Saturn to be $\frac{1}{3482\cdot2}$.

Although the investigations of Professor Asaph Hall on the Parallax of α Lyræ and 61 Cygni terminated early in the autumn of 1882, his results did not reach this country until 1883, so that we may fairly include them in our review of work pertaining to the latter year. The entire research is of the most exhaustive character, and is founded on a long series of observations of the highest class, commencing in the year 1862. As final results, Professor Hall finds the parallax of Vega to be 0·1797″ ± 0·005612″; so that light must occupy 18·11 Julian years in passing from this star to our sun. The parallax of 61 Cygni he determines to be 0·4783″ ± 0·01381″, indicating a distance which light takes 6·803 Julian years to traverse.

Our remarks with reference to the date of the appearance in England of Professor Asaph Hall's work apply, mutatis mutandis, to the perfectly masterly monograph of "The Central Parts of the Nebula of Orion," by Professor Edward Holden, recently issued as an appendix to the "Washington Observations" for 1878. No one can henceforward attempt the study of the marvellous region surrounding θ Orionis without the aid of Professor Holden's exhaustive account of all that has, so far, been observed and recorded of it.

A preliminary account has been given by Her Majesty's Astronomer at the Cape of Good Hope, Dr. Gill, of his telegraphic determination of the longitude of the Royal Observatory there. It is a most noteworthy fact that this determination is within a single quarter of a second of that made by Henderson from lunar observations about 1833.

M. Stephan continues his Catalogues of Nebulæ observed at Marseilles. 45 new ones appear in that for 1883.

A "monumentum ære perennius" has been erected by Professor Peters, of Clinton, U.S., in the shape of 20 charts, containing from 2,500 to 3,500 stars each, down to the 11th mag. of Bessel's scale, comprised in a belt extending 30° on each side of the equator. Each map covers 20min. in R.A., and 5° in declination, and is on a uniform equal surface projection on a scale of 2·36 inches to 1°. These maps are photolithographed from Professor Peters' original one.

Stellar Photometry is steadily pursued at Oxford, and at Harvard College Observatory in the United States. A very simple and ingenious form of photometer for the measuring of variable stars has been designed by the Rev. T. E. Espin, observer to that very excellent and practical little association the Liverpool Astronomical Society. A description of this instrument from Mr. Espin's own pen appeared on p. 384 of our last volume.

The Great Red Spot on Jupiter, which has formed so marked and persistent a feature on the face of the planet since the year 1879, is now fading perceptibly; in fact, it is only visible in instruments of considerable size and power.

The Observatories of Copenhagen, Greenwich, Kiel, Milan, Paris, Pulkowa, Utrecht, and Vienna, have fixed upon Kiel as a centre for the transmission of Astronomical telegrams. An annual subscription of £5 entitles any Observatory to receive telegraphic information of every fresh astronomical discovery. During the past year, Mr. G. H. Darwin has been appointed Plumian Professor of Astronomy at Cambridge; and Dr. Doberck has been transferred from Dunsink to the Directorate of the Observatory at Hong Kong. M. Houzeau has resigned the Direction of the Royal Observatory at Brussels, causing, it is to be feared, [illegible] our own National Observatory sustained by the retirement of Sir George Airy.

The [illegible] glass for the equatorial of the Lick Observatory approaches completion, and the great French refractor of [illegible] feet in focal length, which is to be [illegible] the Observatory in Paris. [illegible]

THE NEW PATENT RULES.

[illegible]

working of the new Act would mainly depend. It is too early to say definitely that the new rules will spoil the Act; but it is too clear that red tape has had the usual amount of influence in framing them. As we announced last week, no applications would be received if they bore an earlier date than Jan. 1, 1884; but it is doubtful whether any one had authority to make such an order, which practically precludes inventors from entering their specifications on the first day of the new Act, because it is next to impossible for country residents to get the declaration sworn and the other documents into the office on the same day. Communications from abroad are not abolished, for a special form is provided in the schedules (A1), by which an agent or any other person can obtain a patent for an invention communicated to him from abroad; and although there is nothing about it in the Act, Rule 31 imposes on the applicant the duty of furnishing the Comptroller with a drawing illustrating the features of novelty constituting his invention, and a concise explanatory statement, in addition to the specification—the object being evidently to save the office the cost of preparing abridgments, and to obtain ready-made copy for the new illustrated journal which the Board of Trade will issue. The third clause of the 45th Section of the Act, which distinctly states that as regards the amount and time of payment of fees, the Act shall extend to all patents granted before its commencement, is put on one side by Rule 43, which provides that the fees payable before the expiration of the eighth year according to the Act shall be payable before the end of the seventh in the case of patents granted prior to 1884. It would seem, then, that all existing patents, and all those to be granted which will bear dates anterior to Jan. 1, 1884, the rule is "as you were"; for the Act having been overridden so far as section 45 is concerned, it would seem that even the new method of paying the £50 and the £100 by instalments will not apply to patents bearing dates prior to 1884. It appears to be tacitly admitted that section 45 in the new Act, so far as [illegible] is a mistake, [illegible]

[illegible]

pointed to receive such declarations; and all other documents or communications between the Comptroller and the applicant may be signed or made by an agent duly authorised to the satisfaction of the Comptroller. The application should be made on the printed form provided for the purpose, and contain an address to which notices, &c., may be sent; but if a printed form cannot be obtained the application should be written in large and legible characters in the English language upon one side of strong wide-ruled paper 13in. by 8in., leaving a margin of 2in. on the left-hand side. That applies to all documents and copies of documents sent to or left at the Patent Office. The applicant having procured the form and stamp (£1), will fill it up in accordance with the directions, giving merely the title of the invention (which, however, must clearly indicate its nature), and get it signed by the magistrate before whom the declaration is made. (The fee is usually 1s.) This document must then be forwarded to the Patent Office, accompanied either by a provisional or a complete specification in duplicate. No stamp is required on the provisional, but £3 is payable on the complete specification, one copy of which must have the stamp affixed in the regulation manner. It is advisable to purchase these forms, which are sold at a cheap rate; but where it is impossible to do so, or where the form is not large enough to contain the whole of the description, the continuation must be written on wide-ruled foolscap with a margin as above mentioned. When drawings are necessary, they must be made on half-sheets or sheets of imperial drawing-paper, and be within a border line of 19in. by 12in. or 27in. by 19in. with a margin of half an inch all round. A copy of these drawings must also accompany them; but in this case they may be on ruled imperial drawing paper, or upon Bristol board; have the same dimensions as above, and be prepared according to the special directions following. The border should be one fine line only, but all lines must be absolutely black, of the best quality Indian ink, and care must be taken to secure the same strength of ink throughout, that is, absolutely black. Shading [illegible] e a drawing with every specification, htsmen will be sorely puzzled! As a the applicant will not send in a com- specification with his application, but est content with a provisional, and g prepared the documents required, y either post them or take them to the t Office. If they are posted, they be deemed to have been left at the t Office at the time when the letter ining the same would be delivered in dinary course of post. "In proving service or sending, it shall be sufficient ve that the letter was properly ad- d and put into the post." Suppose, ver, the packet is lost in transmission gh the post (such losses have occurred), will the inventor prove the posting, at the same time, show that his docu- s contained a description of an invention somebody else has entered, it may ust after the time at which the lost t should have been received in the inary course of post." We have nothing against the Post; it is one of the few rnment departments which is really d well; but an inventor in making ation for a patent should take especial that his "papers" reach the Patent as soon as he is ready to deposit them. ocuments being safely deposited at the t Office, the application will be re- to an examiner, who will report to mptroller as to the sufficiency of the ption, &c., of the invention contained provisional specification. Should the be unfavourable, the Comptroller may to accept the application, or may the amendment of the specification; must give ten days', or such longer as he may think fit of the time when plicant can be heard personally, or by nt, before the Comptroller. If the ap- is not satisfied with the decision of the roller, he can appeal to the law officer, must first pay £3. In this simple hen, every patentee can be mulcted in n of £3 at the will of the Comptroller, an practically compel every applicant eal to the law officer or withdraw his ation. That regulation is manifestly for if the Patent Office compels the ant to appeal against its decision, it itself pay whatever fee is considered ary to the law officer. As a matter of r some reason or other, the authorities Patent Office have latterly refused a many applications for patents, some n no doubt for trivial or absurd so- "inventions"; but as they have ed others equally as trivial or absurd, who carefully watch these matters are ing to wonder what is the cause of nwonted action, and to hint a on that in future many appli- will be refused, in order he applicant may be compelled to extra to be allowed to appeal to the icer. We will assume, however, that plicant obtains his provisional pro- he must, then, within nine months ate of his application, leave or send lete specification, which may, like visional, be refused by the Comp- ntil it is amended to his satisfaction, eal being again open to the law rovided the applicant pays another rther, at this stage, the complete tion having been accepted, anyone t liberty, within two months of the the advertisement, to give notice of on (fee 10s.), and to assist him in a case he will be allowed to inspect plete specification on payment of have, in a previous article, com- on this extraordinary regulation, the great blot on the Act, and opens to fraud, for it puts into the hands ested opponents of an applicant ry information they require to ood their opposition. *Should there* be no opposition, the patent will be sealed, and the applicant will then have letters patent protecting his invention, but leaving him to prosecute any infringers at his own risk. Rule 23 provides that where, by inadvertence, &c., an applicant includes more than one invention in his specification, and the Comptroller refuses to accept it, the document may be amended, and the applicant may make separate specifications, which will bear the date of the original application, but each will be regarded as a separate patent, which must be paid for accordingly. The question of what are to be considered separate inventions must be left until, in the efflux of time, we are able to discover from the practice of the office and the decisions of the law officer how much can be included in one patent; but, according to the Act, "invention" means "any manner of new manufacture the subject of letters patent and grant of privilege within Section 6 of the Statute of Monopolies." As this section merely says that patents may be granted to new manufactures, provided they are "not contrary to the law, nor mischievous to the State, by raising prices of commodities at home, or hurt of trade, or generally inconvenient," it will be seen that the definition of an "invention" is left practically to the Comptroller, and beyond him to the law officer. The sooner an authoritative decision is given the better, for if sundry parts of one machine, each of which may form the subject of a claim, are to be regarded as separate inventions, the cost of patenting that "invention" may easily be very much more than it was under the old law. As the Board of Trade has practically unlimited powers to revise, amend, and alter the rules from time to time, it may be assumed that they will soon be brought into harmony with the spirit of the Act, the intention of which is undoubtedly to foster and encourage invention.

HOW TO MAKE A CHEAP LATHE.—VI.

Chucks.

WE have spent several pleasant and useful hours together during the construction of our lathe, and it is complete thus far. But unless we have chucks it is yet practically useless. In the selection of these, however, each one will consult his own special requirements, his pocket, his tastes and hobbies. The wood turner usually contents himself with three only—the pronged, the cup, and the face-chuck, all extremely simple. To these we shall add, for metalwork, the dead centre and carrier, the slotted face-plate, the cup chuck with screws, the drill chuck and plate, and the cone plate. Also a small circular saw. Anything more elaborate than these could hardly be deemed essential or common accessories to a "cheap lathe."

The pronged or fork chuck is used for turning wood between centres, and is made of steel. Its shape is indicated in Fig. 61. Turn the forging in the lathe, using carrier and driver, cut the screw with stock and dies, and file the fork nearly to shape. But before finishing, screw it into its place on its own mandrel nose, and turn the point *a* true. Put the finishing touches to the prongs, and have their tips hardened.

The cup chuck, Fig. 62, and face plate, Fig. 63, will each have a plain pattern, made similar to their castings, except that the holes for the mandrel screws will be cored small enough for tapping, say, with a core $\frac{3}{8}$in. in diameter. Having the castings, take either one of them (the same directions applying to each), and clip it, face inwards, in the dogs or jaws of a face plate. Face the portion which bears against the collar of the mandrel, bore the cored hole with a turning tool, set in slide-rest, in preference to a drill, and putting on the change wheels, cut the internal thread, chase till it fits easily, but without slop, on the mandrel nose, then turn it up truly in its own lathe. Drill countersunk holes for wood screws in face plate, also one $\frac{1}{4}$in. hole through the boss *a*, to receive the driver for the carrier, which is used with metalwork between dead centres. We will also adapt the cup chuck for metalwork, by drilling and screwing $\frac{5}{16}$in. holes, Fig. 64, and cutting tightening screws to match. The trouble of forging and turning these screws can be avoided by purchasing common set screws, say, 1in. by $\frac{3}{8}$in. with square, hexagon, or round heads, and tapping holes to match.

We shall make a dead centre for the headstock mandrel, turning it out of a piece of steel and screwing as in the poppet centre (Art. IV., Fig. 42), the only difference being that the thread will be $\frac{1}{2}$in. instead of $\frac{3}{8}$in. We can finish the point in its place, after which it must be hardened.

Get a carrier forged to dimensions (Fig. 65), drill and screw the boss, and make a set screw. A second carrier (Fig. 66) of smaller dimensions will be convenient, and for turning bits of wire, small rod, binding screws, &c., a carrier or two made from small nuts (Fig. 67) will be found extremely useful. By letting the set screw stand out a considerable distance, as shown, we avoid the necessity of shifting the driving pin in the face plate.

An extra face plate cast with slots will be desirable, on which to bolt metalwork, with or without an angle plate. The slots (Fig. 68) will be cored out, prints being put on the face of the pattern corresponding in position with the slots required, and a core box will be made equal in depth to the thickness of print and plate combined.

A simple square-tapered drill chuck (Fig. 69) can be made without much trouble. When forged and screwed (mine, I may note, is of brass), run it into its own mandrel and drill a $\frac{3}{16}$in. hole $\frac{7}{8}$in. deep. With a $\frac{3}{16}$in. cold chisel chip a taper square hole to the dimensions we intend to make the shanks of our drills. Clean out with the point of a square file, trying the accuracy of our hole with a drill run round from time to time in the lathe, until the drill revolves truly—does not "wobble" in the chuck.

A drill chuck necessitates a "drill plate"; that is, a plate to carry forward the work which is being drilled. Art. 3, Fig. 17. In our case, we shall just slip the plate over the poppet mandrel, temporarily removing the dead centre in order to do so. Make it to dimensions, Fig. 70; and if the hole in the boss is bored accurately, its length of bearing will insure steadiness of the plate while the drilling is being performed. The poppet being screwed down on the bed, the progress of the drill can be regulated with the greatest nicety by the handwheel attached to the traversing screw.

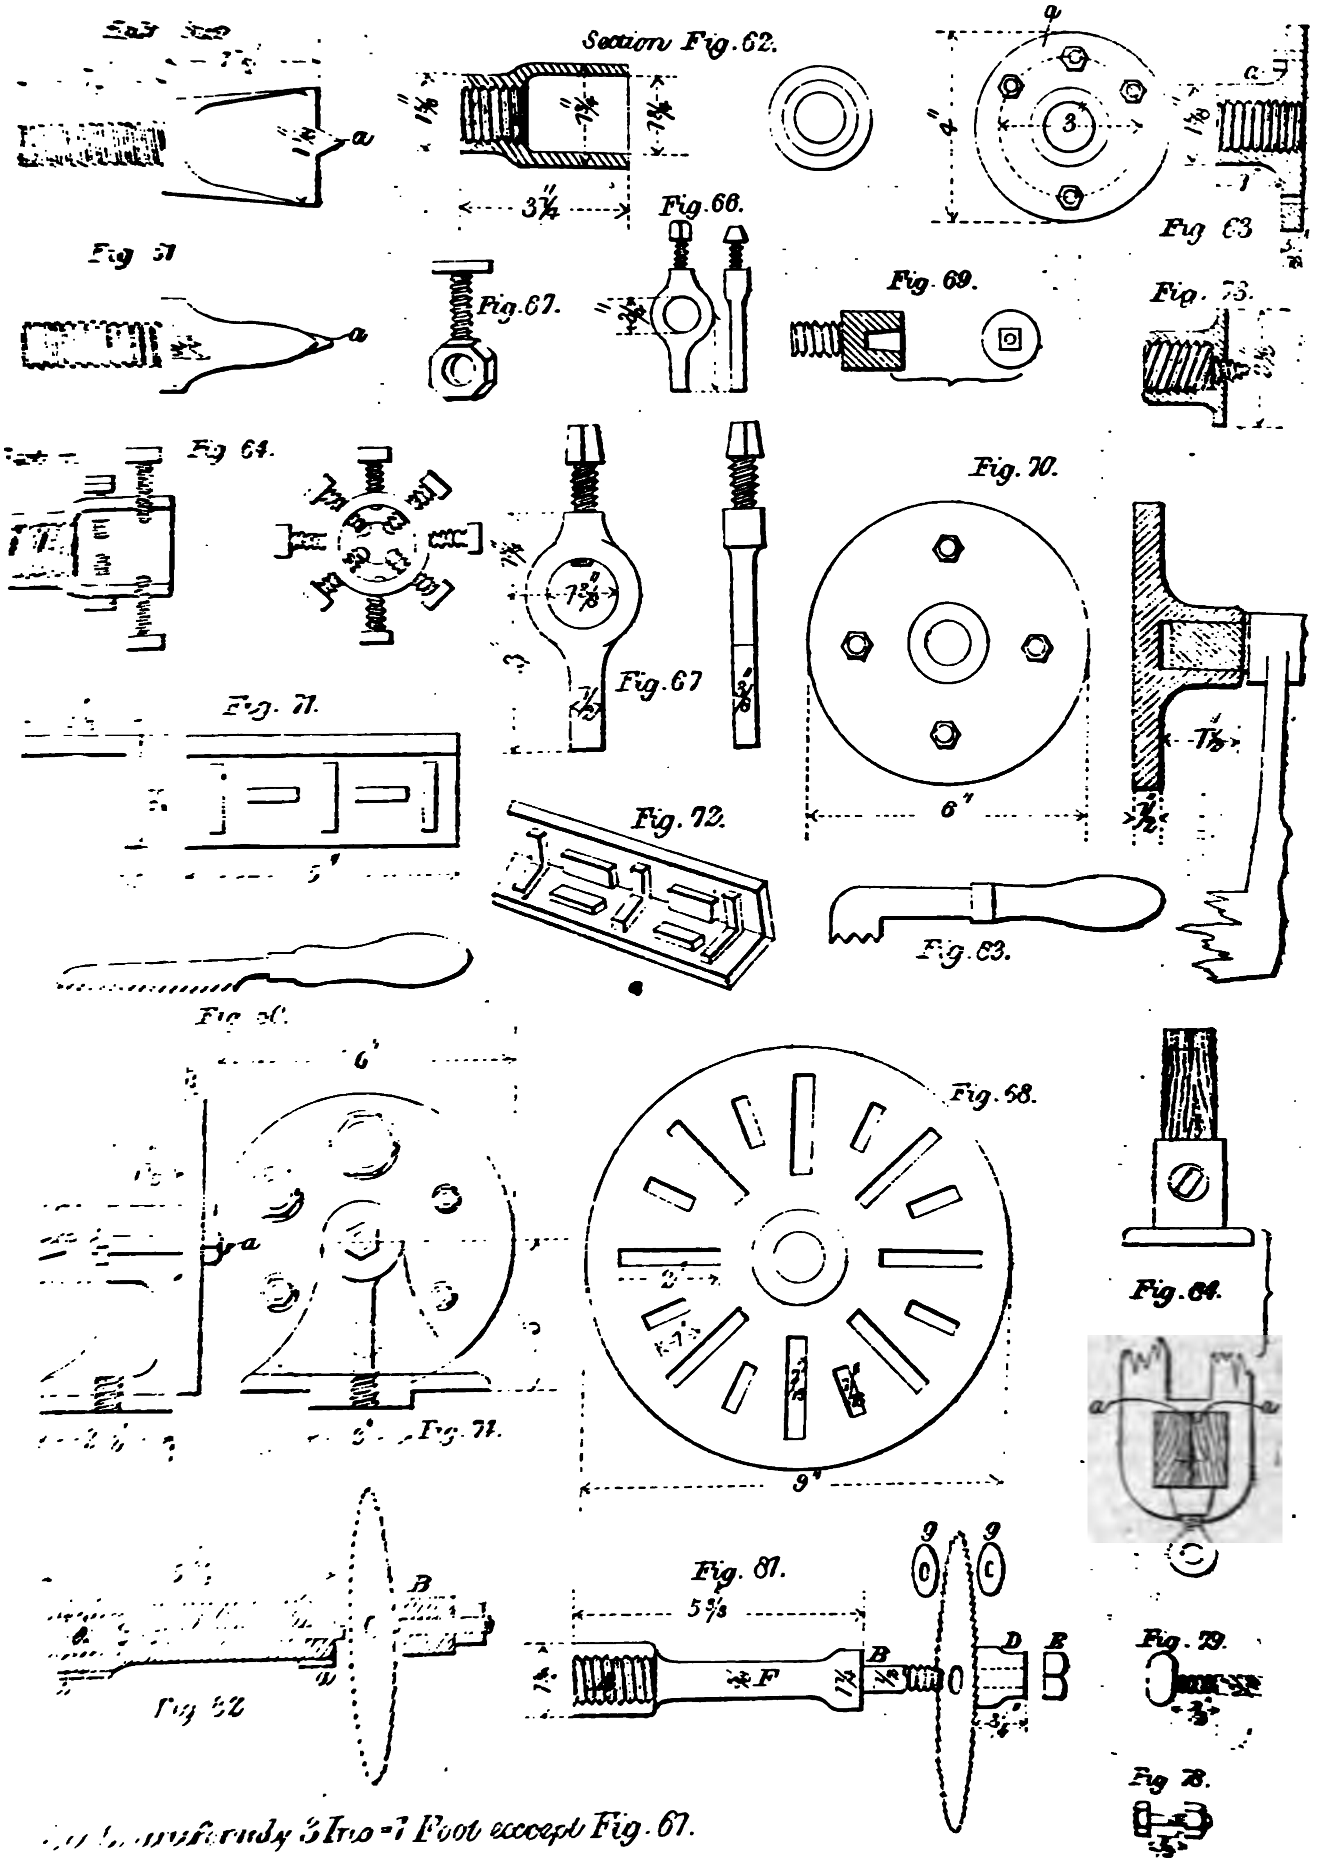
Some of our readers may wish to add accessories to their lathes besides those we have described. An angle plate, Fig. 71, would be found useful for fastening irregularly-shaped pieces of work at right angles to the slotted face plate. In casting the slot holes, it is necessary for moulding that two kinds of prints be used; one set of prints being of the ordinary type, the other set of the type known as "pocket prints." Fig. 72 represents the pattern with prints.

A faceplate like Fig. 73, with a tapered screw, is often used for chucking small articles where wood screws are inconvenient or impracticable. The central hole must not be cored right through, but a sufficient thickness, say $\frac{3}{8}$, must be left, into which to tap the screw. The taper thread can be hand-filed.

An additional cup chuck or two may be added with advantage, increasing thereby the capabilities of our lathe: one of brass, say $1\frac{1}{4}$in. in diameter, and one of cast iron from $2\frac{1}{2}$in. to 3in. diameter.

A cone plate is sometimes desirable, as we found in drilling up the ends of our mandrels. Fig. 74 gives a cone plate adapted to this lathe. Cut the holes out in the pattern, just skimming them round true afterwards in the casting. Note that all the holes are in one centre line corresponding with the lathe centre, 5in., so that angle and cone plate together can be transferred to the lathe in an instant, fastened to the bed, and no further adjustment will be necessary than just to turn the hole we want to use uppermost, and there fix it with tightening bolt, *a*.

A circular saw economises a lot of precious time, and is, therefore, a desirable acquisition. The one sketched, and described in the following paragraphs, I made, with certain slight modifications, after the model used by a wood turner of my acquaintance, who has three saws of various sizes, each rigged up in the same fashion. Fig. 75 shows the tool ready for use. A is the



... uniformly 3 Ins = 1 Foot except Fig. 67.

... guide, C the spindle, D ... combined.

... flanged round its under ... rigidity with lightness. ... purpose of making a ... the headstock, Fig. ... and when finished, ... horizontal with the spirit level. Grind or file the top of the table moderately true, and polish with emery cloth. Treat the edges in a similar manner. Drill a couple of holes, and file them to ⅜in. square in positions indicated (Fig. 76 *b b*). These are to receive the square shoulders of the bolt for the movable slide, and we have two holes in preference to a long slot, which would weaken the plate.

The movable slide, (Fig. 77), should have i face and edge *a a* filed flat and square, and th guide strip is also to be filed to a right angle wi the face. The slot *c* is cast in, and cleaned ou with a file. The bolt (Fig. 78) tightens it in an required position.

Drill a ⅛in. hole in the side of each bracke which comes from underneath the table, i

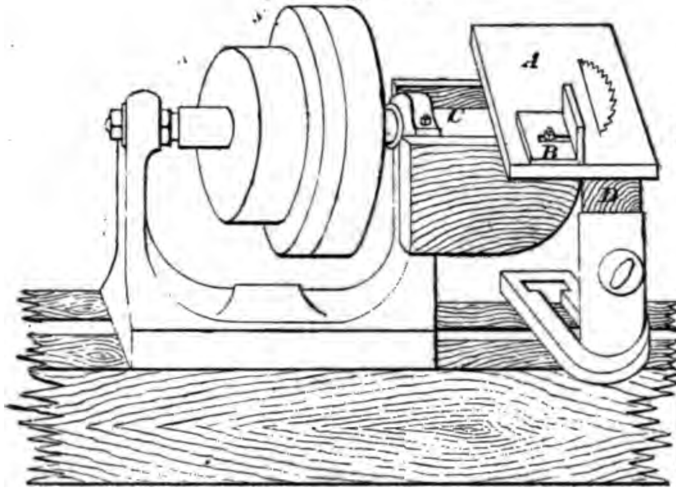


Fig. 75.

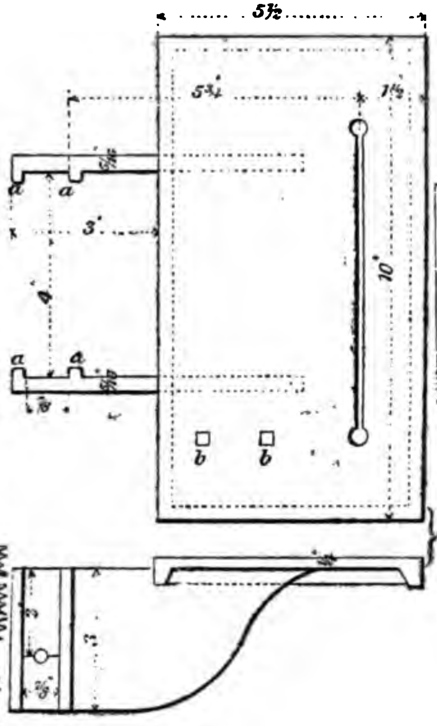

Fig. 76

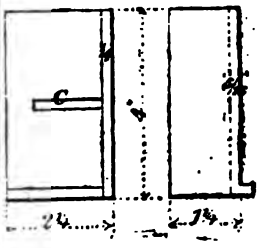

Fig. 77

position given (Fig. 76). Slide them over the headstock until the top of the table stands about ¼in. above the centre of the lathe mandrel. While in that position mark two holes with a scribe on the edge of the headstock face, corresponding with those just drilled. Drill in about 5/16in. deep, quite enough for the work they have to do, and tap. Make a couple of thumb screws (Fig. 79) tapped to fit these holes. They simply prevent the table from slipping downwards, the bearing strips retaining it in other ways.

Now, while held in its permanent position by the screws, mark a line as nearly at right angles with the axis of the lathe as possible, at a distance of 5¼ away from the collar of the mandrel nose. Better lay a straightedge in winding with the edge of the bed, sighting down from above, and mark the line off from this with a set square. On the line so obtained set off 2⅞in. on each side of the axial centre line, and in these two points drill holes with a 3/16in. drill. Get an old stump of a keyhole, or compass saw, about 6in. or 7in. long, and file just double the usual quantity of teeth in it; that is, convert each tooth into two, making them hacksaw shape, Fig. 80. Start at one of the drilled holes, and saw a slit down the iron plate, terminating in the other hole. This is to receive the saw.* A portion of the flange underneath the table will have to be cut away to clear the spindle, and this will complete the plate.

The spindle which carries the saw I made of brass; but those I copied from had spindles of hard beechwood. I will describe each, and leave my readers to choose between the two.

Fig. 81 is a solid piece of brass casting, screwed to fit the mandrel nose A. At the end marked B there is a parallel portion turned to fit the hole in the thick washer D, beyond which there comes a ¾in. thread for the tightening nut E; *g g*, are two leather discs put, one on each face of the saw to prevent it from slipping round. I think I would recommend anyone making a spindle of this kind to have the narrow shank marked F a little larger in diameter, and to lighten it out with a core. Make it ¾in. in diameter, with a ½in. core, for instance. It would thus be lighter, yet equally strong.

The wooden spindle, Fig. 82, is shown in section. The screw A can be cut either with a V-tool by the change wheels, or with a chaser by hand. A chaser made to fit the mandrel thread, Fig. 83, will be always handy for rigging up a temporary chuck, and a little practice will enable one to use it readily. We imagine the initial difficulty got over, and our screw cut to fit the mandrel nose. Get a ⅜in. button-headed bolt 5in. long, having a square shoulder under the head, and bore a hole in the lathe half way through the block of beech to receive this bolt. Take the block out of the cup chuck, screw to its mandrel, and bore from the other end till the holes meet. Face to 5⅜in. long, turn the outside, and drive on a ferrule at each end (Fig. 82, *a a*). Then shoulder the hole at the backend to receive the square neck of the bolt, and drive it in. A hard wood washer B completes the arrangement, and the friction of the wood is amply sufficient to prevent the saw from slipping round.

The packing block (Fig. 84) serves for packing and for support. It fits in the socket of the rest, and touches the underside of the table, thereby deadening vibration. It is grooved to receive the saw, and has two recesses *a a* to take the oiled hemp packing by which the saw is kept cool, and the steadiness of its motion assisted. In cutting thick stuff, say, 1½in. thick, it may be well to support the spindle by bringing the poppet centre up to it; but there is no need of additional support in light sawing.

These various accessories are not likely to be procured at once, since they involve a deal of manual labour in their construction. In all probability, after making the lathe itself, most will remain content with the prong and the cup chuck, and the face plate for awhile. Considering the cheap lathe as being complete at this stage, the cost is:—

		s.	d.
Face plate and cup chuck (brass) 3¾lb. at 1s.		3	9
Fork chuck, say		1	0
Miscellaneous fitting (Art. V.)		15	0
Woodwork (Art. II.)		10	0
Castings (Art. I.)		15	0
Total	£2	4	9

Say £2, and mine had not cost me quite so much at this stage.

In the articles remaining, the labour is greater than the expense, which latter is approximately as follows:—

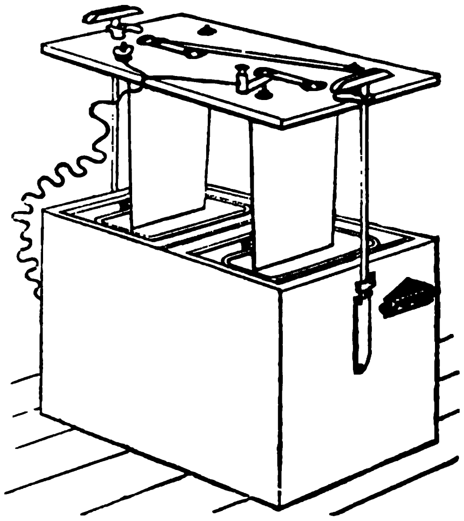
	s.	d.
Spindle for saw and washer (brass) 2lb.	2	0
Cast-iron work, 30lb., at 2d. per lb., being very light work	5	0
Wrought-iron, bolts, &c., 3lb.	1	0
6in. saw (German or English), from 4s. to 6s.	5	0
Total	13	0

---

* A word about this cutting of the slit. It would occur to many that it might be cast in. In that case its opposite edges would most likely become buckled, or perhaps be out of parallel, in consequence of the metal not running up clean and sharp. And, with respect to the sawing it down, a soft saw will be of no use, nor, indeed, any saw if the metal is hard. With a piece of an old, highly-tempered saw, approaching in hardness to a hacksaw, and a plate cast from "No. 1 Scotch" iron, the task is easily accomplished. But in the absence of such a saw, and having, perhaps, some hard metal in the plate, the best way will be to get a drill a full 1-16in. in diam., and to drill a quantity of holes all down the centre of the intended slit, just touching one another. Then opening two or three of the end holes with the point of a file, complete the slit with a flat ward file of 1-16in. in thickness. The holes can be drilled rapidly in the lathe by means of a drill chuck.

THE NEW "EDCO" BATTERY.

THIS battery consists of a wooden box divided into two lead-lined compartments. The zinc plates are screwed in holders on a board, and the carbons, to avoid breakage, are fastened permanently in the cells. The inside measurement of each compartment is as follows:—Height 12in., width 8in., length 6in. The plates, of which there is one zinc for each cell, and two carbons, are all 10in. by 6in. by ¼in. thick. The zincs weigh exactly 3lb. each, and cost retail 2s. each. A porous pot is used, and in the outer compartment is put a solution containing 1½lb. bichromate of potash, and 3lb. of sulphuric acid. These are supplied by the makers of the battery to their customers respectively at 6d. and 1d. per pound. Six ounces of sulphuric acid are put in the porous pot, which is then filled up with water. With this charge, costing as above, 1s. ½d. the battery will run motors and light incandescent lamps with absolute steadiness for 60 consecutive hours, or about 90 hours if worked at intervals of, say, 10 hours at a stretch. During this period the only attention the battery requires is refilling the porous pots every 20 hours. Each cell of the battery gives on short circuit two volts and five ampères steadily. The method of filling the battery, and an illustration of it are given below, and it may be seen at work at the offices of the Electro-Dynamic Company, Archway House, Bush-lane, E.C.

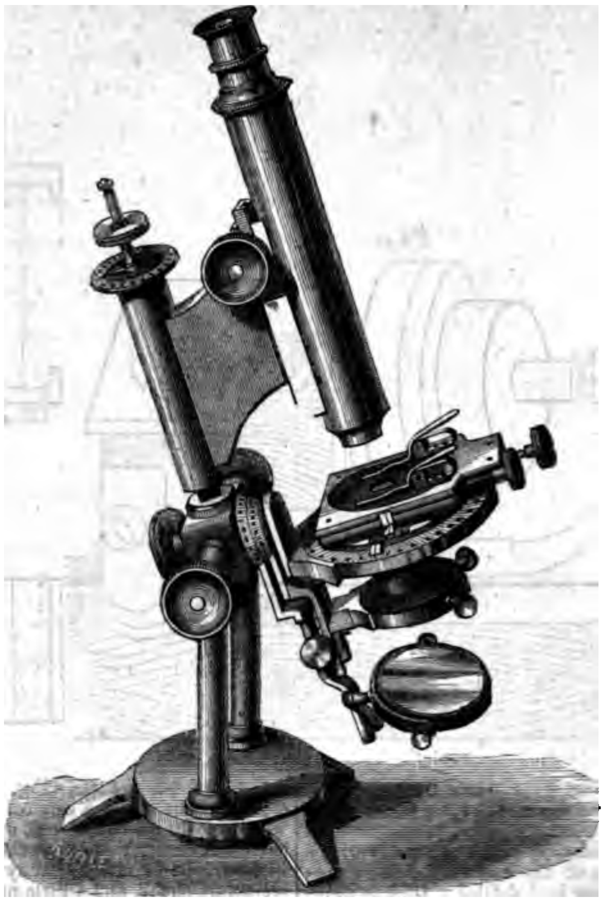


The following is the method of charging the two-cell "Edco" battery with porous cups:—Have ready twice one and one-half pounds of bichromate of potash and twice three pounds of sulphuric acid. In each lead cell pour six pints of water, and in each repeat following operation: —Fill the colander with bichromate of potash, and hang it in the cell so that the crystals are just immersed in the water. Pour about one-fourth of the three pounds of sulphuric acid over the crystals in the colander slowly, stopping occasionally when the liquid boils. As fast as the bichromate of potash gets dissolved, add more, and continue pouring on sulphuric acid as before, until there are used up for each cell, all of one and one-half pounds of bichromate of potash and three pounds of sulphuric acid. When the liquid is entirely cool, it is ready for use. After the porous cups have been put in the red fluid, this should not reach higher than within about 2in. from the copper strips on the carbon plates in each cell. Should it not come up that high, add water.

The porous cups which receive the zinc plates are to be filled with water to within about 2in. from the top, and then add six ounces of sulphuric acid.

It will be noticed that after the porous cups have been in the cells about 24 hours (whether the battery has been in active use or not), the surface of the liquid in the porous cups has gone down about an inch, which must be brought up by adding water, or better still, water to which sulphuric acid has been added in about the same proportion as the original contents. After the battery has been in use ten or twelve hours, it is advisable to amalgamate the zincs, as by doing this they are kept in very good condition, and do not require much attention for some time.

PELLETAN'S "CONTINENTAL" MICROSCOPE.



THIS microscope has been issued by Dr. J. Pelletan, of Paris, and claims notice not for any distinctive feature in design, but as a combination of several points which have hitherto been confined to English or American models, together with the focusing arrangements and connection of the body-tube with the pillar generally adopted on the Continent.

The principal novelty to the Continental public is the adoption of the swinging tail-pieces to carry the substage and mirror, each moving radially to the object on the stage, after the plan modified by Bulloch, of Chicago, from Zentmayer's "Centennial" microscope.

The substage, with centring movements, fits on the first tail-piece behind the stage, and is worked by rack and pinion. The mirror is mounted on a crank arm on the second tail-piece. The tail-pieces swing laterally either together or independently; each is provided with a graduated collar for registering the lateral rotation, and a spring-pin drops into a corresponding notch, fixing each in the normal position when axial light is required.

The stage is circular, and rotates about [illegible]ths of a turn; it has graduated divisions near the edge. "[illegible]" are applied to the mechanical rectangular movements. It is attached to the lower end of the inclining column by a conical axis passing through and secured at the back by a large milled nut. This stage can be removed and a glass friction-stage substituted, which can be used reversed for oblique illumination from the mirror, &c. The friction-stage is fitted with a hemispherical lens so that its plane face is flush with the surface of the stage as in Tolles's and other microscopes.

The focussing arrangements are of the usual Continental type. A scale is applied on the side of the body-tube working against a fixed vernier on the limb for recording focal distances by the coarse adjustment, while for finer measurements a graduated disc is fixed on the top of the column carrying the limb, and the fine focussing screw rotates with an index pointer, by which the number of turns and fractions can be registered.

The body-tube is much larger than is usually adopted on the Continent, and will admit an extra draw-tube supplied with the microscope, [illegible]. As arranged in the figure, [illegible] the larger [illegible] in the body-tube and carrying the smaller, in which the [illegible] gauge of eye-pieces are used. The [illegible] is applied at the top [illegible].

The suspension of the inclining column between the standards appears to have been devised without regard to the balance of the instrument.

The trunnion axis is very nearly at the lower end of the column, so that the stability of the position of inclination is entirely dependent on the tension of the clamp-screws on the ends of this axis; if the unwary operator should loosen the clamp-screws without supporting the column the optical part of the microscope falls forward or backward, in either case striking the table, as no stop-pins are provided either to mark the vertical or the horizontal position.

The microscope is manufactured by E. Lütz, and appears to us to require thorough revision both in design and construction.

PRACTICAL NOTES ON PLUMBING.—XC.*

By P. J. DAVIES, H.M.A.S.P., &c.

(*Continued from p.* 361.)

Dormers.

THESE are sometimes covered all over with lead, and at other times part slated, &c., as shown at diagram 428. First put on the apron Y, then the cheeks C H E E K, which should go over the springing as at G, and from 4in. to 6in. under the slates according to the pitch of the roof. The cheek should also go up under the valley lead V T, and the valley lead over the cheek, under the slates, both on main roof, and on of the dormer, as shown by the dotted lines, finished as shown. Let the cheek lead go r the jambs of the window, and be turned w welt as shown at W to cover the nails. nails are shown under the welt by the lines.

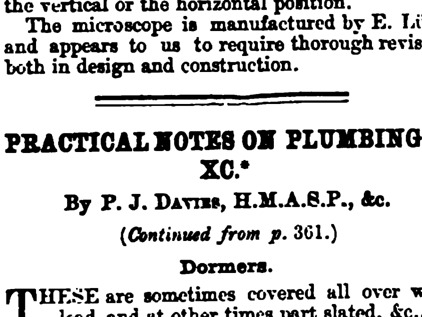


Fig. 428.

Hips and Ridges.

The method of doing this work is sh diagram 429. A is the roll, S the s

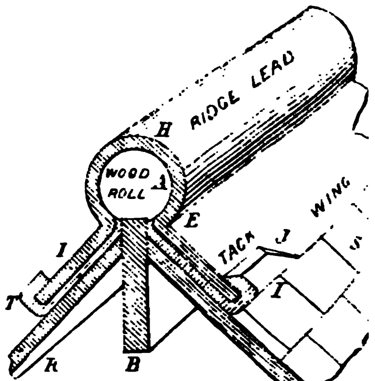

Fig. 429.

I H E J the lead work, I J the tack to l lead firm in the roll. In doing this w that the lead is well home to the angle of and slates, and that the tacks are put, a 2ft. 6in., and of at least 7lb. lead. Th of the work depends greatly upon the of putting the tacks. After the lot i place, trim the lead true to a line.

Spires, &c.

I shall now give two or three methods this kind of work, although it is not one out of twenty who will ever be called cover one. Hence the reason why I sho little more minutely into the work. I w at diagram 23. This is composed si straight pieces of lead nailed on to the b as at 1, then the roll nailed on over the of the first bay. Having the first bay nailed on, and the ends of the bays to

---

s. next proceed to work the bay No. 2, which ıld be worked to form an overcloak to the : roll, and in such a manner that you can work overcloak down round the roll, and leave a d splash-lap properly tacked to prevent it ving. The rolls should be nearly round, so the lead may rest well in the angle of the and boarding, which will prevent the from getting away. Having the bay No. 2 y, put it in its place and *well* nail it along :op and down the side rolls. After this fix No. 2 over the bay No. 2, and so on, all up side. In this method the ends of the bays worked over the side rolls, or hips. Some ıbers lay the bays and afterwards cover the with separate pieces of lead; but when this is done it is more work without getting any advantage.

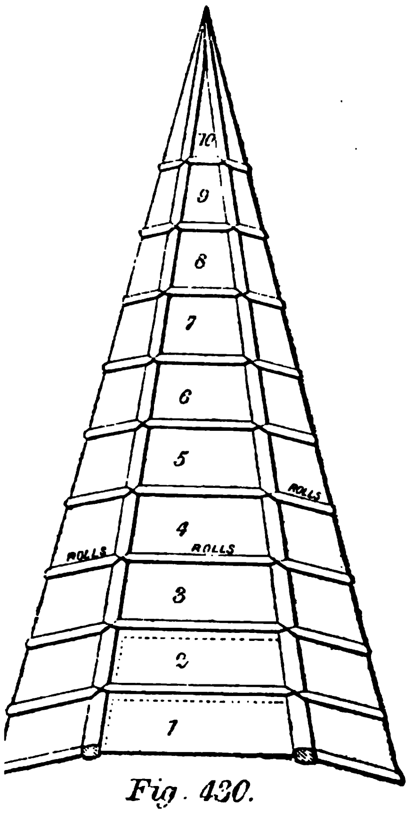

Fig. 430.

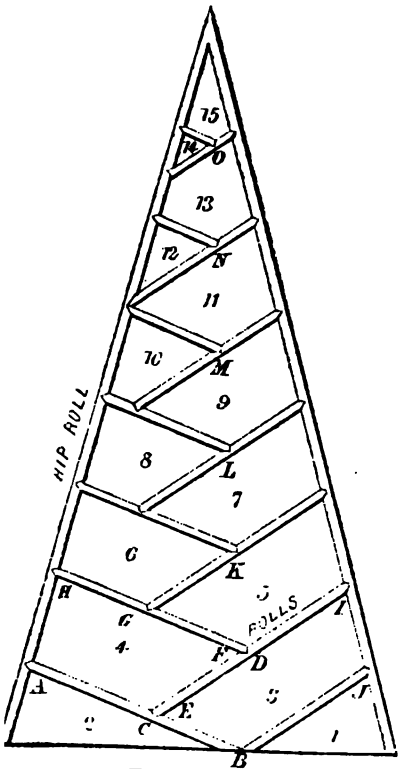

Fig. 431

Zig-Zag Work.

This is shown at diagram 431. It is very useful in places where long lengths of lead cannot be used, and where the spire is over 9ft. across. see 1, 2, 3, 4, 5, 6, 7, 8, diagram 431. First fix the bays either 1 or 2 with the undercloaks, as you did in diagram 430, or as you would do in a common flat. For my part, I prefer to nail the undercloaks under the roll, as from what I have lately seen this stands much the best, to say nothing about the work. Having got bays 1, 2, and 3 into their places with good rounded rolls and plenty of tacks, proceed to work down the overcloak over the first roll from B to C, and from B to J, and so on all up the spire. You may work the side rolls with the ends of your bays, or by separate pieces of lead as before mentioned. When executing this class of work there are several objects to keep in view. The first is perfect soundness of work. Second, that the pieces of lead put on are not too large, as they will be affected by the temperature of the atmosphere. Third, that the point of the rolls are in a line as at B D K L M N O, and their intersections perfectly worked; also that the other line of roll ends are running straight. These two lines of roll ends cannot be maintained unless every bay is set to a different width, which makes a great difference in the cost of the work. Such work is shown at diagram 432, and notice that it is impossible to work the ends of the bays at diagram 431 on the square as in diagram 432—namely, up against the side rolls. In diagram 432, the ends of the bays may be cut square, A B C D E F G H, &c., and if so, the bays will become smaller from the bottom upwards—that is, if the intersecting line is maintained. The top part may be varied as shown at 16, 17, 18, 19, and 20.

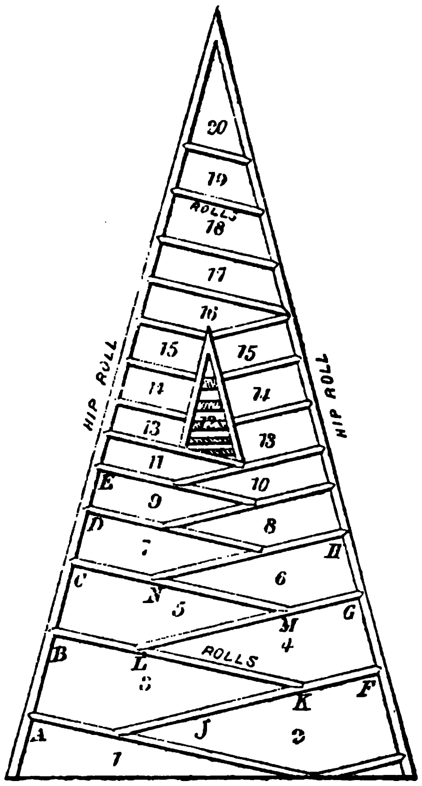

Fig. 432.

(*To be continued.*)

LANTERN TRANSPARENCIES BY THE ALBUMEN PROCESS.*

IT may be interesting to many to know the old system of working, so that they can realise the difficulties attendant upon it, which gave rise to so much prejudice against the albumen process, particularly amongst amateurs. Accordingly, before commencing the details of the modern method, we shall digress for a moment to give a brief outline of the old process, so that the more "recent" improvements may the better be understood and, therefore, appreciated. In the earliest methods the plate was coated with plain uniodised albumen, and then dried. The iodising of the film was afterwards effected by exposing it to the vapour of iodine, in the same manner as in the daguerreotype process, until it became decidedly of a yellow tint. It was then sensitised by immersion for a short time in a solution of nitrate of silver strongly acidified with acetic acid, similar to that employed in the calotype process. An improvement on this plan was effected by adding an iodine to the albumen itself, which simplified matters considerably, as it did away with at least one troublesome and disagreeable operation. The method of working was this:—A certain quantity of albumen was taken, and to it was added the proper proportion of iodide of potassium. The addition of bromide was also made by some workers. The whole was then whisked into a stiff froth. The directions usually given for this part of the operations were that the albumen should be whisked until the vessel containing it could be inverted without the contents running out. After standing some hours for the albumen to subside it was ready for use.

The plates were coated in the following manner:—They were first affixed to a plate-holder, which consisted of a piece of guttapercha fastened on the end of a stick, as pneumatic plate-holders had not been invented at that period. The guttapercha was made sticky by melting it in the flame of a spirit lamp, and the plate attached. The albumen was now poured on and distributed, and afterwards equalised by centrifugal force, by giving the plates a rapid rotary motion by spinning the stick between the fingers. The plate was then detached, and put into the drying-box. This consisted of a box containing a number of grooves into which shelves of porous wood fitted horizontally, the box being mounted on levelling screws. Previously to using the box the shelves were removed, and placed, together with the box, either in the sun or in front of a fire to thoroughly desiccate them, so that the wood should be rendered as absorbent as possible. The shelves were now replaced in the grooves, and the box carefully levelled. It was then ready for the reception of the plates, which, it will be seen, were dried entirely by the moisture from them being absorbed by the wood of the shelves and box.

Now it is clear that if the box were not accurately levelled, or if the shelves had become warped, the films would be of unequal thickness, and the plates, consequently, useless. Up to this point dust was the greatest enemy, for the smallest particle settling on the film was almost certain to cause a spot, and it will be noticed that up to this time the plates were always in a position to favour floating particles coming into contact with them. The sensitising was effected in a bath of aceto-nitrate of silver in much the same manner as at present. But the development was materially different to that now practised, inasmuch as the picture was brought out with a saturated solution of gallic acid, with a few drops of aceto-nitrate of silver added, instead of, as now, with pyro-gallic acid. The time occupied in the development of a picture by gallic acid was rarely much less than half an hour, and it frequently took as much as a couple of hours if it were at all under-exposed. But, by the method about to be described, it does not take much longer to develope and fix an albumen than it does a gelatine plate.

Having thus given a short outline of the old-fashioned albumen process, we shall proceed with the details of the present system of working. In the first place, we commence with the preparation of the albumen itself—say of ten ounces. This will require from a dozen to fifteen eggs, according to their size. These, if available, should by preference be "new laid," though good French eggs will answer nearly, if not quite, as well. The eggs must be broken, and the whites carefully poured away from the yolks, keeping the latter in the shells. The germs should then be separated. To ten ounces of the albumen half a drachm of glacial acetic acid in half an ounce of water is added, and the whole intimately mixed by stirring with a glass rod. No attempt should be made to cause it to froth, which if done would give rise to trouble. Half a minute's stirring is all that is necessary. The acid will produce a precipitate, and render the albumen exceedingly limped. After standing a few hours it is passed, first through a piece of muslin to remove the coagulum, and afterwards filtered through a piece of sponge plugged in the neck of a funnel. After filtration forty minims of ammonia, ·880, is added, which causes the albumen to regain much of the viscosity the acid had destroyed. Albumen thus prepared will keep quite good for many months, if preserved in well-corked bottles. This method of preparing the albumen, if our memory serve us correctly, was first published by Mr. William Ackland.

For use, the albumen is iodised by adding one drachm of iodide of ammonium dissolved in half an ounce of water; sometimes ten or twelve grains of

---

* From the *British Journal of Photography.*

[illegible] The albumen being ready, [illegible] the plates. For this purpose [illegible] is required. Any common [illegible] that has been used for a length of [illegible] to yield an even and [illegible] be very old it will possibly [illegible] film, in which case a little [illegible] must be added to give it body.

The glass plates being thoroughly cleaned and [illegible] is taken and coated with the [illegible]. After this has been allowed to set the plate is immersed in a dish of common water, where it is allowed to remain, with occasional agitation, until all greasiness has disappeared. It is then rinsed under the tap and placed standing on a pad of blotting-paper to drain, while another plate is being collodionised. Now take the drained plate and pour over it, beginning at one end, a little of the iodised albumen. Flow it over in a wave, so as to carry the superfluous water before it, which, with the albumen, should be allowed to run off into the sink. Drain the plate somewhat closely and apply a second lot of albumen, avoiding air-bubbles, and keep it in motion on the plate for half a minute or so in order that the albumen may penetrate into the collodion film. Then pour off into a measure, and stand the plates in a rack to drain. The second lot of albumen from one plate will do for the first application to the next, and so on. By this means the albumen will be economised.

After a dozen plates have been coated, take the first one and hold it in front of a clear fire until it is dry, and so, in turn, with the remainder. When the plates are dry it is a good plan to make them as hot as the hand can bear, for this treatment will prevent the films from blistering in the after operations, which otherwise they may have a tendency to do with some samples of collodion. Instead of drying the plates by the fire some prefer to allow them to dry spontaneously; but, in this case, it will be found a good plan to make them thoroughly hot, for the reason just mentioned. Plates thus prepared will keep for years if preserved in a dry place. It need scarcely be mentioned that all these operations may be performed in open daylight.

ALCHEMY AND MODERN SCIENCE.

THE course of six lectures to juveniles at the Royal Institution was commenced by Prof. Dewar on the Thursday following Christmas-day, and, as usual, the theatre of the Royal Institution was crowded. The full title of the series is "Alchemy in its Relation to Modern Science," and the lecturer said that the topic had been chosen because it appealed to youthful imagination and led up from "striking" experiments to matters of not less interest than utility. The word "alchemy" blended the Arabic definite article with the name for Egyptian science, which reference to the country of its birth still held its ground in our word chemistry. Some etymologists emphasised in this connection the original meaning, "heat," in the national name Chemi, for "the land of Ham," or "of heat." For alchemy could do nothing without "heat." It had especially to do with the changes wrought by this great agent in the crucible or the furnace, changes promising its votaries a royal road to health and wealth. It aimed at the transmutation of the baser metals into the nobler, silver and gold, and at the production of the elixir of life. The mainspring of its research was thus the securing of human happiness. The five periods of the grand science were (1) that during which it was practised by the Egyptians, Hebrews, Arabs, Indians, Greeks, and Romans, when it was nearly co-extensive with metallurgy. (2) that of the Alexandrian school, when it became occult, sacred, religious, [illegible]. (3) that of the Middle Ages, during which many valuable discoveries was stumbled upon by those who hardly dreamt of their importance to medical science in general; (4) the period of the study of facts for their own sake, during which alchemy touched its vanishing point; (5) lastly, alchemy became altogether sublimed into modern chemistry. Speaking briefly of the first epoch, Professor Dewar reminded his youthful audience that the earliest thing to impress itself on the minds of men wherever their history could be traced, from the Arctic Circle to the Torrid Zone, was [illegible] and the method of its production. Fire was kept [illegible] burning in Egyptian temples and in [illegible] of the Vestal Virgins at Rome. It was [illegible] of fire that made it a symbol of life. [illegible] shown of the diverse effects of [illegible] and sulphur respectively, and of [illegible] in the residual products where there [illegible] at all. Wood and charcoal left [illegible] sulphur which in burning created an [illegible] atmosphere, possessing, however, the [illegible] bleaching, quite vanished. The [illegible] of the changes brought about [illegible] kindled speculation, and alchemy in [illegible] into metallurgy, which, again, [illegible] the metals in the order of their facility [illegible] gold, silver, copper, tin, iron, lead. Pottery gave the rude alchemists the advantage of earthen furnaces, instead of the rock-crevices before used. The metals were classed as noble or base according to their ability to stand fire without change. A great passion then seized upon the alchemists to transmute the baser metals into the nobler by purging them from all alloy. Quicksilver shared with sulphur the wonder of the ancient alchemists, by whom the metals were ranked according to their relations to these two mysterious agents. Professor Dewar's second lecture was delivered on Saturday, the theatre being crowded with boys and girls, who evinced a keen and intelligent interest in the instruction imparted, especially in the experimental illustrations. The lecturer told them that the ancient Egyptians were acquainted with many chemical facts and phenomena as long ago as about B.C. 2,000, as could be proved by their extant monuments. Recapitulating what had been said about sulphur in the first lecture, he said these ancient chemists appeared to have thought its relation to the metals analogous to that of mercury, whereas it really disguised them, as was shown by combining sulphur with red hot iron, the product being seen by the audience to be utterly unlike either of the elements employed. The old chemists knew a good deal about the mixtures of metal with metal, which are termed alloys, as well as about amalgams, the special names given to the combinations of mercury with solid metals. They doubtless had many things to learn; so had we, as, for instance, in the discovery quite lately of a new peculiarity in gold, which, after having been handled chemically for more than 3,000 years, had now first been observed, after subsiding from the dazzling brightness of its molten state into dulness, to flash forth once more into all its former brilliancy. After interesting experiments on pure silver and its amalgam with mercury, the metallurgical operations of the ancient Egyptians were illustrated by the pictures painted on the walls of their tombs. The first slide passed through the lantern reflected on the screen their use of the blowpipe, their hammering and forging into shape the metals under treatment, their careful weighing of the raw materials and of the manufactured articles, their use of fluxes, and the like. He next represented the goldsmith working at his trade and mystery, surrounded by all his tools and appliances. A third wall-painting showed the Egyptian god Thoth—the Hermes of the Greeks—in his laboratory; for he was the tutelary god of the science, and the writings conned by the alchemist were styled in honour of him the Hermetic books. In literary works of this kind could be traced back to about the beginning of the Christian era such curious knowledge as this, that water sometimes loses its quenching power and fire forgets to burn. There was a story on record also of a Zoroastrian pontiff who made many converts by allowing 18lb. of molten copper to be poured over his naked body without suffering harm. To show the possibility of a fact which might easily have grown into such a myth, Professor Dewar, having first carefully washed his hands in distilled water, plunged the right, while still moist, into molten lead, and repeated the experiment thrice with perfect impunity. In point of fact, as he remarked, his hand and the molten metal into which he dipped it for an instant never came into contact. The very early acquaintance of the Egyptians with the alkalis and with the art of making glass was also demonstrated. To illustrate the elasticity and ductility of glass, about a league of glass silk was spun from a wheel, to the great delight of the children, at the rate of nearly a mile a minute.

THE CANNON, THE STEAM-ENGINE, MAN, AND THE INSECT CONSIDERED AS MECHANICAL MOTORS.

UNDER the above title, we give a *résumé* of some very curious and interesting information published in a recent work of Mr. E. Jouffret, entitled "Introduction to the Theory of Energy."

These examples, which are submitted in a simple and clear way, are well calculated for disseminating a knowledge of the phenomena of conservation and transformation of energy, by presenting them under a concrete form accessible to all those who are not making a special and continued study of them.

A 100-ton cannon (Italian model of 1879) cost 400,000 francs. It requires a 250 kilogramme charge of powder, and throws a projectile weighing 917 kilogrammes, with an initial velocity at the mouth of the cannon, of 523 metres per second.

The energy possessed by the projectile, in the form of live power, is 12,772,000 kilogrammetres.

The energy represented by one kilogramme of powder is, according to Noble and Abel, 300,000 kilogrammetres, or 75,000,000 kilogrammetres for the charge of 250 kilogrammes.

The cannon considered as a machine, converts, then, into work seventeen per cent. of the total energy of the combustion of the powder. This figure is higher than that furnished by the best steam-engines, as these convert into work less than ten per cent. of the total energy represented by the coal.

It is the animal machine in which the performance is the highest, and this fact may be established in a particular case, as follows:

According to the Guide Joanne, the ascent of Mont Blanc, starting from Chamounix, is effected in seventeen hours, resting spells not included. The difference of level is 3,760 metres. A person ascending, who has a mean weight of 70 kilogrammes, produces, then, in order to rise, a work of 3,760 × 70 = 263,000 kilogrammetres. This work is borrowed from the heat that the carbon and hydrogen contained in the food eaten disengaged upon being burned in the lungs. For the sake of simplicity, if we reduce the entire energy to a combustion of carbon, and recall that a kilogramme of the latter furnishes 3,000,000 kilogrammetres, we find that the 263,000 kilogrammetres represented by the ascent correspond to a consumption of 94 grammes of coal—a consumption that comes to be added to the normal rations necessary for the operation of the organs during a state of rest. Such consumption is 8·35 grammes per hour, or 142 grammes for the seventeen hours. The total consumption of coal is 256 grammes, representing 708,000 kilogrammetres. The performance, then, is:—

$$\frac{263.000}{708,000} = 37 \text{ per cent.}$$

The performance of the human machine drops to 21 per cent. when we consider a period of 24 hours composed of ten hours of work and 14 of rest, and a mean daily work of 280,000 kilogrammetres.

The cannon, considered as a machine, is incomparably superior to the steam-engine as regards the time necessary to produce a given quantity of mechanical work.

Thus, for example, the 100-ton cannon develops in one hundredth of a second a quantity of work equal to that which would be *yielded* by a 47 horse-power steam-engine in *one hour.* A man of average strength is still lighter than an ordinary steam-engine of equal power, *but he is much* inferior to the other animals *of creation,* and particularly to insects.

Thus, for example, the libellula, which is capable, without apparent fatigue, of following a train of cars for several hours, giving its wings during this whole time some thousands of backward and forward motions per second, is a hundred times lighter than a steam-engine capable of producing an equivalent work.

This is what renders the problem of aërial locomotion so difficult, and, as, Mr. Hirn says, it explains why we can fly in imagination only.—*La Nature.*

Two Remarkable Needles.—The International Exhibition of Needlework, which is to be held at Sydenham in July, 1884, will include, among other curiosities, two things which will not be the least of the attractions of the exhibition. One is the famous needle presented to the Emperor of Germany last year under circumstances worth recalling. The Emperor was visiting the great needle manufactory at Kreuznach, and was desirous of seeing for himself the relative power of machinery compared with skilled hand labour. A bundle of superfine needles was placed before him, 1,000 of which weighed less than half an ounce, and he expressed his astonishment that eyes could be bored in such minute objects. Thereupon the foreman of the boring department asked His Majesty to give him a hair from his beard, and receiving it, he bored an eye in it, threaded it, and handed back to the astonished Emperor this improvised and most peculiar needle. The other curious needle was manufactured at Redditch, and presented to the Queen. It is a sort of miniature Trajan's column. All round it are represented scenes from the Queen's life, executed so minutely that a magnifying glass is required to distinguish them. This needle can be opened, and within it are a number of very fine needles, on which also scenes have been engraved.

HERR NAUSCHAFF has constructed a delicate instrument for registering earth currents. A sensitive galvonometer is enclosed in a case with a clockwork arrangement for moving a photographic plate about eighty mm. per hour. By a total-reflection prism, a ray of light is reflected on to the galvanometer and focussed on the plate. Thus the slightest variations are constantly registered.

AT a recent meeting of the Edinburgh Royal Society, Professor Tait read a paper by Mr. W. F. Petrie, on the old English mile. The old mile was longer than the present, and consisted of 5,000ft. of 13in. It seemed to be identical with the old French mile. The furlong had no connection originally with the mile, which was modified to suit the former.

SCIENTIFIC NEWS.

NOTES about the remarkable sunsets continue to be published, and accounts are beginning to arrive from the more distant parts of the earth. Mr. Ellery, at Melbourne, thinks the gorgeous sunsets are caused by aqueous vapour in certain conditions in the higher regions of the atmosphere, and he predicted wet weather, which followed the peculiar sunsets in November. Mr. J. Birmingham, writing from Tuam says, "Dust clouds driven from the Javan eruptions may be the reflectors of the strange sunlight from beneath the horizon; but I should rather seek for the agency of ejected gases lighter than our air, such as hydrogen now settled high above the earth." This hydrogen might have been provided by a gaseous comet or meteor stream, and he hopes that no oxygen comet will follow suit in striking us, or there may be a new deluge. It may be mentioned that in 1783 somewhat similar phenomena were witnessed in Europe, Asia, and parts of America, and White in his "Selborne" speaks of the sun at noon looking as blank as a clouded moon, and shedding a rose-coloured ferruginous light on the ground, being particularly lurid and blood-coloured at rising and setting. In most of the accounts the phenomena are attributed to a dry fog or haze. Prof. Brooks, while comet sweeping on November 28, observed a shower of telescopic meteors near the place of the sun.

Of the fourteen circum-polar expeditions eleven have safely returned. The Russian at the mouth of the Lena, and the Finnish at Sodankyla, will be continued for another winter, while the fate of the American expedition to Lady Franklin Bay is unknown.

The death is announced of M. Yvon Villarceau, one of the staff of the Paris Observatory, and an eminent French mathematician.

Mr. Richard Talling, a well-known student of English mineralogy, committed suicide in a fit of temporary insanity at Lostwithiel. He was in his 60th year.

Prof. Owen is to be made a K.C.B.

Last week, Prof. Chrystal and Mr. J. Murray made the ascent of Ben Nevis, and remained for the night at the observatory. Up to an altitude of 2,600ft. they found the road in good condition and practicable for horses, but above that point it had been carried away in parts by landslips, and above 3,000ft was more or less covered with snowdrift. On the summit, which was covered with snow to about the level of the roof of the observatory, they found a blue sky and clear sunshine; beneath the sun the sky was bronze or copper colour, but just above the horizon it had a peculiar pale green tinge. During the night the sky was cloudless, and the temperature was 32-36° Fahr. Mr. Omond reports the weather at the time as the best they had experienced, for on Dec. 12 they were unable to get out of the Observatory for several hours. The "Brocken spectre" is frequently seen on clouds in the valley to the north-east. The Observatory building is described as most comfortable.

It having been decided to republish the papers of the late Prosector of the Zoological Society, W. A. Forbes, as a memorial volume, Professor Sclater will undertake the editorship; Mr. H. H. Johnston will prepare a biographical notice, and Mr. Bell will act as secretary and treasurer of the committee.

Notice has been given by the British Electric Light Company that they have petitioned the Judicial Committee of the Privy Council for a prolongation of the Gramme patent, which was granted to Z. T. Gramme and E. L. C. D'Ivernois, on June 9, 1870. Notice of opposition must be given on or before the 1st of March next.

The Tilghman Sandblast Company have also given a similar notice.

In a paper read recently before the Royal Society Prof. Hughes gives an account of some experimental researches made with a magnetic balance, from which he concludes that we can find the electric conductivity of iron or steel from a simple reading of its magnetic capacity. Thus the best Swedish charcoal iron annealed has a magnetic capacity of 525, while that of crucible cast steel annealed is represented by 84. The electrical resistance of the same is respectively represented by 192 and 350.

A "Syndical Chamber of Electrical Workmen" has been formed in Paris to promote the technical training of the artisans engaged in what may be termed the electrical branches of industry.

The examiner of applications for patents in the United States has rejected nearly all those which, since the adoption of the new "standard" time, have been presented with the idea of securing a monopoly of watch and clock dials with figures arranged to show the twenty-four hours in a convenient way. It appears that an old record exists, in which it is stated that Prince Soltykoff possessed a watch made in 1547, which contained the 24 hours arranged in concentric circles.

M. Bert has presented a note to the Paris Academy of Sciences, in which are described further experiments by M. Bloch, to determine the rapidity of visual and other perceptions. Vision is the most rapid; hearing occupied 1-72nd of a second longer, whilst the sensation of touch required 1-21st of a second longer for transmission than a visual perception.

A conference of science teachers, under the auspices of the National Association of Science and Art Teachers, was held at the Technical School, Manchester, on Saturday, 22nd December. Professor H. E. Roscoe, F.R.S., was in the chair, and the various branches of the Association were well represented by delegates from Liverpool, Birmingham, Newcastle-on-Tyne, &c., &c. After the transaction of routine business, the secretary (Mr. W. E. Crowther) called upon Dr. Henry Evers (Newcastle) to read a paper concerning the expenditure of the Science and Art Department; and Mr. Wm. John Grey (Newcastle) afterwards read a report on the Examinations in Inorganic Chemistry. The delegates were then entertained at tea, and during the evening Professors Roscoe and Boyd-Dawkins delivered addresses, and Mr. Grey gave a science lesson on Nitrogen and its Second Oxide. Professor W. A. Tilden was among those representing the Birmingham branch.

The Bacillus of Phthisis.—M. Vignal has been trying some experiments with the view of ascertaining whether the sputa of phthisical patients as found in the streets still contained bacilli. He collected a certain quantity of such sputa and submitted it to desiccation; he then moistened it and let it dry again at different times, so as to place it as much as possible in the condition in which it would be found in ordinary circumstances in a room. He discovered that the sputa thus treated contained bacilli as numerous and as well-formed as if they had just been expectorated. He inoculated two guinea-pigs with the matter; one of which died in a few days from obstruction in the bowels, and he could not, in consequence, come to any conclusion; but the second animal, though it increased in weight during the first few weeks subsequent to the injection, afterwards began to lose flesh, and died in about three months. At the autopsy it was found that in all the organs there was a great number of tubercles which contained bacilli. M. Vignal concludes that sputa of phthisical patients, as found on the ground in the streets or in apartments, are far from being inoffensive, and might become agents of contagion to persons predisposed, or in whom the bacilli would find a favourable soil for propagation.—*Lancet*.

Plant Life.—It has been shown by Professor Schubeler, a Norwegian plant-geographer, that most plants in high latitudes produce much larger and heavier seeds than in warmer regions nearer the equator. This effect he attributes to the prolonged influence of sunlight during the long summer days of the high latitudes. The difference of seed development was very remarkable in some cases. Dwarf beans taken from Christiania to Drontheim—less than four degrees further north—gained more than 60 per cent. in weight, and thyme from Lyons, when planted at Drontheim, showed a gain of 71 per cent. The grain of northern fields is heavier than when grown in more southerly localities, and seed from Norway planted at Breslau decreased greatly in the first year. The leaves also of most plants are larger and more deeply coloured in higher latitudes, as was first noticed by Griesbach and Martins. The same is true of flowers, and many which are white in the southern climates become violet in the far north. While on this subject of the changes in flowers, it may be mentioned that a "chameleon sort of flower which grows in the United States is white in the morning and red at night. It has been named the Confederate rose, on account of its blending these two beautiful colours. The plant is odourless, it grows in great bunches, and is susceptible of a high degree of cultivation.—*Times*.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

A PUFF BY A PRESIDENT—FOCAL ADJUSTMENT OF A TRANSIT INSTRUMENT—LUNAR PHOTOGRAPHY—LONG-FOCUS TELESCOPES—THE NEW BRUSSELS OBSERVATORY—SOLAR PARALLAX FROM THE LAST TRANSIT OF VENUS—LIGHTNING CONDUCTORS—RAIN-GAUGE—SUN-SPOTS VISIBLE TO THE NAKED EYE.

[22188.]—I COULD not help laughing—in common, I believe, with every one else who is at all behind the scenes—at a couple of paragraphs in the address delivered on St. Andrew's Day to the Royal Society by its President. I mean those having reference to the expedition to observe the eclipse of May 6 last. "In December last," said Professor Huxley, "the President received from the Lords of the Treasury a letter, addressed to their lordships by the Lords of the Committee of the Privy Council on Education, recommending to the favourable consideration of the Treasury a memorial from the Solar Physics Committee, suggesting the organisation of an expedition for the purpose of making observations during the solar eclipse of May 6, 1883; and the President was requested to communicate his views upon the subject to the Treasury. After careful consideration, the President and Council reported in favour of the projected expedition; but they added that they did so *on condition of its being possible to find someone, whose position in the scientific world would command the confidence of the public, to take charge of the expedition* (the italics are mine). Unfortunately, for one reason or another, none of the men of science who fulfilled this condition were able to go; and at the meeting of Council of January 18, the projected expedition was abandoned. The President was, however, requested to place himself in communication with the American authorities, and to ascertain from them whether a photographer and assistant could be allowed to accompany their expedition to Caroline Island. On doing so, he at once received an invitation for two observers, who were accordingly sent out, their expenses being defrayed, partly by a contribution from the Government grant, and partly by a special sum of £500 provided by the Treasury." Unless Mr. Huxley is a much less astute person than the world gives him credit for being, how he must have laughed in his sleeve as he read the words which I have italicised above! Why, C'est le secret de Polichinelle, that the original memorial of the "Solar Physics Committee" was presented in the full hope and belief that one of its own members would have been sent out, and that it was only when the "Department" refused point-blank to suffer a man who was receiving public pay for specific work to leave his post, that any hitch arose at all. Few Fellows of the Royal Astronomical Society will have forgotten the ridiculous and contemptible exhibition made at the meeting of December 8, 1882 (ENGLISH MECHANIC, Vol. XXXVI. p. 334), nor that when a gentleman whose knowledge of Solar Physics and of the phenomena of Eclipses generally is unsurpassed in this country, *did* volunteer to go out, he was snubbed by the persons professedly anxious to secure efficient observation of the phenomena. It is notorious that his opposition to the jobbing little Ring at Brompton was the sole cause of his application being refused. Either, then, Mr. Huxley knows all about this, and must be thoroughly aware that the gentleman to whom I have referred would have enjoyed the entire confidence of the British *Astronomical* public—in which case I would rather not trust myself to say what I think of the Professor's method of lending himself to the glorification of the Brompton Ring—or he is ignorant of the story, and was only repeating a South Kensington lesson like a parrot; in which alternative the value of his utterances on this subject needs no Solon to

AFTERGLOW.

[22195.]—Among the flood of letters written during the last few weeks about the curious *afterglow*, I have not seen one which alludes to the strange phenomenon being visible at midday, as has often been the case here; in fact, on *any* day when that part of the sky near the sun was free from cloud. On the 1st December, an astronomical friend and myself noticed it very distinctly, and it was still more marked on the 16th, when it presented the appearance of a beautifully delicate rosy halo, the inner edge of which seemed to be about 5° from the sun, the *glow* extending some 20° to 25° outwards. **T. E. Clapham.**

Austwick Hall, West Yorkshire.

SYSTEMATIC STUDY OF SELENOGRAPHY — FRACASTORIUS AND NEIGHBOURHOOD—AN APPEAL.

[22196.]—The large number of our readers who are interested in selenographical matters will be pleased to hear that a goodly number of members of the Liverpool Astronomical Society have combined to make a systematic study of this interesting formation and its neighbourhood, acting on a valuable suggestion by your esteemed correspondent, Mr. Elger. We have adopted the following plan of operations. In the first place, we shall endeavour to obtain a correct outline of Fracastorius itself, showing the position of the valleys which intersect the S. wall, also the depressions on the E. and W. walls; and further, to describe, and if possible to delineate, the interesting details on and about the N. border. This done, we shall endeavour, in the second place, to carefully draw the principal objects outside the limits of Fracastorius from "Rosse" and "Beaumont" on the N. to "Piccolomini" *e f* and A, and Fracastorius *c* and A on the S.; also for about an equal distance towards Santbeck on the W., and Polybius A on the E.

The object aimed at, and which will be accomplished if the work is carefully done, is to secure a number of objects to which the craterlets and other features on the interior of Fracastorius may be referred by the method of alignment.

This plan, especially as regards the first part of it, provides work eminently suitable for the employment of telescopes of small apertures, say, 2½in. to 3½in. or 4in.; and my principal reason for intruding upon valuable space is to heartily invite the co-operation of those of your readers who, possessing such telescopes, are at a loss as to the direction in which to turn them to accomplish really useful work. The opportunity is a splendid one, and I shall be pleased to hear from any who can see their way to assist us. We hope before long, with our Editor's kind permission, to publish in these pages such results as we have been able to arrive at.

As regards the interior of Fracastorius, the minute details of its surface are such as can only be satisfactorily studied with telescopes of larger aperture; and this section of the work we propose reserving for the future. **W. Goodacre.**

Clova-road, Forest Gate, E., Dec. 25.

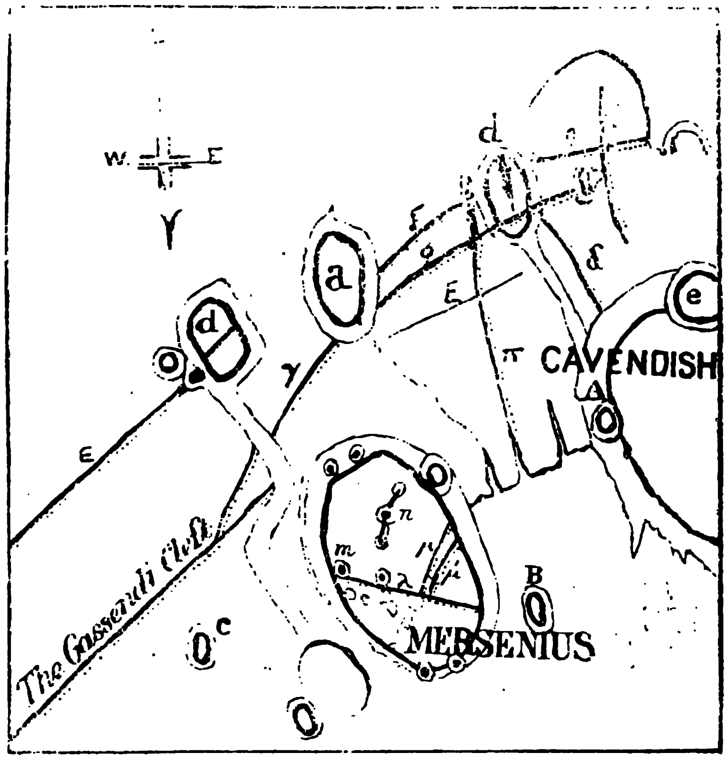
P.S.—To those who would like to join the Liverpool Astronomical Society, I may mention that our secretary is—

Mr. W. H. Davies, 55, Great Newton-street,
Liverpool,

who will be doubtless pleased to hear from such.

SELENOGRAPHICAL — THE CAVENDISH RILL-SYSTEM—CLEFTS ON THE FLOOR OF MERSENIUS—FRACASTORIUS.

[22197.]—The accompanying diagram shows the clefts seen in the region south of Mersenius and Cavendish on November 11th and 12th with a power of 400 on an 8½in. mirror, the definition on both evenings being very good. With a few exceptions it agrees fairly with Neison's map of the district, to which I will briefly refer. A well-marked cleft, δ, was traced from the N.E. side of Cavendish *d* to the S.W. border of Cavendish, which does not appear in Neison's map, and is also omitted by Schmidt. On the west side of the same ring-plain, *d*, is a very distinct row of confluent craterlets lying at the foot of the wall, and crossing clefts ξ and ϕ, which is clearly shown by Neison, and in part by Schmidt. At 10h. on November 11th a fine cleft was seen to extend from the N. termination of this row to a point about midway between Mersenius and Cavendish. It is marked π in my diagram. Neison draws a cleft running in a N.E. direction from the north side of Mersenius *a* to a point rather nearer Mersenius than the N. end of π, but I was unable to see it, though a ridge, occupying nearly the same position, was a prominent object. Neison's cleft ξ appears to be a ridge, and not a true cleft. The crater-row and cleft which traverses Cavendish *d* and extends in a northerly direction nearly to cleft ϕ, where the latter crosses the floor, was a noteworthy feature.



Mersenius.—In Dr. Klein's "Anleitung zur Durchmusterung des Himmels" (a book, by the way, very similar in plan to Prebendary Webb's invaluable "Celestial Objects") is a copy of the fine drawing of Mersenius by Schmidt, in which two short parallel clefts are shown running in a westerly direction from the inner slope of the E. wall. On November 11th both these objects, marked μ μ', were well seen and traced more than halfway across the floor; μ, however, was the easier of the two. On the following night, November 12th, 9h. to 9h. 30m., another delicate cleft, λ, was visible, extending from craterlet *m* to to the N.E. border in a direction which, if prolonged, would intersect Mersenius B. On the N. side of λ is a row of hillocks. These clefts, together with that which appears to connect the central row of craterlets, discovered by Mr. Gaudibert, probably form a connected system.

Fracastorius.—In reference to Mr. S. Maitland Baird Gemmill's observations (letter 22121) of this formation, I should like to know if he saw the bright object C as a craterlet on November 18th? I invariably find it very difficult to see as such with my 8½in. reflector, though in times past it seems to have been visible as a prominent crater. **Thos. Gwyn Elger.**

Kempston, Bedford, Dec. 20, 1883.

SELENOGRAPHICAL—ALPHONSUS.

[22198.]—On p. 339 Mr. Gaudibert asks, What has been observed by others in the dark patches on the floor of Alphonsus? He mentions having seen a whitish craterlet in the centre of the triangular patch on the E. of the floor. This craterlet has been seen by Dr. Klein for some years, and forms the subject of a paper on the volcanic formations of the moon in "Petermann's Mittheilungen" in 1882, and was translated in the *Observatory* of that year. The paper is illustrated by a sketch of the dark patch *p*, and the floor and border of Alphonsus around it, and there is a full description of the details observed. Dr. Klein considers the crater cone, which he calls A, to be one of a few instances of recent volcanic action on the moon, and that the dark matter flowed out from it in a fluid state, and spread itself in a thin layer over the ground around. The other instances of similar crater cones are surrounded by a ring of smoky grey material, which Dr. Klein supposes to become bleached in time, forming the so-called "light-surrounded craters." If Mr. Gaudibert can refer to this paper of Dr. Klein's, he will find a full account of all that that observer has seen in this patch. The round patch on the S.W. is not mentioned by Dr. Klein. I have seen nothing in this patch; but the crater cone A in the patch *p* I have seen well, together with a minute craterlet on the N.W. edge of the patch. The patch has not always appeared triangular to me.

On p. 322, letter 22122, for "craters N. of Theophilus, shown by Mr. Neison," read "*not* shown by Mr. Neison." **M. A.**

CONTINUOUS BRAKES.

[22199.]—"Traffic" (letter 22148) seems to have put a construction upon my letter, on page 323, I by no means intended. When I said, "the amount of stopping power stored up by the train is proportional to the velocity," I did not mean this to be considered with mathematical accuracy, but only that "the greater the velocity, the greater the power," of course, within certain limits. In this, I think, "Traffic" will agree with me. The limit, of course, is theoretically atmosphere pressure; but practically a pressure of about 12lb. per square inch. I merely mentioned the G.W.R. vacuum brake as a case of a continuous brake in general use, the stopping power of which depends upon the speed, and in this case at least, I was right in stating that the application was not satisfactory. I did not mention the ejectors, because, if the trains stop at least 1½ minutes at a station, the brake leaks off by itself.

"Traffic" seems to think that I am trying to disparage the Parker-Smith brake. My opinion on this point is to give the brake a fair trial to see what it can do. In my letter I have merely stated objections to mechanical brakes, which have already been discovered in their practical working. These letters were written chiefly because "Imprimatur" did his best to disparage the Westinghouse brake, when running against the facts of the case.

As to vacuum brakes, *impartial* engineers have condemned them, not only on account of their want of power, but chiefly *because they cannot be relied upon to act when required.* **Meteor.**

ELECTRIC MOTOR FOR MODEL LAUNCH.

[22200.]—In the Strand, in the window of an optician (Apps, I think), I saw lately a neat model launch, whose propeller was connected by a thin rubber belt with a tiny motor set on deck just over the stern like a small cannon—occupying next to no space on the vessel—and connected by a couple of wires with a small battery placed amidships in the hold, the battery circular top being level with the deck. On return to school, my rough sketch on blackboard of what I had seen seemed to give such an evident thrill of pleasure to my pupils that I felt the time taken from "Mr. Feeder, B.A.'s" operation of grinding away at "pello, pepuli, pulsum, pellere" was well spent, and the only regret was that the mechanism having been so small, and my own vision not double-magnifying, I could not give the working details of the engine, and so gratify the curiosity of the more ingenious of the young fellows. Would some correspondent versed in those matters gratify teachers and parents of little boys all eager to be practical, by rather minute details as to how to construct a concern of this sort, in the same painstaking way (but not necessarily at so great length) as has been done in these ever-interesting pages in the case of the lathe, model steam engine, blowpipe analysis, electric bell, microscope, photography. Messrs. Bottone, Sutcliffe, Goold, or "Nun. Dor." are, any of them, I feel sure, competent to initiate, little by little, such docile but dull duffers as myself. If, in Mr. Sutcliffe's sketch, p. 113, No. 967, two more arms were given to the revolving magnet, could their cross-piece cross or be welded into the darkened cross-piece already in sketch? I have seldom felt so exquisite an intellectual pleasure as when I read Mr. Bottone's clear description of "Pacinotti's Ring Armature Dynamo," p. 188, No. 971: (yes. I must confess. I've been lending over and over the "E. M.," containing the article, to some score of pupils by way of a treat, and in compassion for their dreary toiling at ablative absolute, iambuses and trochees, metaphors and similes, discount, stocks, and the usual staple of modern high-class schooling). I could wind the wire on magnets and ring, use files, heat and hammer iron rods in a small way, but those "prolongations" look formidable, and would not iron or brass radial arms interfere with the electricity generated in the ring?

I hope some correspondent will kindly forward detailed description, and show step by step how to fit up on a small scale, devices and apparatus of such profound interest at the present day.

A Big Bairn.

CONCERNING LOCOMOTIVES — TO "HISTORIAN," MR. STRETTON, AND OTHER RAILWAY MEN.

[illegible]—ABSENCE from home has prevented me replying earlier to the letters of "Historian" and Mr. Stretton, contents of which I carefully note. I have devoted some time to looking over Vol. XXVI., to which Mr. Luis kindly referred me some time ago, and at page 170 of that volume I find very full dimensions of a Midland express engine given by Mr. Stretton, who said that the engine could take 15 carriages on a level at 60 miles per hour. Allowing [illegible]tons for engine and tender, the total weight of the train was 210tons, and the total resistance was [illegible]lb. This resistance was overcome through [illegible]ft. per minute; so the number of units of work done in that time was [illegible] and dividing this by 33,000 we get [illegible] as the actual horse-power of the engine. Again the driving wheels were 7ft. in diameter, and must have made 4 revolutions per second, which corresponds to [illegible] strokes a minute. The stroke was [illegible]in., which gives 1,640ft. per minute as the speed of the piston. The diameter of the cylinders was [illegible]in., and piston area, therefore, 255 square inches. Taking the average pressure in the cylinders as [illegible]lb., we get pressure on piston [illegible], and work per minute in each cylinder [illegible]lb., whence the h.p. comes out as [illegible], which agrees very closely with the other calculation. I particularly wish to have the opinions of our railway correspondents as to these figures, because there seems so much uncertainty as to the actual horse-power of loco. engines. I have asked many persons likely to know, and have received very various replies; but in no case was the power [illegible] even approximately equal to the above results. I do not forget that Mr. Luis said (page [illegible] last volume) that it is not [illegible] mode of expressing the power of [illegible] engine; but what I want to know is: Are the above figures correct?—and [illegible] usual or the reverse. It is interesting to notice that the piston speed given [illegible] exactly the same as that suggested [illegible]. I have not yet had time to [illegible] Mr. [illegible]'s letter, but as far as I [illegible] it seems to be in disagreement with "Historian's" statement as to the impossibility of [illegible] the speed of an engine.

Wm John Grey.

[illegible]

THE LIGHT OF OTHER DAYS.

[illegible]—[illegible] light occupies a definite [illegible] together with the [illegible] vast distances [illegible] before it reaches our [illegible] which we can see, [illegible] quite fanciful, [illegible] domain of the [illegible] at least conceivable that [illegible] may be endowed with [illegible] greater than anything [illegible] may be possessed [illegible] as we can have [illegible] possible for them [illegible] detail at distances [illegible] imperceptible by our [illegible] the existence of any [illegible] by the light which [illegible] we know that it is [illegible] of them may have been [illegible] at some time prior to the [illegible] have their exist[illegible] hand, others which [illegible] within reach [illegible] not yet reached [illegible] shot fired from a [illegible] we have of the [illegible] really see, not at [illegible] subsequent [illegible] facts to compare, [illegible] longer interval of [illegible] the full in[illegible] which we had seen. And by the time this knowledge was *present* to *us*, it would have been a thing of *some time past* to the person who fired the shot. Now, taking this idea in conjunction with that which I before mentioned—namely, the possibility of other beings possessing powers of vision capable of minute observation as far as light can reach, the strange thought is suggested that to such beings occurrences on this or other worlds which have long since been past and gone, and perhaps forgotten, may at the present, or at a still future time, be present to their sight as *actually happening in the present*. Supposing *we* were endowed with such form of vision, and that we were able to travel unfettered by space, we should, for instance, only have to retire to the respectable distance of "α Aurigæ," whence light would require some 70 years (*vide* p. 310) to travel in order to become *actual spectators* of, say, the Battle of Waterloo. Of course, we know that, according to the laws with which we are acquainted, the light of this earth would not be visible from "α Aurigæ"; but who can say but that under conditions with which we are *not* acquainted it *might* be?

J. H. C.

MICROSCOPIC TEST OBJECTS.

[22203.]—IN reply to "Monachus" (22151), I began to realise the uselessness of oblique light for the determination of true structure during a lengthened examination of a Nobert's 19 band plate. I was much struck by the appearance of a single line of the 1st band, when viewed by an oil imm. $\frac{1}{25}$ N.A. 1·25, illuminated by a large angled cone of direct light. The groove, which the diamond had ploughed in the glass, was most distinctly seen, and along the sides of the groove there were places where the chips of glass had flown off. With oblique light all this was lost; the line appeared as if it had been painted on the surface of the glass. This showed me that if definition was wanted direct light must be used.

I do not intend for one moment to affirm that a higher band of Nobert can be resolved by direct than by oblique light: but this I do say, that the ultimate structure of a diatom can only be demonstrated by direct light.

No microscopist in the present day would uphold the theory that the ultimate resolution of the P. angulatum was six sets of lines or grooves, inclined at an angle of 60° to one another. But a similar view of it was held in Quekett's time, for in the frontispiece of his book there is a beautiful engraving of it, exhibiting diamond-shaped marks all over it; a false conclusion, the result of oblique light. Neither will anyone insist that the ultimate resolution of the N. Rhomboides is represented by two sets of lines, at right angles to one another, a picture produced by the employment of two beams of oblique light, Fig. 1. In the days of Griffith and Henfrey they got beyond that, and dotted the Rhomboides, Fig. 2.

Fig. 1

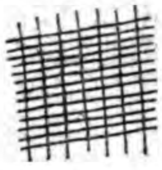


Fig. 2.

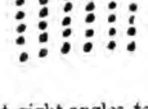

Fig. 3.

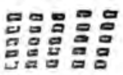

It is quite natural to expect that with the increase of aperture and the improvement in objectives there should be simultaneously a development in the resolution of the diatoms. One misses too, with oblique light, all that beautiful tracery inside the hexagonal areolation of the coscinodisci, which can only be seen by direct light; for with oblique light the blur of the hexagonal structure blots out the fine markings. When we come to the very finely-marked diatoms, such as a Pellucida and some of the Nitzschiæ, we must be content with lines, by oblique light, until we can get sufficient aperture to enable us to see the ultimate structure.

I will now close by giving a sketch of the development of the resolution of N. Rhomboides.

Dec. 28. **Edward M. Nelson.**

[22204.]—THERE is an additional point in Mr. Nelson's letter (No. 22134) which is no less puzzling than his other statements; but which your correspondent "Monachus" does not notice.

Mr. Nelson considers it absurd to test an object-glass by oblique light, as thereby the central part of the object-glass is not used—"it might as well be stopped off altogether."

This involves one of the most curious *petitiones principii* that I remember to have seen in microscopic matters. The answer to Mr. Nelson, of course, is, that the method we pursue in testing a thing is necessarily entirely decided by the purpose to which it is intended to be put. If we are concerned with a cannon or a racehorse, we test the one in relation to its power of resisting the tendency to burst, and the other to its power of speed: but we don't reverse the process, because we don't require the horse for any service in which it will be liable to be burst, nor the cannon for any in which it will have any temptation to run away.

So with the object-glass which we are intending to use for the examination of the diatoms mentioned by Mr. Nelson. For their resolution it is the marginal part of the object-glass which alone is used. The centre is unused, and might as well be stopped out: a conclusion similar in words to that of Mr. Nelson; but otherwise very different.

The origin of Mr. Nelson's mistake is simply that he has failed to grasp the action of those diffraction spectra of which he writes. If he will follow out that subject, he will not engage himself in future in the useless task of testing what "might as well be stopped off altogether."

T. T.

MICROSCOPIC MOUNTING.—VI.

Chloroform—Vegetable Objects.

[22205.]—1. *Chloroform or Benzol for Thinning Canada Balsam.*—In the first place, I have very heartily to thank Mr. Wright for his criticisms: for work can be done and methods brought out only by interchange of ideas. Balfour ("Manual of Botany," p. 784) prefers benzol. The chloroform solution has been in use for nearly fifty years, I believe; it is commended by Frey, in his work "The Microscope," and by Beale, in "How to work with the Microscope," p. 57 (Beale also mentions the benzol solution, p. 90); and Carpenter mentions both, without giving the preference to either. I am informed that in chloroform and C.B. many of old Mr. Topping's best slides were mounted, and I do not remember to have previously seen or heard that it produces spottiness, of which, again, I have no personal experience, though I have mounted more than two hundred slides in this way within the last eight years. By spottiness, I presume Mr. Wright means disintegration or break of continuity of the Canada balsam which remains after the media used with it have evaporated. In a slide of *Surirella gemma*, mounted by I. D. Möller in phosphorus, which I got some little time ago, a cavity has appeared among the objects near the centre of the slide. In another, of *Arachnoidiscus Ehrenbergii*, the same thing happened under one of the objects while I was examining the slide; the speck disappeared on applying warmth. The truth seems to be that whenever there is under the cover, along with the object, a mixture of several substances, some of which evaporate, while the rest solidify, the escape of the volatile ingredients is liable to leave interspaces. Even if simple Canada balsam is employed, the same thing *may* perhaps happen, as its turpentinous part will in time escape. It must be more likely when there are only scattered particles of balsam, though the space beneath the cover be filled with liquid, as if too weak a solution of the balsam were used; and more likely again if the object is sopped with turpentine, oil of cloves, of cajeput, lemons, &c., in being mounted, so that there is scarcely any balsam in its immediate vicinity. I believe, then, that the best resinous mounting is balsam as stiff as the object will stand, and as can be managed without air-bubbles; that as little turpentine as possible or other fluid in which the object has lain should be introduced with it into the balsam, and that as much as possible of what is introduced should be allowed to evaporate before putting on the cover. But if the object is too delicate to be thus treated, some solvent must be employed; and on the above principles I believe that the great point is not to make the solution too weak, and to allow the solvent partly to evaporate before covering. The greater volatility of chloroform is here, of course, distinctly advantageous. But I admit that the evaporation may be inconveniently rapid when complicated objects, such as an insect or the head of a blowfly, have to be arranged on the slide. A skin may form over them, and entangle delicate parts, so that, e.g., the antennæ may be broken. But touching the part which it is required to move, with a minimal quantity of chloroform, or turpentine, releases it, while the other parts remain fixed. However, this would not be so likely to happen with benzol, a smaller quantity of which, moreover, it is my impression from experience of seven years or so ago, renders a larger amount of balsam of an oily or creamy consistency. The rate of evaporation, moreover, does not depend solely on the solvent employed, but balsam solutions harden more rapidly in proportion to the hardness of the balsam from which they are made. The plan recommended by Beale for benzol (which is the most detailed I have met with) is to bake the balsam in an oven below 200° Fahr. till it becomes chippy. Stiff Canada balsam is useful for very many purposes; hence I recommended balsam to be bought in a corked bottle, in which it stiffens more rapidly. To make the chloroform solution I let it stay there till it retains the same position when the bottle is slanted or inverted, which is a less violent method than baking it. I then dissolve it in chloroform (not methylated chloroform), and keep the solution in a stoppered bottle for use.

I have taken for granted that by spottiness Mr. Wright does not mean the milkiness or dirtiness which appears in objects where the water has not been well taken off by spirit, or the spirit by turpentine, benzol, oil of cloves, cajeput, lemons, bergamot, or some other "bridge." Both water and alcohol render Canada balsam milky, so that the object should remain a day or two in spirit to remove the bulk of the water, or for a longer time if bulky or containing cavities or tubes. It has remained long enough in turpentine or benzol when it "clears," a change easily recognised in most specimens after it has been seen in a few, and consisting in greater transparency and hardness, and smaller flexibility. If allowed to remain too long, therefore, objects become unmanageable and brittle; they may also contract and tear, or curl from contracting more on one side than the other. The only thing is to remove them before these detriments have occurred. In oil of cajeput an object need continue only a couple of hours or less, and, with oil of cloves, a few minutes suffices, the spirit and water evaporating from the upper surface of the section while the oil penetrates from beneath. I have also supposed that air bubbles are not referred to. Canada balsam and its solutions contract in proportion to thinness, so that after a longer or shorter time a space is left at the edge, between the slip and the cover. This is easily filled up by slanting the slide and putting a drop of Canada balsam, or a solution of it, close to the edge. It runs down and fills up the space. The process has to be repeated as long as evaporation and contraction perceptibly go on, after which a ring of Canada balsam and chloroform (or, if the reader prefers it, benzol) may be laid on at the edge of the cover, the slide having previously been cleaned. Finally, as Canada balsam becomes brittle with age, a ring of goldsize may be added. In all this, I have been speaking of the preparation of the ordinary small microscope slides; I have no experience as to larger ones often sold for the magic lantern. I ought to add that the milkiness (which appears as soon as the water or spirit have had time to escape from the recesses where they lurk) often vanishes with time and warmth, and that the contraction is greater with large covering glasses. It must be more dangerous in proportion as the cover is nearer the slip.

II. *Non-fructifying Organs of Higher Plants.*—In the last two letters I have described the process of cutting sections by hand and the action of the common chemicals or reagents. Both of these are employed, both on animal and on vegetable preparations. I will now take up the preparation of vegetable objects in particular, which form a considerable and important part of a microscopical cabinet. The most difficult vegetable and animal preparations, as a rule, are those by which the lower divisions of the two kingdoms, and the embryology or early development of plants and animals, are attempted to be illustrated. It is best, therefore, to start with the higher plants, about which, again, most of us have already a larger amount of pre-existing knowledge to help us in further investigations, rather than with the lower, where the tissues and organs, if they exist at all, are very delicate and minute, and present only in an inchoate and imperfectly formed condition.

By non-fructifying organs are here meant leaves, petioles, or leaf stalks, stems (including branches and twigs), with scales, hairs, and any other appendages they may possess, and roots, with tubers, &c. With stems are to be counted rootstocks, which are underground or almost underground stems. The primary organs are the leaves, which are cakes or expansions of cellular, pithy, or fundamental tissue, so-called because it is the only kind of tissue found in very lowly plants, and because the other kinds are modifications of it. It forms the pulp of the leaf, green towards the outside, but often little coloured internally. It is covered in aërial leaves, as distinguished from those whose surfaces are immersed in water, by covering tissue consisting of epidermis coated by a sort of glaze of cuticle, and is strengthened and supported by the so-called veins, which consist of fibres and vessels, and not only strengthen, but help to maintain, the circulation of juices in the plant. The bundles of fibres and vessels arrange themselves more or less symmetrically at the base of the leaf, proceed down the leaf-stalk, which may be regarded as an unfolded part of the leaf, re-arrange themselves on entering the stem, which may again be viewed as a compaction of leaf stalks, and from the trunk or ascending axis pass into the root or descending axis of the plant, where they are redistributed among its branches and twigs, till it at last ends in delicate cellular tissue similar to that of the leaf.

These and other points may best be illustrated in the first instance by dicotyledons, where they are very symmetrically exhibited. The following examples are easily procured and identified:—Thick leaves, most of which are obtainable at any season: rhododendron, laurel, holly, ivy, begonia. Petioles, soft and thick, some channelled, or with ridges and furrows, others without: celery, carrot, parsley, and most other umbelliferous or hemlock-like plants; fig, mulberry. Annual stems, also soft and thick: sunflower, bean, yarrow, most umbelliferous plants, cabbage. Soft perennial stems: poplar, willow. Roots and tubers: potato, radish, turnip, parsnip, carrot, and umbelliferous roots generally. The structures may then be followed into endogens, then into ferns, and their allies the adder's tongues, horsetails, and club-mosses; and finally pursued into the mosses and liverworts, which are the lowest and least characteristic of the higher, vascular, cormophytic, axial, or leaf, stem, and root plants. The structure of the stem, &c., in gymnosperms resembles that of dicotyledons. The common English gymnosperms are the coniferous or cone-bearing plants—firs, pines, cypresses, yew, the arbor vitæ, &c.—easily distinguished by their foliage, and often containing much resinous matter. For the transport of this to the stem there are conspicuous resin-ducts in the leaves, which render transverse sections of them interesting microscopical objects. The following are easily procurable examples of endogens or monocotyledons:—Valisneria spiralis, anacharis, stratiotes, hydrocharis (all with wholly or partly aquatic leaves, and familiar to aquarium keepers); orchids, the iris, black bryony (a common hedge plant: good root), lilies, tulips, onions, asparagus (a good stem), rushes, sedges, and grasses, including wheat, rye, oats, &c. No English endogens have perennial stems; all our shrubs and trees are exogens; *i.e.*, either gymnosperms or dicotyledons, so that for woody perennial endogens (palms, bananas, dragon tree [specially recommended], lily tree, sarsaparilla, cane), we must be content with dry specimens, or have recourse to a hothouse.

III. *Ways in which Vegetable Sections should be Cut.*—It follows from what has been said that the best places for cutting sections of the above objects are—(1) In the course of the root or stem where no branches or leaves are being given off, and in the course of petiole; and (2) where branches or leaves are separating, and where the petiole and blade of the leaf are passing into each other. The first set exhibit the ordinary lines of rails, as it were. The second, which are often fine polarising sections, help in understanding the construction of the junctions; for which, however, a stem may be steeped till it has begun to macerate, and the bundles then be carefully scraped clean. Heat, or the addition of a little nitric acid to the water, accelerate the process.

The sections must be cut either *exactly* vertically or parallel to the length of the stem, petiole or root, or exactly horizontally or transversely to its length. If this is not attended to, the lumen or aperture of the smaller tubes will not be seen in horizontal sections, or, at least, the section will have a twisted and overlapping appearance; while in perpendicular section tubes or fibres will pass out of sight. Horizontal sections are most instructive for obtaining a general view, and longitudinal, which may be either axial, or through the axis or centre of stems, &c., or tangential—i.e., on one side of it, for examination of details. Oblique sections are useful supplements to combine the horizontal with the longitudinal views.

Stems and the like have been here supposed to stand upright. Leaves, on the other hand, are conceived as lying flat, so that with them a horizontal section is one parallel to the surface of the leaf. This can scarcely be obtained, unless with thick fleshy leaves; but its place is partially supplied by tearing. If a leaf be bent, till it partly breaks, or the epidermis just cut through with a sharp knife and raised a little at the edge—as in cutting a small piece of blotting-paper from a pad—the piece may be taken by its edge between the finger and thumbnail, and torn away from the cellular tissue beneath. This is easy in endogenous plants which have straight-veined leaves; in exogens, whose leaf-veins are forked or netted, it may be difficult. It is, however, facilitated by steeping the leaf in water, or in water with a few drops of nitric acid; or, again, in the nitric acid and chlorate of potash solution. The skin of the other side may be first torn roughly off. The action must not be allowed to go too far; or not only the subjacent cellular tissue, but the epidermis itself, will become unmanageably soft. Adhering pieces of "parenchyma," as cellular tissue is called, may be cautiously scraped off, especially if previously softened by immersion in the nitric acid solution. Their presence, however, is not always objectionable (*e.g.*, in the under side of a begonia leaf), and they do not stand out if bleached. Indeed, the whole thickness of a thin previously-bleached leaf may be mounted. Almost horizontal sections may be secured by shaving a leaf with a razor. Vertical and oblique leaf sections, which are longitudinal if from base to tip, and transverse if across the leaf, may be made by folding a leaf several times, or taking several leaves together, cutting through the whole, and afterwards picking out the best sections; or a piece of carrot may be cut in two, a portion of a leaf inserted, and the whole cut together. Transverse sections of leaves are usually the most instructive. Petals and sepals, which are really leaves, the first of the corolla, or (usually) the coloured leaves of the flower, and the second of the calyx, the (usually, again) green, leaf-like envelope which protects it while in bud may be dealt with in the same ways. Scales, as in ferns, may be simply picked off, dried between slips, steeped and heated on a slip with turpentine to expel the air, and mounted resinously to polarise. Hairs may be taken off with the leaf skin, or their insertion seen in section.

IV. *Bleaching.*—The best staining for a general view of the object is obtained when the sections are cut from perfectly fresh tissue, and immersed in the staining fluid, immediately, or as soon as any tags, &c., which adhere to them have been washed away. Vegetable objects, however, have often a strong colour of their own, which would combine inharmoniously with the stain. Strong solutions of caustic soda ("E. M.," No. 979, p. 367) not only remove or change and diminish the colour, though that of the suber or cork (yellowish-brown) sticks to it obstinately, but have the simply invaluable property of rendering opaque trial sections transparent in a minute or two. All that is necessary is to put a drop of the solution on the section as it lies on a slip; see that the drop thoroughly penetrates it, cover it, and leave it for a moment. It is destroyed as the action proceeds. But a weaker solution, 5 p.c. or so in glycerine, regard being had to any special delicacy of the object, allows of subsequent mounting, if removed by thorough washing with acidulated water, glycerine and water, or glycerine ("E. M.," No. 979, p. 366) before it has produced its full effect. Alcohol and bisulphide of carbon also decolorise. But they do this less perfectly than solution of chlorinated soda, the following recipe for making which is given by Cole in the first volume of his "Studies in Microscopical Science." To a pint of distilled water add 2oz. of chloride of lime. Stir, and shake well, and at once add a saturated solution of washing soda till the mixture becomes thick and turbid. Allow it to settle, pour off the clear part for use, and keep it in a well-stoppered bottle in a dark place. To use it, immerse the sections in it for from six to twelve hours, and afterwards wash them with five or six changes of water in the course of 24 hours. If allowed to remain too long in the chlorinated soda, they will become disintegrated. The solution is alkaline, though not very strongly so, and removes or renders transparent the ordinary contents of the cells, permitting only the cellulose walls to be afterwards seen. I have not tried sulphurous acid solution or chlorine water; but I presume they might also be used for bleaching vegetable sections.

V. *Staining.*—Cole recommends the sections then to be double-stained as follows:—1. Leave them in a mordant for twelve hours or so. The mordant is prepared by mixing one fluid ounce of a 5 p.c. solution of sulphate of alumina with thrice that quantity of a 5 p.c. solution of lead acetate, leaving the mixture to settle, pouring off the clear fluid, and diluting it with four or five parts of (distilled, preferably) water for use, filtering. 2. Then wash the sections, and immerse them in alkaline carmine till well stained. To prepare this the receipt given is 15gr. carmine, the same quantity of strong ammonia, and two fluid ounces of water. Dissolve the carmine in the ammonia with a little water by the aid of heat, and add to the rest of the water, keep in a stoppered bottle, or the ammonia will evaporate, the carmine or carminic acid, which is retained by it in solution, concomitantly precipitating. On account of the varying strength of ammonia, what has practically to be done is to add it till no carmine settles, and then to add a little more.

The next step is to drain off the staining fluid, of which no more than enough to cover the sections, which may be little more than a dessertspoonful, need have been applied. They are directed then to be washed rapidly in dilute nitric acid, thirty drops little apparatus which I call a hand-warmer, and after giving it a thorough trial I have not the slightest hesitation in asserting that I would not be without it for *twenty times* its cost. It consists of a neat oblong lamp or stove, which is adjusted to the front of the keyboard opposite the middle octaves. It burns four small lights, and by using the best kerosine oil no fumes whatever are caused in the room. By thoroughly warming the hands and wrists, it also keeps the whole body at a very comfortable temperature on the coldest day. I can adjust or remove it in a moment; and so far from being any disfigurement, it is quite as ornamental as the brass candlesticks frequently attached to pianos.

The cost of my own was 21s; but the maker informs me that as he has now all the tools and appliances exactly required, and knows precisely how to go to work, he can make others at 12s. 6d. each. **W. Ritchie.**

KEY CHARACTERISTICS IN MUSIC.

[22211.]—I am sorry to divert N. E. Child (letter 22184) from his main issue to what must be, at best, a side subject to him. My discourse did not regard "bird crumbs," but the opening of a hung window, which is fitly enough comparable to the opening of the highest-pitched reeds in the voice harmonium. So also is the lengthening of a reed tongue, which implies alteration of pitch, not unlike the lengthening of a forefinger. N. E. Child's "say," notwithstanding, I *know* that when the reeds are set on end in the voice harmonium the high-pitched ones *give no sound at all*. I live near Fort Matilda, on the Clyde, where soldiers at times practise their exercise with reeds tipped with fire. Every cannon used has a throat, but when it speaks the neighbouring hills, even to a distance of many miles, are as if they were all throat together. The application of this to the matter in hand is brief, and definitely carries my meaning. The voice harmonium, as it is, is not acceptable, and is comparatively useless. Stripped of its keyboard, and hung up in its bones, and only allowed to reply to another pure-tuned instrument played upon, it would be, in a small way, like the Highland hills replying to Fort Matilda's guns.

Gourock, 31st Dec. **George Templeton.**

AMATEUR MUSICAL INSTRUMENT MAKING.—IV.

[22212.]—Having now fixed the position of the two holes F and A (Nos. 1 and 19, see Figs. 5 and 6) near the extremes of the body, we obtain the expected positions of those between them thus:—On a strip of paper, make two marks at 29·6 cent. from each other, representing the above two holes, shift this paper on the geometric scale till it incloses 15 lines between the above, F being thus No. 1 and A being No. 17. This position will be found on the 23in. parallel, placing F on D sharp, and A resting on G natural. The intervening lines are then marked off on the strip, and will represent the various semitones between F and A. To check the accuracy of scale it may now be laid on the 19¼in. parallel, between C and E, which should exactly correspond with the lines or marks already on the strip. We thus get distances correct for holes that gradually decrease in size, and that are ventilated more or less the same as the two we have chosen to start with; but other considerations now arise, such as holes Nos. 6, 8, 10, 12, 15, 16, 17, all require to be covered by the fingers. Nos. 6 and 8 have rings round them, and as it will not do to have small holes alternately with large ones, the other holes must be sometimes modified to be somewhat uniform with them. So that every hole on this instrument is a compromise, the holes not being in their theoretical position at all. To accomplish this would involve alterations of fingering, increasing the number of holes, and the result would be a doubtful advantage. I may remark in passing that the Boehm clarionet does not give so fine a tone as the Albert, and the Albert is not so good as the old instrument with six keys. It thus appears that the number of holes closed by pads are either not kept tight, or that the pads interfere with the tone somewhat. By a large number of keys we gain in facility of execution, and have the instrument in better tune.

"J. J. D." asked, on Aug. 24th, if the holes were placed at nodes. Now, in a tube containing vibrating air a node is a place of no vibration, so that nodes should be between the holes, the centre of a neutral segment being under the sounding hole. Some time ago I drew out carefully the theoretical and actual vibrating segments of a number of tones on this instrument, and found that sometimes a node occurred close to a hole. Generally speaking, in the range from lowest note to C on second ledger line above, the holes are fairly placed, and near the centre of vibration. If a hole is opened at the node of a note sounding, it usually interferes and breaks the tone. For example: if, when lower B natural, 3rd line, is sounding, we open the key No. 19, Fig. 6, no change is perceived, as this key is then at the centre of a neutral segment; but if the octave B natural is sounded, key 19 being then at a node breaks up the note. Also at top E natural the harmonic key No. 21 should not be used, as it is near a node. A hole widened or placed higher allows the point of greatest vibration to shift higher up, the clarionet being usually reckoned as a stopped pipe; the point of the reed is at a node, and the length of its vibratory wave is *four times* the length of the tube when sounding its lowest note. Our clarionet tube being now ready for the metalwork and keys, the next step is to determine where each hole must be, so I now give their position both on the C and B flat instrument, referring at the same time to Fig. 5 and 6 for general place and form. Clarionet makers first bore all the holes on the body, and then put on the keys, &c.; but this cannot be well done by amateurs, the easiest way being to wrap white paper round the body, fastening it with gum, then draw the keys, pillars, and fittings in their proper places, and mark the pillars through the paper with a small point or drill. The paper can then be removed, the pillar holes bored, screwed, and the pillars and keys, &c., fitted to their places on the body. The sounding holes are then marked carefully on the wood of the body by drawing a sharp point round the metal key cups. The keys are then removed, polished, the springs added, and the pads put on. The sounding holes are then bored, roughly tuned, and finished round the edges. The keys are then put on, and the instrument is ready for final tuning and regulating.

To those who are making a clarionet I will give full-sized lithographs of keys and parts, if they advertise their addresses within two months and pay postage. This will save them some drawing, and explain matters clearly, as Figs. 5 and 6 contain a few errors, and are not intended for working drawings. Those who make the body all in one piece, please correct the distances as follows:—

Hole No. 10 place at 29 cent. and bore at 6 mill.
Key No. 11 place at 27 „ „ 5·5 „
for the C clarionet.

Also correct the B flat positions thus:—

Hole No. 10 place at 33·1 cent., and bore 7·6 mill.
Key No. 11 „ 31·2 „ „ 6·6 mill.

Keys of Instrument. See Figs. 5 and 6.	C Clarionet.			B flat Clarionet.

18th December. **Vulcanite.**

THE MARTINI-HENRY RIFLE ON PICKET AND SENTRY DUTY.

[22213.]—As far as my experience went, sentries and picket guards always kept their rifles loaded (I mean in war time): I presume it is the same in the English service. But how can this be managed with the regulation Martini-Henry, which is always at full-cock when loaded? I understand that on the first introduction of this arm into the British army there was a safety stop to it, which enabled the soldier to carry it safely when loaded, and that this stop was afterwards abolished. Would some of your military readers give us the reasons for this step? For mere firing in line the weapon in question may be well adapted; but that is only one part of a soldier's duty. In wild and wooded countries the scouting soldier should take a leaf from the hunter's and trapper's book, and then, I think, he would find his present gun not the best adapted to his needs.

Last night I had a practical illustration of its unfitness for this sort of warfare. When I left the frontier, soon after the close of the American war, I never expected again to creep along in darkness and rain, rifle in hand, with eyes and ears at their utmost tension to detect an enemy lurking in the brush, and yet this has come to me. One of my tenant's houses having been fired into by Land Leaguers, I patrolled about the place for some time in the night, intending, if the game was attempted again, to try to make these gentry feel in their own persons what they so freely administer to others. Well, I actually was afraid to keep my gun loaded (a regulation Martini-Henry carbine) on account of the defect alluded to. I got two falls, and they showed me plainly enough that a loaded rifle at *full-cock* was not desirable under such circumstances. At last I abandoned the dangerous weapon and trusted to my pistol alone, and everyone knows that is a poor tool except at very close quarters. Next night I shall take a double smooth-bore with buck shot.

By the way, under any circumstances, this is the best arrangement for a dark night; except in very bright moonlight, one can't see the sights of a rifle at night. One thing that struck me at once, is the difficulty of walking on a road without making a noise with the feet. Under ordinary circumstances one would never notice this; but last night the contrast between it and the prairie or the forest was very marked.

December 28. **Ex-Frontierman.**

AN EIGHT-INCH SPARK COIL.

[22214.]—It may reasonably be supposed, from the frequency of recent inquiries, that the interest felt by a large section of our readers in the subject of the construction of induction coils is not exhausted. I, therefore, describe a coil which I have lately completed, and which gives sparks 8in. long, with a battery power of five-pint Grove cells. The general dimensions were based in part upon information gathered from the back volumes of the English Mechanic; but very numerous preliminary experiments were found necessary for the determination of certain points, such as the most favourable distribution of the secondary wire along the core, and the minimum of efficient insulation.

The core is of No. 20 B.W.G. iron wire, of good quality, and was carefully annealed in charcoal. It is 1ft. long, 1¼in. in diameter, and weighs 2lb. 12½oz. The primary is of No. 14 copper B.W.G. single silk covered, wound in three layers upon the covering of silk tape which envelops the core, no insulating material being interposed between the layers of wire. The weight is 3lb., the length about 140ft., and the number of turns 345. The finished primary and core were immersed for several hours in melted paraffin. They are inclosed by an ebonite tube, 14in. long and 3/16ths of an inch thick, having an internal diameter of 2in. The secondary is of three gauges, each single silk covered. It contains 1lb. 7oz. of No. 36 B.W.G. and 6lb. 8oz. of a wire which was purchased as 35 B.W.G., but proved to be a mixture of 35 and 34 in unknown proportions. The total weight is 7lb. 15oz., and the resistance 4,970 ohms. An exact statement of the length can hardly be made; but even if the whole of the nominal 35 were genuine, the total length could not exceed six miles, and, in point of fact, it is probably much less than this. The secondary is wound upon Ritchie's or Apps' method, in 37 vertical compartments, each compartment being 3/16 of an inch wide, and containing, roughly, three ounces of wire coiled to a height of about 1in. from the insulating tube. The winding was begun in the centre, with the number 36, which occupies the exact middle of the primary, and the other sizes were so disposed that the diameter of the conductor increases with as much regularity as was attainable towards the extremities. All the wire was baked, and passed through hot paraffin, in winding, and *the superfluous paraffin was not wiped off*. Each convolution of the secondary is, therefore, imbedded in solid paraffin, and no accidental interstices occur wherein leakage can set up. The discs or partitions are of stout white blotting-paper, baked and steeped in melted paraffin; two thicknesses were placed between each pair of compartments. The diameter of the coil, including its casing of thin sheet ebonite, is about 4⅜in., and the length 9½in. Protection is afforded the ends of the secondary, and any brushing or leakage towards the primary prevented, by thick discs of paraffin wax. Readers who desire fuller details of the mode of coiling the wire, &c., are referred to my communications on page 598 of Vol. XXXV., page 118 of Vol. XXXVI., and page 18 of Vol. XXXVII. of this journal.

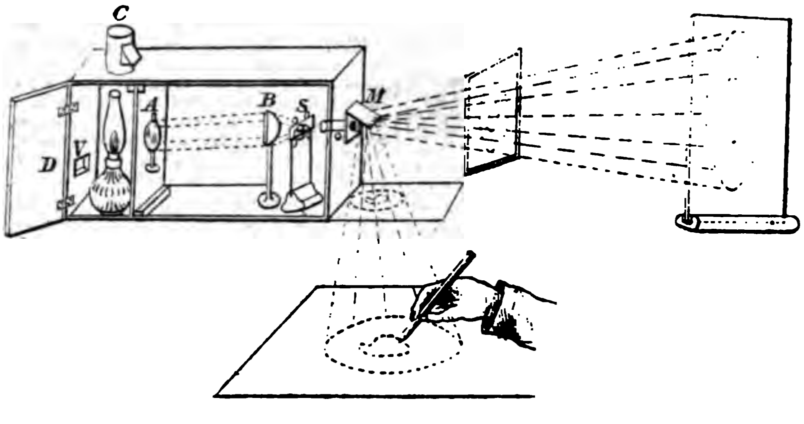
The amount of condenser surface required was arrived at by careful experiments, and the foils were built up to a capacity of half a micro-farad. The contact-breaker is of Apps' patent form, described and illustrated in Vol. II. of Gordon's "Electricity," where it may be studied. One of the greatest difficulties in the construction of a large coil, or of any coil containing a *large core*, is the arrangement of the break in such a way that it can be made to act slowly enough to bring out the full power of the instrument. An interesting

Respecting a cheap drilling machine, though I should be very willing to comply with "W. F.'s" suggestion, let me say that my hands are full for many weeks to come. When, however, the articles for which I am under obligation terminate, I will place my services at the disposal of our indulgent Editor once more. J. M.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[52126.] — **Microscopical.** — Presuming the camera lucida is required, for utility I strongly recommend the following substitute for drawing or enlarging purposes:—I use a box about 21in. by 15in. by 8in., without lid, sideways, on the left-hand side of which I put my lamp, flame edgeways, closed in with a sliding partition, carrying a condenser. This throws the light in parallel rays on a second condenser, near the focus of which I present the object desired. This I advance towards an objective (preferably 1in.) screwed into the inside end of the box. So far, this constitutes an excellent micro-magic lantern. The image can be received on a screen of tracing-paper, amplified as much as loss of light will permit. Just outside the hole which carries the objective I hook on a small piece of looking-glass at an angle of about 50°. It reflects a distinct image in natural colours on a sheet of paper placed on the table. If I want a diagram larger than usual, I simply place my box on a chair on the table. It has the advantage that, in moving the object, you need not touch the optical arrangement. After sketching you may replace the object by a slide, specially made to show a measured scale, and the amplification of the diagram may then be registered. Of course, the room must be darkened, and light must not be permitted to escape from your lamp, except through the condensers.—A. Dean, 57, Southborough-road, South Hackney.



A, 1st condenser; B, 2nd condenser; V, ventilator; C, chimney; D, door open; S, slide; O, objective; M, mirror.

[52181.]—**Balance (?) Gear of Omnicycle.**—The vague reply of "E. G. M." to this query tells nothing, and is, moreover, misleading. In the Omni there is no sort of "balance" gear in any way analogous to Starley's invention or its numerous copies. The Omni belongs to the class of tricycles nowadays called "clutch drivers," which includes the Devon, Cheylesmore, and many others. It drives both wheels when travelling straight only, for when rounding a curve the outer wheel ceases to be driven. The *spécialité* of the Omni is its highly ingenious "segmental gear," which was one of the first, and still is, perhaps, the best, means for varying speed and power.—W. H. S.-W.

[52261.]—**Screening Gravel.**—If Mr. Booker would take the trouble to look at some of the stone-breaking machines, he would get an idea how to construct his gravel-sorting machine. I don't wish to make any unkind remarks; but it seems to me that such a query as this is purely for the personal benefit of an individual, and is of little interest to anyone else. If Mr. Booker, with all the information he can easily find in his back numbers, cannot make a machine of the kind he wants, he should seek professional assistance, and pay for it. As his query stands, an answer to it would involve several drawings and several columns of letterpress; but briefly he may be told to make an iron cylinder with holes of the size he requires, and erect it over a tank. The water must be let into the top end of the cylinder by a pipe, the other end extending over the side of the tank, and depositing the gravel in one or more heaps, if Mr. Booker requires it in two or more sizes.—Ilford.

[52263.]—**Engine.**—"Luir" should look through his back Nos. for the sketch he wants. The size of the ports depends on the work the engine is to do, to some extent; but as a guide he may make them $\frac{3}{16}$in. wide, by $\frac{3}{4}$ to an inch long; the exhaust should be $\frac{3}{8}$in. wide by three-quarter inch long: the bars about $\frac{3}{16}$in. wide. What size passages are there in the cylinder? for it is clear that it is no use leaving the ports with twice the area of the passages; they should be larger—that is all. I think the querist will find several drawings in back volumes that will be of use.—Model Maker.

[52264.]—**Fan Blower.**—The blast from such a fan ought to be quite sufficient, and a 1in. nozzle is large enough. With the fan itself and the forge surely you can easily ascertain the best speed and the best dimensions yourself—that is, if you like to take a little trouble, which apparently you do not. —S. M.

[52265.]—**Steel Burnishing.**—The only burnishers required will be pieces of steel with rounded edges, long enough to be grasped each side, so that they can be rubbed over the surface while applying as much pressure as possible. No solution at all is used. Why don't you read up the subject, if you know nothing about it? There are several articles on burnishing in back volumes. The whole art consists in getting a high polish by means of a forcible compression of the particles on the surface. No specially-shaped tools can be required for flat surfaces 5ft. by 5in.; all that is needed is a bit of good hard steel with a suitable face, elbow grease, and the will to apply it.—S. M.

[52270.]—**Simplex Telephone.**—"H. B." cannot use a telephone for business purposes without being liable for royalty. The connections seem clearly indicated in the illustration referred to; but there is no line from E to L, as supposed by querist.—E. M. P.

[52274.]—**Packing.**—The quantity of packing consumed by a locomotive depends on so many things that it cannot be stated definitely. A loco. stuffing-box properly packed will last for months, whereas one carelessly done will not last a day.—Driver.

[52277.]—**Oboe.**—If "One in Trouble" really pays 2s. each for his reeds, no wonder he is in trouble. The prepared reeds cost about 2d. each. Let your correspondent refer to pp. 20, 41, 92, Vol. XXIX. The querist should also look up his recent numbers, as, if I recollect, there was a good deal about the oboe lately.—Squeaker.

[52285.]—**Focal Adjustment of Astronomical Transits.**—You will be able to use a meridian mark 30 or 40 yards off by contracting the aperture to about one-fifth of an inch. My transit instrument has a hinged shutter for that purpose.—R. P. G.

[52287.]—**Organ Query.**—"Organ Grinder" should look up his volumes. A pipe organ, the height of which does not exceed 4ft. 6in., is really verging on the absurd; it is in every way better to have a reed instrument when so cramped. The longer pipes must be off the chest proper, and the bellows be small and inadequate. The whole thing is out of place, for the one thing needful about a pipe organ is size.—Organon.

[52290.]—**Powdered Cellulose.**—The only way of obtaining this is to grind it between millstones. —S. M.

[52291.]—**Polishing Aluminium.**—Polish in the usual way with buff-wheel, using crocus and dry lime to finish. Nickel can be brought to the highest degree of polish from the reflective point of view.—S. M.

[52307.]—**Gas-Engine.**—This query should be addressed to the makers. Perhaps they know how to do what "Volt" wants.—S. M.

[52315.]—**Ejector.**—There is no method of determining the quantity without making experiments.—X. M. M.

[52325.]—**Paper-Making.**—The microscope is the only test. Lime, plaster, china clay, &c., are the chief adulterations.—Sittingbourne.

[52338.]—**Holtz Machine.**—In your issue of the 7th inst., "A Subscriber" recommends the use of glass in preference to vulcanite for these machines. As I had made very full inquiry upon the point, I thought his recommendation very true, and am therefore surprised now to see, in a recent issue, that a contributor under the signature Paul Ward, gives opposite advice. Which of the two contributors can be right? Fortunately, we can get at the facts. Your readers will be better able to judge with these before them. They are as under —viz.: Good glass may be bought at 2d. per super. foot (it has just now risen in price); 30in. discs can be bought cut to circle at 1s. 3d. each; the drilling of the hole is done with emery and water, it takes about five minutes to bore; the total cost of a 30in. glass disc therefore is, say, 1s. 6d. I attach to this, for your own inspection only, the printed price-list of the largest makers of vulcanite, by which you, Sir, can verify the fact that 30in. discs of that material cost 50s. each, to which add the trouble and cost of "scrubbing the surfaces and dexterously coating with paraffin," making them, after all, paraffin discs. "A Subscriber" stated there was difficulty in keeping the surface of vulcanite in order. Does not the necessity of a paraffin surface go to prove this? On the other hand, I have a great many of the cheap glass discs in use; they give, I think, better results, and none of them have given trouble. As to the ozone, I dare say the machines I have had to do with were equal to vulcanite; but my nose is now so accustomed to ozone that I really don't notice it, much less do I walk in the country "to deodorise my clothes." I think I have plenty of data to enable me to put the other points mentioned by "P. W." in a different light; but I leave this to abler pens; my present object is to save any of "ours" leaping ere they look.—Another Subscriber.

[52379.]—**Banjo.**—If "A Lunitick" has not yet done anything to his banjo, I should strongly advise him, from five or six years' experience as an amateur banjoist, not to meddle with its construction in the way recommended on p. 312 by Mr. Davies and "Fiddler," as I think he would probably do a great deal more harm than good thereby. Neither should he on any account oil his vellum, unless he doesn't mind the risk of spoiling it. It might not spoil it—I cannot say whether it would or not; but I should be very much afraid myself of trying it on any but a very bad and worthless skin. A good skin should be almost as transparent as glass all over. If "A Lunitick's" banjo has a large portion of the vellum thick, white, and comparatively opaque, I think he will do well to get a new skin, and take care to choose a thin and clear one. I shall be happy to tell him how to put it on if he finds any difficulty about it. Most probably a great deal of the "tubbiness" he complains of is due to his fingers being soft at the tips and unskilful. It requires a good deal of practice to be able to bring out the full tone of a banjo. Time and practice will cure both these defects, and the tone of the instrument will improve by being played on, just as fiddles improve with use. By all means let him put marks across the fingerboard to mark the notes. They are an immense help; but they should be flush with the fingerboard, and on no account raised, as in a guitar, for the places where the strings require to be stopped in order to be in perfect tune have a curious habit of sometimes altering their position nearly $\frac{1}{2}$in. towards the hoop when a new string is put on to replace a broken one. So that, so far from the raised "frets" making it impossible to stop out of tune," they may sometimes "make it impossible" to stop *in* tune. This is a curious fact which I have often noticed, and for which I have never been able to account. I should be glad if someone could throw some light upon it. As a last hint, let "A Lunitick" make a higher bridge out of a piece of an old cigar-box, which is a first-rate material for the purpose, and let it be full $\frac{1}{2}$in. high in the middle, and I shall be much surprised if he does not find a considerable improvement in the tone.—Patent Plate.

[52390.]—**Dynamo.**—Your proportions of wire are right. The amount of iron in the armature should depend on the strength of the magnetic field—that is, it should have sufficient capacity to condense the lines of force within itself, and so prevent any of them from passing directly from pole to pole. If the inside turns of the coils cut any of the direct lines of force, currents are generated in the opposite direction to the proper or which fits tightly on to a cog-wheel, and I is the spindle which carries the minute hand (not drawn). Hope above will explain diagrams; if not, further explanations will be given with pleasure. Of, course, the bell does not ring above four or five seconds as a rule, simply because I feel it my duty to get up and stop it by unswitching a button attached to the wires.—Kiko.

Fig. 1.

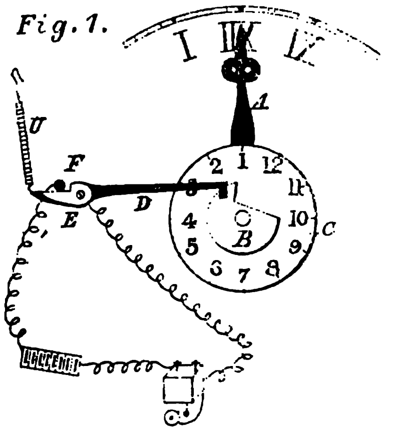


Fig. 2.

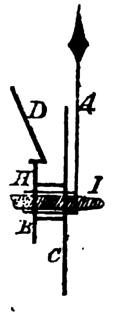
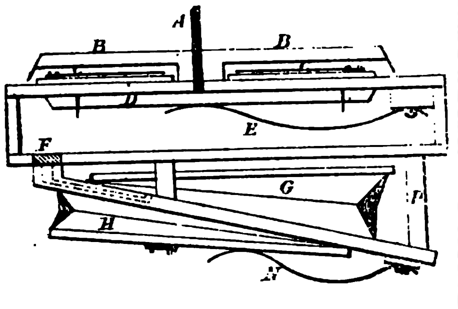


[52480.]—**Barrel Organ.**—I inclose sketch of a plan which may be successfully adopted for a barrel organ with two sets of reeds. A is the plunger; B B, the tubes; C C, the suction reeds; D, the large pallet; E, the pallet-spring; F, aperture through which the wind is drawn downwards by the reservoir G; H is the feeder, shown partly open; N is a spring used to close the feeder. Two feeders may be employed with greater advantage if preferred, though perhaps in this case one feeder may be sufficient. P P are uprights, to support bellows in position, which is on the horizontal plan. A row of short levers should be made to actuate the plungers as the barrel revolves. The feeder or feeders may be actuated by a small crank and lever. I can answer for the success of this arrangement, as it has been actually tried.—G. Fryer.



[52510.]—**Engine Speeds.**—Your first machine pulley makes 175 revs., and that on the second machine 113¾. But as you wish to reduce the first to 140 revs. I should advise you to put on it a 5ft. pulley and not meddle with the engine pulley at all. Whether you do this or your own way, the pulley on second machine must be 2ft. 8in. in diameter.—Engineer, Dewsbury.

[52510.]—**Engine Speeds.**—$140 \times \frac{5}{4} = 175$ = revs. of 1st machine. $140 \times \frac{4}{4} = 140$ = new rev. of 1st machine with 4ft. driving wheel. $175 \times \frac{2\frac{1}{6}}{3\frac{1}{3}} = 113\frac{3}{4}$ = revs. of 2nd machine. $\frac{140 \times 2\frac{1}{6}}{113\frac{3}{4}}$ = 2ft. 8in. = size of driven pulley to replace the 3ft. 4in. on 2nd machine to have the same number of revolutions as before.—T. B.

[52510.]—**Engine Speed.**—If "W. C. F." will multiply the diameter of his driving pulleys together, and the speed of his engine, and then multiply the diameter of his driven pulleys together, and divide the driver, by the driven to find the speed of his last shaft; and then multiply this speed by the diameter of pulley on this shaft, and divide by revolutions on first shaft to get the diameter of pulley required, I think he will see there is not much engineering nor mechanical skill required, or thus—26 × 60 × 140 = 218,400, and 48 × 40 = 1,920, 218,400 ÷ 1,920 = 113·75 revolutions. Then 113·75 × 40 ÷ 140 = 32·5 inches diameter of pulley required.—Firer, Dewsbury.

[52511.]—**Engine Power.**—To "Anxious One."—The way that I obtained the numbers 52,45·2, and 56·7, was by dividing the length of the stroke in inches, by the number of inches the piston had travelled when the steam was cut off, to obtain the number of expansions, and then multiply the terminal pressure by the hyberbolic log. plus 1 of the number of expansions at different points of cut-off. I think if querists would look up back numbers they would find plenty of information on "Engine Power," as the subject is nearly expended. For the benefit of our readers I will here give a few numbers of expansions, and also the hyperbolic logarithms:—

[52514.]—**Siemens Dynamo.**—If you have these diagrams and cannot understand them, I am afraid I cannot help you. The diagram I should have sent was one of these. The difficulty of winding these A.'s is that to make the coils all alike you must wind one layer of each coil at a time, so that you have 16 coils to wind all at one time, which is rather trying, as the wire is so apt to slip off.—W. H. E., Coventry.

[52518.]—**Waterwheel.**—500 gallons of water weighing 5,000lb. per second = 300,000lb. per minute; falling 5ft. = 1,500,000 foot-pounds per minute; divided by 33,000 = nearly 45½ h.p. A wheel for this fall would be an "undershot," or perhaps a "half breast," developing, at most, 35 per cent. of power = 16 h.p. The "creation" of the complement up to 70 h.p. would be a peculiarly interesting mechanical problem.—R. J. L.

[52518.]—**Waterwheel.**—"Tinker" cannot obtain 70 horse-power from the fall he describes. A waterwheel is only an appliance for utilising the power inherent in the fall. With the Editor's permission I will show in plain figures what this power amounts to. As 33,000 falling 1ft. per minute is a standard horse-power, we must find how many pounds of water is going over the fall per minute, and multiplying this by the height, which will give us the foot-pounds, dividing this by 33,000, shows the horse-power, thus:—

500 = No. gal. per sec.
60
30,000 = No. gal. per minute.
10 = Wt. of 1 gallon.
300,000 = Wt. of water falling per minute.
5 = Height of fall.
1,500,000 = Total ft. pounds.

Divide this total by 33,000 and we have 45½, nearly, as the theoretical horse-power of the fall in question. Practically, however, not more than about 65 per cent. of this power can be utilised by any machine at present invented; therefore, we must submit the result obtained to another short arithmetical process as follows:—45½ multiplied by our percentage of 65 and divided by 100 gives us (leaving out the smaller fraction), 29½ as the effective horse-power obtainable from the fall. "Tinker" does not state the purpose he wishes to apply the power to when obtained; as this will govern the kind of wheel to be erected, so as to obtain the best practical results. I shall be pleased to pursue the matter further if he gives this information, some kinds being adapted for a slow pumping motion, and others for quick speeds. Noticing that questions of general interest like "Tinker's" are often answered by formulæ, which is usually an algebraic statement of figures and signs only intelligible to those who have been fortunate enough to receive a higher education than most of us of the old school can boast of, and having at various times been disappointed at finding answers to such questions are given in "ours," after this manner, I have answered the above in the plainest possible way, trusting other writers will also take the hint, and not forget "ours" is the Mechanic, and not a paper circulated entirely amongst members of some scientific society who have mostly received a university education. It has not escaped me that a little extra space is required for detailed answers; but we must hope that our Editor is willing to dispose of a portion of his stock of the milk of human kindness for the benefit of his readers.—Moorman.

[52529.]—**Aluminium.**—Thanks to "K. G.," "Sigma," and "S. R." The quotation from *Industrie Blätter* is both useful and interesting; the greatest difficulty I have found, especially with copper, is the oxidation of the metal itself, a thin cake of the copper peeling off with the aluminium; with gold this is not so. It is with copper I am most anxious to succeed: any suggestion to obviate this difficulty will greatly oblige. I employ a low heat.—Zelia Naien.

[52536.]—**Bricks in Wall.**—If the wall is to be of solid brickwork, the number of cubic inches in the wall divided by the number of cubic inches in a brick will give the required answer. Thus,

$$\frac{50\text{ft.} \times 25\text{ft.} \times 9\text{in.}}{9\text{in.} \times 4\frac{1}{2}\text{in.} \times 3\text{in.}} = 13{\cdot}333 \text{ bricks.}$$

—J. M.

[52536.]—**Bricks in Wall.**—Cubical content of wall = 50ft. × 25ft. × 9in. Bringing each of the quantities to inches, we have—

$$50 \times 12 \times 25 \times 12 \times 9.$$

Cubical content of brick = 9 × 3 × 4½. Dividing cubical content of wall by cubical content of brick—

$$\frac{50 \times \overset{4}{12^*} \times 25 \times \overset{4}{12^*} \times 9^* \times 2}{\underset{3}{9^*} \times 3^* \times 9^*}$$

By cancelling, we get $\frac{40,000}{3} = 13,333\frac{1}{3}$. Therefore, 13,333⅓ bricks will be required to build the wall.—J. Byatt.

[52540.]—**Incrustations in Boilers.**—If "Ferro" will communicate with me privately, I can arrange for him to see a softening apparatus in work. I have four boilers and a large water supply (about 10,000 gallons per diem) under my charge, and since using the softened water have had no incrustation. The operations of softening, filtering, and pumping are performed simultaneously. This is not the Porter-Clark process; but judging by my own experience, this system may perhaps be as suitable to "Ferro."—Aqua, 39, Kynaston-road, Stoke Newington, N.

[52541.]—**A Curious Photographic Experience.**—I am surprised at your not obtaining a trace of a photograph with an exposure of ten minutes in limelight, for I once tried to photograph a picture of statuary thrown on a screen with a three-wick oil lantern, and I exposed two plates, one for five minutes and the other for ten minutes. On developing, the first plate was without a trace of an outline; but the second showed up the picture, but not strong enough to print from. My plates were "Derby" extra rapid, and I developed with hydrokinone and ammonia. So you ought to have got a picture with limelight.—J. S. Gladstone.

[52548.]—**Wharf Crane.**—"Vaga" should say what power he intends using. If hand-power, I can give measurement of a very satisfactory and light-working crane not to exceed 10 tons. Six men at handles; chain barrel, 9in. diam.; large wheel, 4ft. 6in. diam.: 2nd wheel, 2ft. 9in. dia., and pinion 7in., the last pinion 7in. also. It is good to remember that no one can tell how much too strong a crane is; but it is easy, if a crane falls carrying destruction with it, to understand that it is too weak. A crane calculated to lift 10 tons by engineer's rule, should be used only to 5 tons.—Wm. Hosken.

QUERIES.

[52578.]—**Aniline Ink.**—I should like to know if there is any permanent aniline colour of the same tint as a weak solution of iodide of potassium, and in what form it could be obtained?—C. T. THRING.

[52579.]—**S.E. Engines.**—Are there any single engines on this line besides Cudworth's 7ft.? and if so, a few particulars of them would oblige.—W. B. P.

[52580.]—**L.B & S.C. Engines.**—Would any one give a short account of Craven's engines on this line, their dimensions, where built, &c., especially of the 6ft. double-framed singles and the old goods? Were outside cylinders ever used on the L.B. & S.C.R.?—W. B. P.

[52581.]—**Thimbles.**—Could any one give me information respecting the manufacture of thimbles, how they are pressed or moulded into shape?—W. J. B.

[52582.]—**Copperplate Printing.**—Could any of your readers give me full details for making copperplate printing press to print etchings, largest size 9in.? A sketch, with dimensions of rollers necessary, would be esteemed.—COPPER.

[52583.]—**On Demand.**—How long is a bill "on demand" of value as a security, and can it be written "to bear interest"?—G. HARLEY.

[52584.]—**Magic Lantern Lamps.**—My three-wick refulgent lamp, burning paraffin, gives off an offensive smell when in use. It is kept as free as possible from any oil on the outside. Is there any remedy? What is the best way to trim the wicks so as to avoid as much as possible a pointed flame?—ROBERT JAMES.

[52585.]—**L. & S.W.R. Engines.**—To "CLYDE." Can you kindly give me numbers of 190 class (well tanks), 46 class (bogie tanks), 10-wheel tanks, new bogie passenger, and say how many of 380 class are there?—CARSTAIRS.

[52586.]—**L.N.W.R. Engines.**—Can any one kindly say what are the dimensions of engines 1182—1187, which were known as the low-domed Bury's?—CARSTAIRS.

[52587.]—**Incandescent.**—Will Mr. W. E. Dawson kindly give size of cells and zincs, carbon, &c.? Also the proper quantities of bichromate of potash and sulphuric acid to charge each cell, mentioned by him in answer to Bunsen Battery (query 52248)?—THERMO.

[52588.]—**Fireclay Furnace.**—I wish to make a small furnace for melting iron and brass? It must be large enough to take a No. 10 Morgan's plumbago pot. I have a 12in. fan to supply the blast to two tuyeres opposite one another. I think of building it of firebricks and clay inside a sheet iron case. Will some reader kindly give best shape and dimensions? Also inform me to what extent the size of the fuel and power of the blast modify the capacity of the furnace?—J. M. BESEAL.

[52589.]—**Battery.**—I am making a battery to light a small lamp for household purposes, and I wish to know how many cells I shall want, and how long they will last without recharging when made in the following manner? I have an outer earthenware jar containing a saturated solution of sulphate of copper, in which I immerse the copper plate and a porous jar containg sulphate of zinc, and the zinc plate immersed therein. Any hints will be thankfully received by—ROBERT S. HARGREAVES.

[52590.]—**Boring Head.**—Will some correspondent give description and drawing of a boring head to bore 3in. cylinder on 5in. slide lathe? Slow speed, four revs. of flywheel to one of mandrel. Please show number, size, and shape of cutters. What is loam—as used for casting?—SAILOR.

[52591.]—**Elliptograph.**—Can any correspondent describe the elliptograph exhibited at the Amateur Mechanical Society's conversazione on the 5th inst. by Mr. Inwards?—P.

[52592.]—**Theory of the Sun's Motion.**—To what does the President of the Royal Astronomical Society refer, when, as at the last meeting of the Society, he says, "When a change is made in the theory of the sun's motion, it will necessitate a corresponding change in the length of the mean day"?—P.

[52593.]—**Clayey Soil.**—My new garden is most of it of a very clayey soil. How will such soil suit for potatoes, cabbages, and fruit trees? If unsuitable, would some reader kindly suggest a plan to improve the ground?—SKEELIM DARG.

[52594.]—**Power for Lathe.**—Will some of our engineering friends kindly inform me what would be the stroke and diameter of cylinder of an engine required to drive a 3¼in. centre lathe, and about what would be the length and diameter of Cornish boiler to supply the same with steam not exceeding 50lb. per sq. in.—LEG-WEARY.

[52595.]—**Rapid Lens Shutter.**—Can some reader kindly give me an idea for making a rapid exposure shutter to be worked by springs on the inside of the lens tube, and to open and close in the centre, and if possible to be made so that any length exposure may be given? I should like to know whether such a shutter can be worked without cutting the lens tube.—C. R. H.

[52596.]—**Engine for Boat.**—I have a boat 26ft. long by 6ft. wide. I should like if any kind reader would tell me what size of an engine and boiler would be large enough to work it, as I intend to make it into a launch? Also what size propeller?—NEPTUNE.

[52597.]—**Soldering Joints of Gutter Buckets.**—Would any reader who has had practical experience in mounting gutter buckets for pumping inform me as to the best way of soldering the joint to make it as strong as the rest of the bucket? Also, what kind of gutter is best for the purpose of pumping?—BUCKET.

[52598.]—**Stenciling Ferns and Grasses on Wood.**—I want to lay fern leaves, &c., on white wood, and afterwards splash them with a brown liquid or powder—the wood being previously sized to receive the powder; but I do not know the *modus operandi* or the materials used, and I should thank my fellow-reader who understands this work to give me full directions, as after it is done I wish to varnish the work, taking away the fern leaves, &c., for such work as drawers or escritoires, &c.—LEO.

[52599.]—**Freezing Mixture.**—Can any of your scientific readers give me a formula and quantities for a freezing mixture, such as Prof. Tyndall used for bursting shells in a lecture room? Also, are the general public admitted to the Royal Institution lectures, or are they restricted to a certain class? Any information on this point would greatly oblige.—A. H.

[52600.]—**Proving Will.**—Having been appointed executor of a will in which I and my brother take shares of the property from our mother, I should be glad to know whether I can, without much trouble, prove the will, and go through the necessary business without the aid of a lawyer. Would the people at Somerset House give me any help?—J. C. WYNDYARD.

[52601.]—**St. Petersburg Standard.**—Will some correspondent kindly explain how boards and deals are converted into this measurement, and extend Std. 2 . 1 . 29$\frac{7}{18}$ at £8?—JN. WILSON, Jr.

[52602.]—**To Chemists.**—In an experiment with soda and lime a pink salt has formed. I should be glad to learn if there is any known compound of these salts of this colour, or if I should look for impurities as the cause?—ZELIA NAIEN.

[52603.]—**Asbestos.**—Can any of ours tell me of any use to which artificially-produced powdered asbestos could be put? I obtain it as a by-product.—ZELIA NAIEN.

[52604.]—**Variations of Draught.**—Can any of your readers tell me how I can make something to show the "pull" or draught of the fire of a Lancashire boiler? I want to ascertain the variations of the draught under different conditions.—KENWAY.

[52605.]—**Earth Contact.**—I have two earth contacts to make. Can any of your correspondents tell me if sheet zinc will do for the plates, as I have some old sheet by me? If so, what would be the best size to make them, and what must I bury them in, and how deep? I want them to ring a bell at a distance of about 200ft., and can get no water or gaspipes to put the earth wire on to.—G. I. C. E.

[52606.]—**Thermometer Box.**—Will some obliging correspondent describe a louvre-boarded box for thermometers to contain the usual wet and dry bulb, maximum and minimum? The particulars I require are—the inside measurements, the size of the timber used in the framework, and the number, distance apart, width, and thickness of the louvres. I presume it should be all made of wood. I know that, for the purpose of comparing records, such boxes should be as much alike as possible. I am sure that "F.R.A.S." uses a properly-constructed box, and hope he will be kind enough to describe it.—AGRICULTOR.

[52607.]—**Soap.**—Would "London Stone," or other soap boiler using steam solely, suggest a remedy for the too rapid weakening down of the leys by reason of the boiler injecting into the pans a quantity of water with the steam, thereby rendering it difficult to open or grain the soap. Would steam in inclosed coils do? I know dry coils are used, but having tried them for melting tallow and failed, I have not much faith in their being effectual. Another trouble: My boiler, pans, and pipes are exposed. What is the best way to protect them from the cold? Some tell me cement is a fraud, others recommend it strongly. Information from any one having experience would oblige.—PHILO.

[52608.]—**To Mr. P. Ward.**—I am at present experimenting on the electrical discharge *in vacuo*, but find some difficulty from the unsteadiness of the strata, and I propose to order from Apps one of the rapid breaks as used by the late Mr. Spottiswoode. I shall be glad to know if that will render the strata steady, and which pattern is the best for the purpose?—H. A.

[52609.]—**Working a Pump.**—I rejoice in immunity from water-rates, but am proportionately punished by having to exercise my corporation daily, Sir, in drawing or forcing by pump-action a double cistern supply, as if I were a galley-slave, or on board a burning ship about to go to the bottom of the ocean. The water is from an Artesian well, and I wonder whether any of your myrmidons of science would hold out hope that the muscular labour could be abridged by aid of some simple form of engine, gas, steam, or electrical, and if so, in what way, and at about what outlay?—DIDASKALOS.

[52610.]—**Paper Scenes.**—Being interested in the getting up of dramatic entertainments for the purpose of raising funds for Sunday-school prizes, &c., I should like to know if I can get any paper that would answer in place of the scenery which has to be hired for the purpose, as it takes all the shine out of the proceeds when about £2 has to be paid for one night's hire. If I can get anything that will do, I have a plan for making the scenes so as to be able to change them when required.—EDWARD MACKENLEY.

[52611.]—**Binocular Eyepieces.**—Will any one who has used Nachet's, Tolles', or Zeiss' binocular eyepiece (or that of any other maker) give the result of his experience? What is the magnifying power of the eyepiece? What is the highest power of the objective with which it can be used? Is the definition impaired to any appreciable extent? Is the field contracted? And lastly, Can any one of these eyepieces be used with advantage with any form of telescope?—E. D. W.

[52612.]—**Analysis of Lime.**—Can any of our chemical readers inform me how to make the analysis of Buxton lime used in causticising soda ash? What are the advantages gained by blowing air through the soda solution before adding the lime? The pan I use is fitted with agitators and steam pipe, and my object is to produce a fairly pure solution of caustic soda testing 18° to 26° Twaddell. I should like to know what saving is produced by blowing air through the liquid.—F. H.

[52613.]—**Mandoline.**—I have never heard this instrument played. As compared with the guitar (which I know well), what are its qualities (1) as an accompaniment to singing, (2) as a solo instrument, (3) facility in execution, (4) timbre—i.e., quality of musical sound, (5) does it require music to be specially arranged for it, or can average accompaniments be performed on it without adaptation?—W. H. S. W.

[52614.]—**Chromoscope.**—I wish to obtain an instrument called Stammer's chromoscope, designed for determining variations of colour-depth in beer. The following references from the French work are given in *Polytechnic Journal*, Vol. CCXVI. page 57, and Vol. CCXIX. p. 147. Any information as to these references would be useful, as I cannot find them. The following is a translation of a description of the instrument, translated from "La Bière" par Cartuyvels et Stammer:—"Messrs. Kohlrausch and Schwackhöffer have, in their remarkable works on Austrian beers, made use of the Stammer chromoscope to establish the relations between the composition of beers and their colour. The instrument comprises a reservoir for beer (I.), a tube or measurer (III.) bound to a colour-tube (tuyau à couleur—II.), and movable with it. The coloured glass adapted to (III.) is composed of two identical twin discs. An ocular allows of a simultaneous observation of the coloured discs. The instrument is mounted on a pedestal, having below a white unwrought mat mirror. The chromoscope is regulated so that in looking in by the eyepiece, after removing the coloured glass, one sees a circle uniformly lighted up, exactly divided in two. The coloured glass is replaced, and the beer, filtered and perfectly bright, is poured into the reservoir (I). The movable system is next displaced vertically until uniformity of tint is re-established. The appended table allows of direct expression of the colour of the beer in absolute numbers, comparable for every case and every instrument of like make. After each observation the instrument ought to be thoroughly rinsed with distilled water. A complete cleansing is always indispensable. This washing is much simplified by the special arrangement of all the parts of the instrument." Extracts from the table:—

mm.	Colour.	mm.	Colour.	mm.	Colour.
1·	100·	40·	2·5	2·0·	·50
9·	11·1	50·	2·0		

If any ingenious reader could offer a rough drawing answering to this description, and accompanying explanation, I should be much obliged.—C. T. THRING.

[52615.]—**Copper Reduction.**—I was much interested in reading Mr. William E. Dawson's description of the methods of copper reduction in a recent number, and I hope he will fulfil his promise by giving in your next number the description of the "best metallurgical process" he speaks of. I know of several copper mines, poor in ore, which cannot be worked in the ordinary way, but which probably could be worked to a profit by some cheap wet process. I should like to ask him if the processes he has already described are commercially payable, or if any wet process—such as dissolving the ore in sulphuric acid, and then reducing by scrap iron, &c.—can be made to pay, and if so, what would be the cost of plant, and of reduction per ton?—CHAS. E. BARNARD.

[52616.]—**Gas-Engines.**—Will any correspondent tell me what is the use of the rubber bags that are fixed on the gaspipes supplying engines? Some have one and other kinds two. Do they play any important part in the real working of the gas-engine, or if the engine would just work as well without them?—J. NICHOLS.

[52617.]—**Clarionet Playing.**—(1) I have a B flat clarionet with 13 keys. What is the use of the twelfth key from the bottom? I have not seen it mentioned in the fingering tables of instruction books. (2) Can I do away with transposing by means of the following method? Always playing music as written for the piano, and learning from the beginning to call the note on the clarionet by the same name as a note which is in tune with it on the piano.—W. B. LEIGH.

[52618.]—**Seismometer.**—Will some one please give a description, with diagram, if possible, of a seismometer? I don't mean of a home-made makeshift one, but of a recognised form of instrument, and oblige.—J. BYATT.

[52619.]—**Imitating Bronze.**—I have some small wooden objects which I wish to paint to resemble bronze. Could I make a paint with fine metallic copper, or some other metal, and burnish it?—E. W.

[illegible]—**Pyrotechny.**—What books, French or English, are there on this besides "Browne," "[illegible]" [illegible] "Cassell's Recreator"? Has [illegible] been [illegible]? What is a Mount Vesuvius? [illegible] smoke from balloon contrived? —[illegible]

[illegible]—**Siemens Dynamo.**—I have castings of [illegible] field magnets 8in. [illegible] Kindly give me size of wires and the [illegible]—Constructor.

[illegible]—**Oxy-hydrogen Lantern.**—I have been much interested in recent correspondence on this subject, and I hope that it may be continued. Will some one kindly tell me if I can get a bright disc with [illegible] at a distance of [illegible] from the screen by [illegible]. In other words, would there be much waste of light in working at that distance? I also wish to know if it is possible to show [illegible] satisfactorily to a large audience with the [illegible] I have tried was useless. I am [illegible] beautiful enlargements; but I want to be able to show [illegible] as well.—W. H. [illegible]

[illegible]—**Mural Decoration.**—I am about to paint the walls of my drawing-room with [illegible]—panels of [illegible] with a [illegible] conventional designs [illegible]. Will some correspondent kindly tell me what should be done to the walls as a preparation for painting? [illegible] the old paper will be washed off. Should the walls then be papered with a thin white paper or a [illegible] paper, or should they [illegible] with any preparation of distemper or enamel, and if the latter, what is it called? Any hints will greatly oblige.—[illegible]

[illegible]—**Dyeing Bunting.**—I wish to know how [illegible] bunting [illegible]. The [illegible] blue, red, and white [illegible] the different [illegible]—[illegible]

[illegible]—**Field-Glass.**—[illegible] field-glass, how am I to determine the magnifying power of same? [illegible] About what power and what angle of field of view should a first-class field-glass [illegible]? What are considered the best proportions for [illegible]?—[illegible]

[illegible]—**Wimshurst's Influence Machine.**—To Mr. [illegible]—Would [illegible] kindly tell me where I am wrong? I have just made a Wimshurst's I. M. from description given in "E.M.," Vol. XXXVI. No. [illegible]. My glass plates are 16in. diam., well varnished; the brass sectors are [illegible] wide at the top, [illegible] and they are [illegible] and are cemented on [illegible] from edge. Two of the sectors on each plate [illegible]. I have [illegible] brass tubes [illegible] which are made of fine brass wire and [illegible]. [illegible] the ends of [illegible] brass tubes carrying brushes are fixed by a [illegible]. The plates are [illegible] hard wood bosses by cement, and [illegible] through the plates, the [illegible]. The plates are [illegible] apart [illegible]. The fixed conductors are [illegible] supported on glass pillars. The stand is made of very dry wood. But when I warm the machine and rotate the plates rapidly, I cannot see any [illegible]—[illegible]

[illegible]—**[illegible] Colours.**—Why [illegible] the presence of [illegible] the production of [illegible] and why [illegible] these [illegible] the ex[illegible]—[illegible]

[illegible]—**[illegible] by Machinery.**—[illegible]

[illegible]

[illegible]

[illegible]

[illegible]

[illegible]

and is there any economic advantage in such an arrangement?—W. F. Harcourt.

[52634.]—**Fluorescence.**—Any hints as to the illustration of this curious effect will greatly oblige, especially with stramonium, which is often quoted as very effective and which I have tried in a variety of ways, but with no result. I find the magnesium light superior to both the electric and the lime light for quinine and such experiments.—W. F. Harcourt.

[52635.]—**Singular Convulsions in a Young Child.**—Can any of your numerous readers assist me in discovering what is the matter with my little boy, aged two years and a half? About three months ago I observed that he would suddenly change colour, close his eyes, and go off into a kind of stupor for a few seconds, and afterwards breaking out into a profuse perspiration, leaving him with a deathly pallor over his forehead, and very purple round the eyes, always falling into a sound sleep immediately afterwards. I took him to the Children's Hospital, but they could not tell me what to ascribe these symptoms to. I have also consulted two private doctors; but with no satisfactory result. What I am anxious to find out is, could cutting his back teeth give rise to what I have described, or is it anything more serious? I should add, he sometimes has five or six attacks in a day, and occasionally goes a day, or even three or four days, without any at all.—Anxious Mother.

[52636.]—**Dihedral Angle.**—In my technical trade book, on the application of solid geometry to my work, the above words occur. I have asked the Grammar Schoolmaster here, and he cannot tell me. Will some kind fellow subscriber do so?—Coachmaker.

[52637.]—**Dog-cart.**—Will some fellow-subscriber inform me the true mechanical principle where to put the axle of a two-wheel dog-cart, to carry one, two, three, or four persons, without any luggage?—Coachmaker.

[52638.]—**Cement.**—What is the best kind of cement to use for putting together the mortise and tenon joints of out-door window sashes?—Chips.

[52639.]—**Netting.**—Will anyone kindly give me a few hints to enable me to make a net for lawn tennis? I learnt a few years ago, but have since forgotten it. Is there a book on the subject?—Hammock.

[52640.]—**Gumming Machine.**—Can anyone kindly send me the plain description of a machine for spreading gum or varnish over paper so as to get a smooth surface, say, demy size paper?—Gum Paper.

[52641.]—**Manganese Battery.**—Will Mr. Lancaster kindly tell me the best way to construct this battery? I must just add that I have made one or two up in the ordinary salt jar by placing a piece of thin wood as a porous portion, allowing only a third of the jar for the zinc. Now, is it best to use a small porous pot or a partition of wood? I seal the manganese part of the cell over with pitch, &c.—Onward.

[52642.]—**Copper Deposition.**—I have seen large pieces of work, ships' rams, and calico rollers, with a very thick coat of deposited copper upon them, and I believe the copper is so fast that the two metals cannot be separated, the deposited copper having so far penetrated the pores of the metal to such an extent. I also learn that locomotive and marine steel boiler tubes are done in the same way. Can any of "ours" give some idea how these articles are prepared to receive so fast a deposit, also the kind of solution used? There must be other processes than the ordinary methods for preparing these large surfaces. Smaller surfaces can be deposited upon to stand fast and the burnish applied, but the above must be very fast indeed to allow of the heat and expansion and contraction they are subject to. Any information on the subject will oblige.—An Old Subscriber.

[52643.]—**Silber Lamp.**—The flame of my Silber lamp has an unpleasant habit of jumping up spasmodically, accompanied by a slight report. The shocks at first are very slight, and about sixty to the minute. The speed gradually decreases, but the violence becomes greater till at last the lamp is extinguished. What is the cause, and is there a remedy? I have tried various chimneys.—F. Search.

[52644.]—**Rusty Turpentine Tank.**—My iron tank has got rusty, and turns the turpentine red. Will some fellow subscriber kindly tell me the cause, and its effect on the turpentine, and how to remedy it?—Coachmaker.

[52645.]—**Painting Bicycle.**—Could any of our readers of the "E.M." kindly inform me the ingredients and what proportion to use in painting a bicycle? I have tried common japan, and after the japan has dried, I have applied a coat of copal varnish, but find the japanning will not dry. Can any of our readers help me out of the difficulty?—Dublin.

[52646.]—**Continuous Brakes.**—To Mr. Stretton. Would Mr. Stretton kindly give his opinion on the following mechanical brake? 1. Of brake that could be put on or taken off by enginemen or guards. 2. It would go on in case of coupling breaking, to the detached portion only. 3. It would use the momentum of the train to create brake power. 4. It would not be affected by the weather, as it would require no steam, air, or vacuum pipes. 5. It would utilise all the brake-gear at present in use, with the exception of the cylinders and pipes. 6. It would dispense with the expensive engine brakes in use, and consequently save steam and coal. 7. It would be very simple in action. 8. If anything should go wrong with the gear on one coach, it would not interfere with the brake power on the other coaches, either before or behind. I have partly made a model coach, and am fitting it according to the above; but I should like Mr. Stretton's opinion before proceeding much further. I would have written Mr Stretton privately, but I thought he would rather it appeared in the "E.M.," as I believe he is taken as an authority on this question in your paper. Would he also say at the same time what are a few of the Board of Trade requirements in this matter, if I am not asking too much? As I am a working man, I have not many facilities of getting to know these things, except through the English Mechanic.—Near Sheffield.

[52647.]—**Drainage.**—Would any of our readers inform me if I can claim compensation for damages from the local board of health under the following circumstances? My warehouse has a drain for carrying off spring water, about 15ft. long, with a fall of about 18in. running into the main sewer, which is under the control of a local board of health. At times, this main sewer becomes blocked at a distance of 100 to 250 yards from my premises, causing my warehouse to be flooded with sewage, and putting me to a great expense.—Flooded Warehouse.

[52648.]—**Model Locomotive.**—Will someone who is a fellow subscriber of the "E.M." kindly help me in the above? I wish to make it with cylinders 1in. bore by 2in. stroke; what size and strength ought copper boiler to be to stand a pressure of 120lb., so as to keep steam up when feed-pump is working, and to use coke for fuel? Also, size of firebox and number of tubes. A small sketch of boiler will greatly oblige, and any other particulars as regards engine.—Amateur.

[52649.]—**Varicose Vein.**—Would any of our medical readers kindly advise on the above? Having been subject to the above for the last three or four years, I took very little notice of it until lately, as it has started being very painful, and a tendency to cause a kind of stiffness below the knee. I might say that the vein starts just below the hip-bone on the right leg, and extends below the knee, and finishes like a small bunch of grapes. Any information will gladly be received by a—Poor Sufferer.

[52650.]—**Drain.**—I am laying down a drain 120yds. with 12in. clay pipes. What I require to ascertain is, would the pipes be sufficiently strong enough to carry the water during that distance, with a decline of 9ft., to force upwards a distance of 7ft., to turn a water-wheel for my woollen factory?—Thomas Davies.

[52651.]—**Hot-Air Closets.**—Will someone kindly give details and dimensions for fitting up one of these for private laundry use, with, if possible, and with Editor's permission, drawings, showing plan for racks to run in and out, and description of suitable firestove? Can one be made wholly of wood, so as to be built in the corner of an existing room?—B. O. B.

[52652.]—**Regenerative Burners.**—To Mr. T. Fletcher, Warrington, or Others.—Is the principle, adopted in so-called regenerative burners, of heating the gas as well as the air previous to combustion, sound, or is all the benefit derived from heating the air which supports the flame?—W. F. Harcourt.

[52653.]—**Electrical Currents.**—Do they really differ in quality, so to speak, as well as quantity, and how can these differences be ascertained? After reading most of the ordinary textbooks, I believed that "current" was always of one kind, though differing in amount; and that, in accordance with $C = \frac{E}{R}$, an increase of power in Volts, from battery or dynamo—or a diminution of resistance in ohms in external circuit—simply gave more force of current in ampères. Mr. Sprague's book, however, if I understand it rightly, does not quite imply this; but Fleeming Jenkin says expressly that a current cannot have other qualities than "magnitude, position, and duration," and warns his readers against older theories of "intensity and quantity currents." But in magazine articles, &c., currents are now spoken of as differing in quality of tension as well as in quantity of force. In fact, one illustration is given from the way in which water flows at high pressure from a small pipe—or at low pressure from a larger pipe—the effective power being the same in each case. Supposing this characteristic to exist, what is the formula for expressing it? And can it be measured by the galvanometer and resistance box?—Antares.

USEFUL AND SCIENTIFIC NOTES.

◆

The New South Wales shale yields, on an average, about 150 gallons of crude oil per ton, which contains over 60 per cent. of refined kerosine oil, and the remaining products consist of gasoline, benzine, spongaline, paraffin, wood-preserving composition, and lubricating oil. Its gas-producing capabilities amount to the large yield of over 18,000 cubic feet of gas, with an illuminating power of thirty-eight to forty candles. On this account it has been found advantageous for mixing with ordinary coal in the manufacture of gas.

The grey dust gathered from the lower doors of boiler furnaces after shaking the fires, and sifted through an ordinary milk-strainer, makes the finest of polishing powder for tin, table knives, silverware, &c., not leaving a scratch. Yankee peddlers have been known to sell it, disguised with a fancy colour.

A recently invented Boston machine cuts two, three, or four half-round hoops from a pole, according to size, and at the rate of 20,000 to 50,000 per day. One of the results of its introduction will, it is said, be the utilisation for this purpose of the "tough and almost indestructible ironwood saplings, which resist the tools of the cooper."

Every Workman connected with the Building Trades requiring a Situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make, and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty-four Words, and Sixpence for every Eight Words after.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, JANUARY 11, 1884.

THE DEAD-CENTRE LATHE.

IN face of the excellent articles on the "Construction of a Cheap Lathe," which are, in fact, illustrative of the construction of lathes in general, as well as of that special design, I might hesitate to retrograde a step for the purpose of saying a word or two in favour of one of a different and more primitive class. But it is, in fact, a cheaper lathe still than that described—a lathe that any handy man can make without even the cost of a single casting, or the use of a lathe with which to construct it; and it is, therefore, available even for a mechanically-inclined cottager who may feel the need of such a machine to carry out his work. There are, indeed, scores—nay, hundreds—of such in our villages who, of sheer necessity, hesitate to enter the shops of the cheapest of lathe-makers. And although turners, properly so-called, may despise such a tool, it has its own advantages. That a lathe with dead centres will turn an object accurately is not only beyond question, considering that the watchmaker's turn is just such a machine; but this is theoretically the best way to insure accuracy. Moreover, it is possible that some of our readers may have followed a plan which I have myself adopted when the lathe at hand is too heavy a one for some light job. In this case the ordinary centres may both be used as dead centres, and the work driven from the overhead with a fine cord coming down to a pulley attached to the work itself, the same as is done in turning watch and clock arbors and pivots. Using a pair of fine centres, a drill-bow can be substituted for the overhead, and the ordinary lathe converted for the occasion into a set of "turns." In a periodical, long ago defunct, devoured by the insatiate ENGLISH MECHANIC, I once described a very elaborate bow or pole lathe, from Plumier's work, and I was myself surprised and interested to find how much had been done to perfect that most primitive of all lathes, and I never regretted the time I then spent in examining the elaborate details given in the bulky volume in question. Such lathes were dead-centre ones, but were vastly improved from their clumsy-looking ancestor, the chairmaker's pole lathe. This last, however, strange as it may seem, is not extinct; and is used by preference for turning certain articles, even where the modern form is found in the same workshop. The dead-centre lathe, to which I wish now to direct attention, was the result, no doubt, of the general introduction of the crank and treadle, and was, therefore, one step in advance, and a very important one, as continuous rotary motion was thereby given to the work. The lathe thus modified was constructed mainly of wood, which was of a massive character, as iron was very often turned in these lathes, of which I know a very good specimen in a smith's shop at the present time. In this case, however, there it a large flywheel, turned by an assistant, instead of the more convenient crank and treadle. The movable poppet of beech has an ordinary-pointed iron bolt, with capstan head passing through it, the point of which is steeled, and the poppet is of beech, sawn out of a plank 3½in. or 4in. thick. The under part takes a good bearing on a bed of stout oak, and is made with the usual tenon and clamping screw. The fixed headstock only needs to be sufficiently stiff and strong to carry the bolt, which serves to centre the work at that end; but this bolt must be of such size as not to bend under the influence of the driving strap, as it cannot be supported at both ends. Its point should be of steel, well hardened. Fig. 1 gives a fair notion of the upper part of such a lathe, and details of its several fittings are illustrated below. The main poppet or headstock has not two uprights, as in an ordinary lathe, but is a solid block of wood bored transversely to receive the bolt already mentioned. This bolt is made like B, with a flange at *a*, a plain cylindrical part *b*, followed by a short length of screw *c*, and beyond it the point *d*. Although better turned, it will do well enough merely filed up, the neck *b* being rounded as well as possible. Of course, this bolt should pass horizontally through the poppet; but in this lathe such slight inaccuracies as would be fatal in an ordinary one are not of paramount importance, owing to its having no revolving mandrel whatever. If the points supporting the work are not accurately true, one being possibly a trifle higher or lower than the other, yet this will not necessarily prevent true work from being turned upon them. If a running centre, on the contrary, such as that of a mandrel called the live centre, is but a hair's breadth out of truth, it will describe a circle as it revolves, carrying that end of the work with it, as most turners know to their cost; so that trueing-up the centre is a frequent operation. Here, except when worn by use, no such work is required; and if hardened the centres will last a long time.

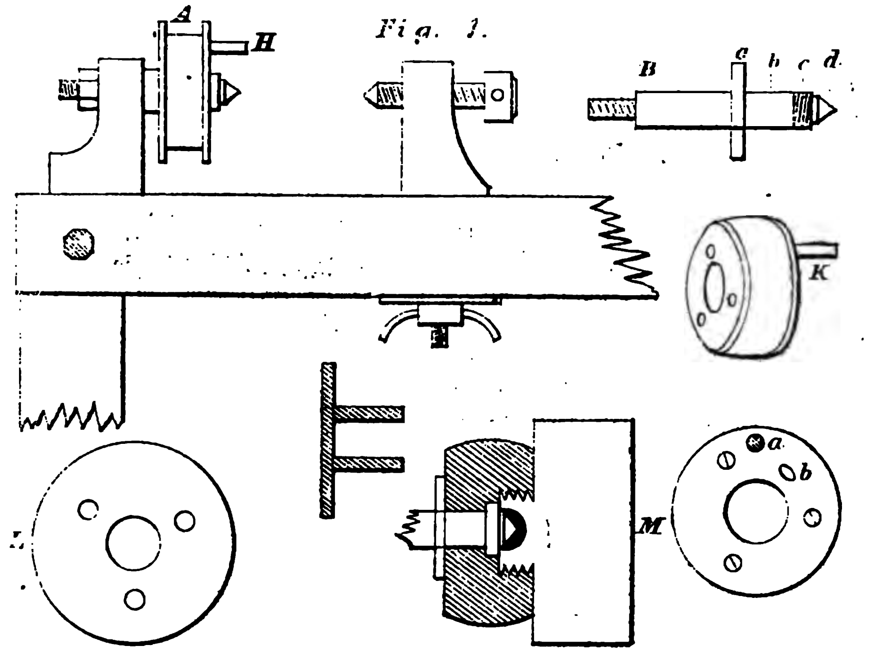

Fig. 1.

But I do not speak of inaccurate fitting not being fatal in order to commend it; and in this, as in other lathes, the better it is made the better and easier it will work, and the longer it will last. Because a big, rough, clumsy affair will enable you to do very decent work, there is no reason why you should be satisfied with such a tool; and this lathe may be made as well and neatly as any other, and gives you this advantage that it is easier by far to make this one well than one of the usual pattern badly. It is a job exactly suited to those who have little money and are not adepts.

It will, of course, be seen at once that this dead-centre lathe is only intended for work that can be supported at each end, and so it is primarily; we can't expect unlimited capacity in such a machine. But what an infinite number of everyday articles can be so made. Nine-tenths of an ordinary woodturner's work is of this kind. Table and chair legs, balustrades, bed-posts, drawer knobs, rolling-pins, towel rollers, rails, and uprights of towel horses, curtain poles, tool handles, handles and stands for many other purposes. All these can be, and are, turned between centres. So can chess men, and many other articles, and I shall presently show how the powers of this simple lathe may be increased so as not to leave even hollow work of simple forms an impossibility. But again I say it is not meant to be set forth as a rival of the more modern lathe, which is, of course, preferable where it can be had; but only as a simple, easily made, cheap and effective tool within certain evident limits;—a lathe which scores of our readers could make in a few days who could not make an ordinary one at all, and a lathe, moreover, on which metal can be turned as well as wood, provided it does not need to be bored. There is no need to describe the construction of the bed and its stand.

Let the former be not less than 6ft. if there is room in the workshop for it, as it is at least sufficiently tiresome to find oneself unable to turn a table leg or curtain pole, or other article of common use, because the bed is too short to receive it. It will not be necessary, though convenient, to make the axle of the flywheel of the full length of the bed, as it can be mounted on a short spindle between independent uprights, or more easily still upon a stud in the left-hand standard, in the same way as many of the small lathes are fitted in the present day. No cranked axle is then needed, and expense and trouble are thus spared.

The pulley A is the most important part of this lathe, and yet is often made very roughly. It revolves upon its bolt, and in reality takes the place of an ordinary driver-chuck used in metal turning, a carrier of some sort being placed on the work to gear with the pin, which projects from its face. It is in respect of this pulley, first of all, that I would suggest certain improvements upon the mere sheave of wood that is often used. To begin with, I would bush it with metal, preferably with steel, hardened, but most certainly with metal of some kind, to retard the wear of the hole in the pulley. Still, suppose this cannot be managed, it may be turned, or even sawn out of a bit of hard beech, elm, or oak, and used thus till a more elaborate one can be procured. It would, however, be a rare circumstance if a bit of tube of some kind could not be obtained, a slice off an old gun barrel or a bit of gaspipe, or some kind of ferrule which could be tightly driven into a hole bored to receive it. A bit of iron tube could be easily casehardened. An iron or

The Medical Annual and Practitioners' Index. London: Henry Kimpton.

THIS useful volume is primarily intended for the study table of the medical practitioner, but it will be of use to a larger circle, for, besides the list of societies and hospitals, it contains a medical gazetteer of the United Kingdom, sanitary memoranda, a list of hygienic homes, and brief descriptions of the health resorts of this country and the more accessible parts of the Continent. Of the purely professional parts of the annual we can say that "the year's work" seems well done, the selections being taken from the recognised organs of the medical world and carefully acknowledged; "the progress of pharmacy," too, will be welcomed by many busy practitioners, as it brings before them the names of any new drugs or pharmaceutical preparations introduced during the year, and similarly the list of new books will be found very useful. For these reasons we think the "Medical Annual" will be considered indispensable by the practitioner, and will be frequently referred to by the general public in search of the special information it contains.

Reed's Engineers' Handbook to the Local Marine Board Examinations. By W. H. THORN. Sunderland: Reed and Co.

THIS well-known work is now in its tenth edition, revised and enlarged, and is undoubtedly the best book that an aspirant for an engineer's certificate can purchase. Judging by the number of queries which reach us as to the method of getting an engineer's certificate, there is no lack of candidates for the post, and intending competitors will find all needful information in Reed's handbook, which contains not only the programme and rules of the examinations, but also the rules in arithmetic and the practical and technical matters on which the examinations are based. The plates and engravings in this volume are numerous, and leave scarcely any part of a marine engine undelineated. No one can sit for the examination who has not been to sea; but anyone who has served the required time, and gained some little practical knowledge, must be sadly wanting in intelligence if, after a diligent study of this work, he cannot gain a certificate as a second-class engineer.

We have also received the fifth edition of the *Natural Philosophy for General Readers and Young Persons*, by E. ATKINSON, Ph.D., F.C.S (Longmans), a work which is popularly known as the Smaller Ganot, and which, like that famous textbook of physics, is gradually growing in size and in public appreciation. In fact it may be described as *the* textbook of elementary physics. The fifth edition contains over 600 pages, nearly 500 illustrations, and a couple of coloured plates. ——*Transit Tables for* 1884, by LATIMER CLARK (E. and F. N. Spon), give the G.M.T. of the transit of the sun and of certain stars for every day of the year. The tables are prepared mainly for the use of those who, having little or no practical acquaintance with astronomy, are desirous of obtaining accurate time by means of the transit instrument. The directions and tables are sufficient, but readers unacquainted with the subject may be referred to Mr. Clark's "Treatise on the Transit Instrument," which we reviewed on p. 488, Vol. XXXV.——*Whitaker's Almanack for* 1884 (J. WHITAKER) is a wonderful compilation for the money, and is almost indispensable. In trying to do so much, the editor sometimes fails. We suppose a list of newspaper offices in London is useful, but that given on p. 456 is anything but satisfactory, for although the "E. M." appears, there are many important omissions, while the titles of several periodicals which are in no sense newspapers are inserted. The Scientific Summary for 1883 has been prepared without due attention to the relative importance of discoveries and inventions. ——*Photography Simplified* (Mawson and Swan) is a very cheap sixpennyworth, as besides giving brief directions for working the collodion process and dry plates, it contains a set of labels for chemicals, which will be useful to the amateur.——*Turning for Amateurs*, by Rev. J. LUKIN (L. U. Gill), is a new edition of a work which we need not recommend to our readers. To those who do not know the book or the author's writings, and are desirous of learning the art of working a lathe, we can say by all means purchase "Turning for Amateurs."——*The Chemical Effect of the Spectrum*, by J. M. EDER, (Harrison and Sons) is a reproduction from the *Photographic Journal* of Dr. Eder's brochure, translated and edited by Capt. W. De W. ABNEY, F.R.S. All scientific photographers will be glad to have these valuable notes in their present handy form.——*Calvert's Mechanic's Almanack* is, as usual, a valuable little "workshop companion."——*Amateur Work* (Ward, Lock, and Co.) is the second volume of a work which will be found of interest to amateur mechanics and artisans. ——*The Practical Ventriloquist*, by F. W. LOCKYEAR (Hart and Co.), is a little book that may be of use to those who aspire to be ventriloquists.——*Artistic Voice in Speech and Song*, by CHARLES LUNN (Baillière, Tindall, and Cox), is a brochure dedicated by permission to Sims Reeves, Santley, and Maas, in which the author shows very good reason for holding his own opinions in opposition to what he calls the pseudo-scientific works of Mr. Lennox Browne and Mr. Behnke.——*An Elementary Treatise on the Planetary Theory*, by C. H. H. CHEYNE, M.A., F.R.A.S. (Macmillan), is the third edition, edited by the Rev. A. FREEMAN, M.A., F.R.A.S., of a work which has been received with much favour, and may be recommended to students of mathematical astronomy.

PATTERN MAKING.—XX.

Miscellaneous Pipe Work.

COMMON pattern bends of uniform section can be very conveniently turned in the lathe if we want two bends of the same size. Jointing four pieces together at angles of 90° and screwing them on the face plate, we can turn the semicircular section with a templet in far less time than would be occupied with gouge and chisel and spokeshave, and with more accurate results (Fig. 112). Removing the four half patterns from the faceplate, we dowel them two and two together, forming two bends.

If the pattern is of a flat curve, as in the common "eighth" and "quarter" bends of the pipe makers (Fig. 113), or if it is a "reducing" bend, viz., a bend tapering from a larger to a smaller bore, the lathe is out of the question. In these cases we joint truly together two pieces of wood large enough to take the outline of the bend, each piece being thick enough to take half the diameter of the bend. We dowel them together, and on the joint face of one mark the outline we require. Cutting to these lines we obtain the longitudinal form, and working with gouge, chisel, and spokeshave, guided by a semicircular templet, we get the transverse section. We mark the outline of the second half from the one just worked, and cut that in turn with the half templet. Socket, bead, and prints are put on afterwards.

Some workmen have a way of cutting a bend, which, though slow, is safe, because there is no risk of undercutting. It is to work the stuff, first of all rectangular in section (Fig. 114), gradually into a polygonal form until a nearly circular section is attained (Figs. 115—116). The last remaining angularities being taken off with a spokeshave, a practically true circle is the result, which will not show wavy lines in the longitudinal direction. This is certainly the better method to adopt with a *reducing* bend, in which the diameter is constantly varying.

When the pattern is to form the elbow of a bend pipe (Fig. 117), it is required to attach the straight pieces of pipe to each end of the curved portion respectively. This we shall effect by means of a double dovetail, which is to be let into each of the portions of pipe which abut against one another (Fig. 118).

Sometimes pipes are made of very awkward shapes, to curve round parts of machinery, buildings, other pipes, &c. There may be two or three different bendings of the pipe not all in the same plane, and the flanges may have their faces at angles other than right angles. The pipe makers supply bends and S pipes of various shapes, by which the desired shape can often be pieced up; but where space is limited, or where a graceful outline is wanted, we make a pattern; and this opens up the question of loam work. In these and many other cases we want but one casting, and if the pipe is of large, or even of but moderate, dimensions, the pattern would cost a great deal more than the casting itself. Then the question of wood *versus* loam becomes one for our consideration. In large castings the answer must be in favour of loam in almost every case, and in small castings also it will usually be cheaper to strike up the pattern in loam. But in those awkward-shaped pipes such as Fig. 119, where the bends are not in the same plane, it costs less to knock out a rough pattern in wood than to strike it up in the foundry. Yet even in a case like this, if the casting were large, say over 6in. in diameter, loam would be the cheaper.

There are a number of "wrinkles" in the striking up of pipes in their various forms, so that a lad who had served his apprenticeship in a shop where no pipework was done would be "all at sea" on getting a start in a jobbing shop where pipes formed a part of the trade. So, beginning at the beginning, I will try to make the matter so clear that a pattern maker who had never seen a plain loam pipe made should be able to prepare his work successfully. In pattern making it frequently happens that though the parts which the workman has to prepare for the moulder's use are few and simple in form, they involve more technical knowledge than work of more pretentious appearance. This is especially the case in loam work. The parts the loam moulder requires are few and simple, and, like many other things, they are easily made —when one knows the way.

Let us commence upon the drawing. Fig. 120 represents the board, upon which we have drawn an S-pipe in longitudinal section. Observe that there is a line drawn parallel with one side of the pipe, and at a distance of ¾in. away from its edge. This is the "guide line." By this line the foundry-smith bends a piece of ½in. or ¾in. square rod, which becomes, as we shall see immediately, the "guide iron" (Fig. 121) for the "strickles." The strickles are the templets used for striking the transverse sections of the pipe in loam, and they have their edges cut in such a way that each strickle is maintained at its own proper distance from the guide iron during the process of striking. Thus, the guide iron being ¾in. away from the body, the body strickle (Fig. 122) will be notched up ¾in. from one edge of its 7in. semicircle. But the metal in the pipe being ½in. thick, the core strickle (Fig. 123) will be ¾in. + ½in. = 1¼in. wide at the shoulder. The edge of the strickle is chamfered like that of a loam board (Fig. 124). They are used thus: The guide iron is laid on a plate on the foundry carriage, and kept in position by sundry weights resting against it. Then the "check," as it is called, of the core strickle is set against the guide iron, and a semicircular body of loam is struck up (Fig. 125), following, of course, the contour of the guide iron. The iron is then turned over and fixed again in a new position, and a similar half-core struck up, but the reverse hand to the first. These are run into the stove and dried. When dry, the *pattern* strickle is set against the guide iron, and a thickness of loam struck over each half-core in turn. This also is dried; then both halves are detached from the plate, turned over joint to joint, and the rough pattern is complete. A little touching-up of the joints and a coat of tar will make it fit for the mould. When moulded, the thickness of loam representing the ½in. metal will be stripped off, and the core placed in the mould for casting.

If a flange is required for a loam-pipe, the hole in the flange will be of the same size as the core, and the body thickness of loam will be shouldered back to afford steadiness to it. Obviously, a socket end would not be formed with strickles very

readily, on account of the dressing off where one diameter blends with another. So sockets are struck separately in the same way as a straight piece of pipe, to be afterwards sawn longitudinally down the centre and slid or threaded over the pipe body. They are held in place during moulding with nails. The socket core is treated in the same manner.

If we require pipes or hollow castings whose shape is not symmetrical, and which cannot, therefore, be struck on a revolving bar, or continuously by means of strickles, the difficulty is first, how to get the core of the proper shape; and then, how to insure an equal thickness of metal throughout. Take, for illustration, a reducing pipe connecting a rectangular valve box or pipe with one circular in section, Fig. 126. Except at the ends, the section is never uniform, so, except at the ends, a strickle or strickles cannot be used. So the core body is first roughed up and dried, then rubbed to its required shape with rasps and glass-paper. A number of strips are then prepared, of the same thickness as that of the pipe. These are laid on the core in various positions, lying flat, and their interstices are filled up with loam, which is strickled off level with their thicknesses. When the loam is set a little, but not baked, the strips are taken away, the vacant spaces filled up with more loam and dried. When moulded, the thickness is stripped off as before, and the core placed in the mould. By this method, castings of almost any size and shape can be made with uniform thicknesses of metal, and with much less trouble to the pattern maker than would be involved in making a core-box with templets.

THE DYNAMO: HOW MADE AND HOW USED—XI.*

By SELIMO R. BOTTONE.

§ 23. BEFORE winding the armature and field magnets with the wire in which the electricity is at once generated and conducted, it is necessary to fit together accurately the different portions, and *mark them*, so as to be able to put them together again in precisely the same position after winding; since no filing or fitting can be attempted on the castings after the wire has been wound without almost certain destruction of the insulation, and certain ruin to the neat appearance of the evenly-laid wire.

The part that calls for the greatest care and attention is the armature, which, as it must rotate in very close proximity to the poles of the field magnets at a rate varying from 1,000 to 3,000 revolutions per minute, requires to be centred most accurately on its bearings or trunnions. This to the possessor of a lathe presents but little difficulty; for the benefit of those who depend on ordinary tools only, the following method, by which the armature can be mounted on its bearings in a fairly accurate manner, is described. With a pair of calipers, the diameters of the two opposite extremities of the armature are taken, as shown at Fig. 18, *a* and *b*. (If the armature casting were finished up quite exact, these two measurements would be exactly alike, viz., a trifle under 1½in. each. But unless turned on the lathe, it is very rare to get such precision.) Two circles, of exactly the same diameters as the two extremities of the armature, are now to be struck out of a piece of hard sheet brass, ⅛in. thick, care being taken to mark the centre and the circumference in an exact and bold manner with the compasses. These circles will have to be cut out of the brass with a saw or file, so as to get two discs, fitting each one to its respective armature extremity; but before cutting out the circles thus marked, three should be drilled in each, viz., one in the exact centre $\frac{3}{16}$in. in diameter, which is to take the driving shaft or trunnion, and one on each side of this centre, $\frac{1}{8}$in. in diameter, to admit the screws which serve to attach these *heads* or discs to the iron portion of the armature. Besides these three holes, which are common to both "heads," another pair, also $\frac{1}{8}$in. in diameter, must be drilled in one of the heads, to allow the ends of the wire which is to be coiled around the armature to emerge from them, and pass through to the commutator. All these holes are shown *full size*, and in their correct position at Fig. 19, where *a* is the central aperture, to take the shaft: *b b* the two holes to admit the screws, whereby the heads are attached to the armature; and *c c*, holes drilled in one head only, to admit of the passage of wires to the commutator. These holes being bored, and the discs accurately cut out, two pieces of hard-drawn iron wire (not galvanised) $\frac{1}{4}$in. diameter and 2in. long, are carefully straightened, and by means of a screw-plate, a thread is put on one end of each. With the corresponding tap, a female screw is cut in the central hole of each brass disc. The two iron rods are then screwed in, particular care being taken that they enter perpendicularly, and centrally. They must be screwed in until they just protrude through to the other side; then the long end being allowed to slip between the jaws of a vice, while the disc rests flat upon the surface of the jaws, a few steady blows with a flat-pened hammer will spread the head of the screw end of the iron rod, so as to rivet it firmly to the disc, and thus prevent it working out. To render assurance doubly sure, a drop or two of soft solder may be run round the flat side of the end of the rod and disc. Now we come to a part of the work that very few amateurs can do at home—viz., drilling the holes in the faces of the armature. Any blacksmith will, however, do this for a few pence. Four holes are required, two at each end of the armature (one end is shown real size at *d d*), and these holes must be tapped with a female screw, so as to take the screws which serve to unite the whole together. It will be well be well to let the blacksmith drill and tap these holes to any-sized screw that he has nearest approaching $\frac{1}{8}$in. in diameter. Now will be also the time to get the blacksmith to drill the three holes, right through the top end of the legs and standard, which serve to allow these portions to be clamped together by means of bolts and nuts. These holes should be about $\frac{1}{4}$in. in diameter. Further details as to position and size will be given a little farther on. If our work has been properly performed, the heads may now be screwed down to the armature, with flat-headed screws, which should project about $\frac{3}{16}$in. above the level of the discs. Fig. 20 gives a representation of the finished armature about half the real size.

ON EYEPIECES.

By W. Bradbury.

If we may judge from various scattered particulars, it would seem that more care was exercised in the *design* of common eyepieces by the early opticians, than what appears to be the case in the present day. It is not, I believe, usual to employ any but plano lenses in common forms; whereas, in old eyepieces, the lenses had a variety of shapes. Whether any marked advantage attended their use may be doubted; still, it is unquestionable that these early artists must have found *some* benefit from the use of complex forms, or they would not have gone to the trouble of working such in place of simpler ones. But in those days of feeble competition, time, I presume, was of little value, provided a good result was got in the end. Nowadays "*Tempora mutantur et nos mutamur in illis.*" The trade workman must use that method which, in the least time, will give a result up to the standard required by his customers.

I am indebted to Brewster's "Ferguson" for the subjoined particulars which relate to early forms of eyepieces. He says:—"In order to correct the error arising from the unequal refrangibility of light in the *eyepieces* of telescopes, we are not under the necessity of using compound lenses of crown and flint glass, as this species of aberration can be completely removed by a particular arrangement of the eyeglasses which are employed for erecting the object. In small pocket telescopes, as opera-glasses, &c., where it would be very inconvenient to apply a long eyepiece, compound lenses of crown and flint glass should be adopted, and may consist either of two or three glasses with the following curvatures:—

Doublets.

I.	Crown lens, equi-convex, radius	·320, focus ·304
	Flint lens, equi-concave, radius	·529, focus ·438
II.	Crown glass, equi-convex, radius	·320, focus ·304
	Flint lens, double concave, radii	·320, focus ·438 1·517

TRIPLETS.

I.	Crown lens, equi-convex, radius	·640, focus ·608
	Flint lens, equi-concave, radius	·529, focus ·438
	Crown lens, equi-convex, radius	·640, focus ·608
II.	Crown lens, double convex, radii	·810, focus ·608 ·529
	Flint lens, equi-concave, radius	·529, focus ·438
	Crown lens, double convex, radii	·529, focus ·608 ·810

If it is required to erect the object as in the Galilean telescope, the middle lens of flint glass must be convex and the other lenses concave, but with the same radii, so that the concavity of the compound lens may predominate.

The following table for arranging a three-lens eyepiece is given. Let F = focus of o.g., and x, y, z foci of eyeglasses, reckoning from tha which is nearest the object:—

1. Distance between first and second lenses	$x +$
2. Distance between second and third lenses	$y + z + \frac{y^2}{x +}$
3. Distance of first lens from focus of o.g.	$\frac{xy}{x + y}$
4. Magnifying power of eyepiece	$\frac{Fy}{xz}$
5. Focus of a single lens of the same power	$\frac{x}{y}$
6. Distance from the eye to the third lens	z
7. Length of the whole eyepiece	$x + 3y + 2z$
8. Length of the whole telescope	$F + x + 3y + 2z$
9. Aperture of the lenses a, a', a''	$a = \frac{xa'}{y}$
10. Aperture of diaphragm (m) placed in focus of o.g., should be a little less than	a
11. The field of view is nearly....	$\frac{\cdot 3438\, m}{F}$.

The apertures of the lenses may be equal to one another, but should never be greater than half the focus of the third lens.

"Although the aberration of colour will be completely removed by making the lenses of any focal length, and placing them at the distances indicated by the preceding formulæ, yet it is preferable to make the first and second lenses of the same focus, and to give the third a less focus, and make its distance from the second equal to its own focus, added to $1\frac{1}{2}$ the focus of one of the other lenses. Besides the simplicity of this combination, it has another advantage, for the magnifying power of the e.p. is always equal to the magnifying power of the third lens. So that in this construction, when we wish to give a certain magnifying power to a telescope, we have only to take such a focus for the third lens as will produce this magnifying power, and make the focus of the other two a little greater than that of the third. By increasing the foci of the two first lenses, the image is not injured by any particles of dust which may be lying on the surface, and the spheric aberration is also diminished. By augmenting the curvature of the third lens, however, we contract the field of view, which ought, if possible, to be avoided. This may be avoided, indeed, as Boscovich has shown, by making the third lens consist of two convex ones of the same glass, their surfaces being in contact and their foci equal. From long experience he found that eyepieces of this construction are superior to all others, and that the error arising from the spheric figure of the glass is greatly diminished by making all the lenses planoconvex and turning the plane sides to the eye, excepting the second lens, whose plane surface should be turned to the object. All the lenses may be made of the same foci, and then the distance between the first and second and second and third will be equal to the sum of their foci. In this case the third and fourth lenses, which are joined together, are considered as a single lens, whose foci is equal to one-half the foci of either of the two.

"In all kinds of achromatic eyepieces composed of single lenses flint glass should be employed, because it has the greatest refraction, and therefore requires a less curvature to give the same foci. The spheric error, consequently, which always increases with the curvature of the lenses, will be less in a flint glass eyepiece. Flint glass, indeed, produces a greater separation of colours, but the error arising from this cause is completely removed by the proper arrangement of the lenses."

"A good achro. e.p. may be made of four lenses" arranged as follows, starting from the lenses next the object:—Foci as 14 : 21 : 27 : 32; apertures 5·6 : 3·4 : 13·5 : 2·6; distances, 28 : 44 : 40. Size of stop in front focus of 4th lens, 7.

Eyepiece of a Ramsden telescope, 8·5in. focus; power, 15·4.

Foci, 0·77 : 1·025 : 1·01 : 0·79; distances, 1·18 : 1·83 : 1·10 (inches and decimal parts).

Dollond's four lens e.p. in the Duc de Chaulnes telescope (measured in lines and decimal parts):—Foci, 14·25 : 19 : 22·75 : 14; distances, 22·48 : 46·17 : 21·45; thicknesses 1·23 : 1·25 : 1·47.

Fourth lens plano-convex, plane side to the eye; the rest double-convex lenses.

Two astro e.p.'s belonging to the same telescope: the first a micrometer e.p.

and it is then brought into exceedingly shallow water and the operation of disconnecting the various sections proceeded with. To each section, while still afloat, will be secured four large light steel wheels, having very wide tires. This being done, the divisions are ready to be hauled out of the water and over land, and what was once a section of a boat now becomes the body of a waggon, of ample capacity to convey the lighter portions of machinery, stores, &c. On arriving at the next navigable part of the river these impromptu wagons are run into the water, the wheels are removed, and the various divisions re-united, forming again an entire vessel. Between the mouth of the Congo and Stanley Pool there are six cataracts, which will necessitate the vessel being taken to pieces, in order to avoid them. The trial on Saturday was most successful, the steering capabilities of the steamer being much admired. The mean draught was 14in. in working trim, and with a steam pressure of 100lb. per square inch a speed of 9½ to 10 miles an hour was obtained. On the deck is a small saloon, which has squares of netting instead of panes of glass—the ventilation being adapted for a tropical climate—and the steering wheel is placed high up on a bridge, some 12ft. above the water, giving the pilot a good view all round.

GEOMETRY IN THE FOUNDRY.*

IN nearly all trades some knowledge of geometry is required. For the moulder no one seems to have written up that which is applicable to his trade. Some may wonder what moulders want geometry for, and think if we understand the use of shovel and rammer it is all we need. This, in many cases, may be true. But often a knowledge of geometry can be turned to as good an account in our trade as in others. It is as essential that many moulders should understand geometry as it is that pattern-makers should do so. The way it now is the pattern-maker generally does our geometry for us; and we, through our ignorance, are forced to submit to other tradesmen, to our own detriment. In green sand, as well as in loam work, moulders are often obliged to call the pattern-maker to explain or to mark out work that requires geometrical knowledge. Mounds are often made requiring the dividing of circles, or marking off of square, oblong, and other shapes; locating of flanges, lugs, or sections of patterns, &c. The lack of geometrical knowledge is often woeful. I remember a case where a moulder was sent for the radius to describe a circle, and returned with a pattern segment. When questioned he said the pattern-maker was absent, and as the segment was upon his bench he thought that was the thing wanted.

To describe a circle is a simple affair. To divide one into any number of equal parts is where a knowledge of geometry is found useful. The number of parts into which a circle can be most readily divided is six, because the distance from the centre of any circle to its circumference, as B, A, Fig. 2, will divide the circumference into six equal, parts, F, D, A, P, E, and S. To divide the circumference into three, take out every other one of the six points. To divide it into twelve equally, divide each of the six parts. To divide it into four parts describe a line through the centre, as K, O, Fig. 3. From the points where X · O intersect the circumference, with trammels or dividers set at more than two-thirds the diameter describe arcs cutting each other, as at N. A line drawn from N through the centre divides the circle into four parts. For eight parts bisect each of the four. Many divide the circle into four parts by the use of a square, instead of by describing the arcs, as at N.

The division of circles into odd, or even equal, sections can be done as follows: At H and R, Fig. 4, the radius, or one-sixth of the circumference, is set off. This radius then divided, by trial, into the number of sections required. With the trammels or dividers set to the chord of six of the parts space off the circumference. This will divide the circumference into the same number of sections as in the radius. Should it fail to do so the fault is yours. It must be remembered that to *exactly* divide the circumference requires very fine manipulation. There are but few men who can go around the circle twice, and come out exactly alike.

One-tenth, one-ninth, one-eighth and one-seventh are simply shown to further illustrate the rule. To obtain one-fifth, the radius is divided into five, and, in order to have the six points, one is added to the radius length as shown. If by this rule the circle was to be divided into four equal sections, the radius chord would be divided into four sections, and, in order to have six points, two would be added to the length.

For the divisions of circumference into small parts for the purpose of gear-making, &c., rules implying mathematical calculations are required. The plan here given is such as requires no figures, and can often be used by the moulder to good advantage.

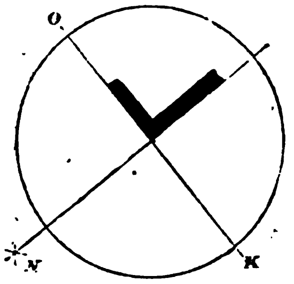

Fig. 3

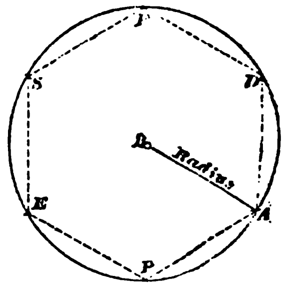

Fig. 2

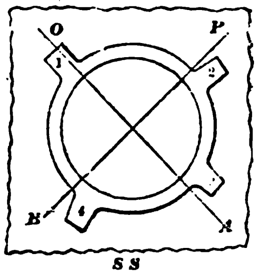
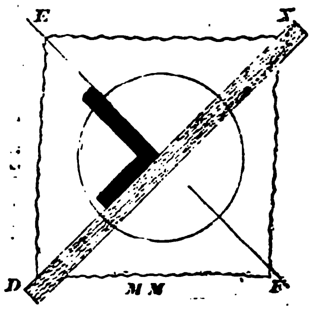
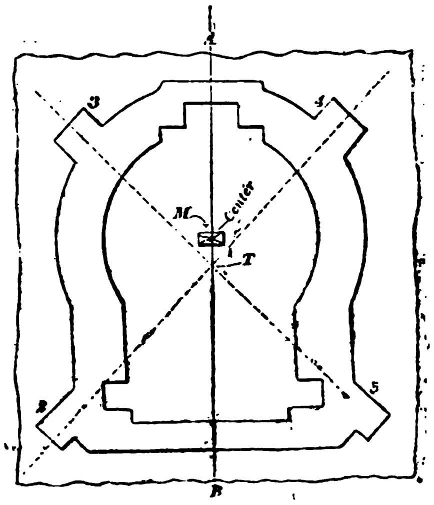


S S



M M



Cylinder Plate

In loam moulding plates are required that in the hands of some moulders will be made without any visible shape of pattern, while others will require almost a full pattern. There are some loam moulders who can make any number of loam plates and rings entirely from the drawings and not have a mistake in the lot. To be able to lay out a lot of rings and plates, and have them all come right, requires one to understand the reading of drawings and a few of the elementary rules of geometry, besides sound judgment.

In marking out upon a sand-bed for any ring or plate having irregular shapes, a centre line to work from is required, the same as the draughtsman as-quires in making a drawing. The cut showing a cylinder plate ring will to the novice convey ideas of laying out that may be useful. The bed being made, the first thing done is to drive a centre stake M. In this stake is made a small hole, for the dividers or trammels' point. Crossing this centre is marked the centre line A B. From this line all right-angle lines and measurements are taken. The circular lines being described, the next to follow is marking and locating the lifting handles 2, 3, 4, and 5. This often requires careful consideration, that they may be placed in the best position to insure or assist the mould being balanced when hoisted up. In locating lifting handles upon square or round plates, they should, as a general thing, be set square with each other. This will be better understood by referring to the cuts M M and S S. In M M the square and straight edges seen show the manner of squaring off the bed. The straight edge having its edge over the centre, the square is set against it, so as to have it lay at right angles from the centre; the lines D, E and X are then described, after which the square and straight edge, are removed. The straight edge then being laid alongside of the line E, the line is carried through to F, thereby squaring off the bed.

---

* By Thos. D. West in the American Machinist.

In the cut S S, the lines O, P, A, and B describe the square, while the handles 1, 2, 3, and 4 are out of square. The objection to such random dividing of handles is they will not come plumb under the lifting cross, which is usually made square. Also, handles thus placed upon rings, square or round plates, do not make them uniformly carry their load, thereby giving them a chance to spring and cause the mould to crack. Some may say that they are often compelled to locate handles out of square to make them balance their load. This may be true in some cases, but, when possible, instead of distorting the square, the centre point should be moved to where the best judgment points out will be the mould's balancing centre.

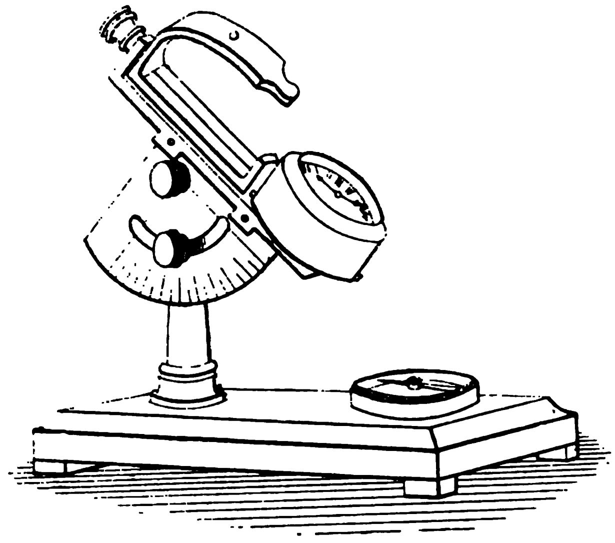
To illustrate this idea, instead of having the cylinder plate shown squared from the centre, square it from T. This, while it does not distort the square of the handles will bring the balancing point wherever desired.

Sometimes plates are required oblong. This does not always call for the handles to be set oblong. If necessary handles can be set square upon an oblong plate as well as upon a round or square one, as long as the lines are at right angles to each other; coming towards the centre does not alter the square. Of course, it is not here advocated to set handles square at the sacrifice of oblong plates being sprung when their load comes upon them. The thing is to understand what is best, and then be able to do it.

Improperly placed handle have been the cause of much trouble in adjusting and balancing moulds, and have caused many moulds to crack. This fault, and other faults, are not so much from carelessness as from the want of a little geometrical knowledge. There are but few loam moulders who, from a drawing, are able to order their sweeps, &c., and make the jobs required. Our trade demands something higher than loam daubing and shovelling sand, and he that tries for the highest cannot but find himself benefited.

A NEW SOLAR REGULATOR.

AMATEURS and owners of country seats who like to consult the hour by the sun, and are satisfied with but relative accuracy, have long needed an apparatus that had a neat appearance externally and was easy of management. This want is now supplied by the solar regulator, an apparatus constructed according to data furnished by its inventor, M. Corneloup, a manufacturer of clocks. A description of the apparatus will be easily understood by the aid of the annexed figure, which represents it half the actual size. Upon a pillar carried by a quadrangular base there is mounted a support which has its extremities bent at right angles, and which revolves in a vertical plane and on a centre at which ends the apex of a graduated sector. This latter gives the measurement of the inclinations that the support can take, and which should always correspond to the latitude of the place. The sector, having been brought to the proper point, is fixed by means of an adjusting screw. At the base of the support there is fixed a small case which is provided with a dial and hands. The style, and the plate upon which the noon line is traced, are independent. The plate pivots between the two upturned extremities of the support. Upon the prolongation of the lower pivot, which enters the dial case, there is adjusted a pinion which, through the intermedium of wheel work, causes the hands to revolve. A compass fixed on the base of the apparatus serves to place it in proper position. The instrument is regulated when the aperture in the style, the solar noon line, and noon as shown by the hands on the dial are exactly in the same vertical plane. The instrument having been regulated, it will be only necessary to incline the style to the right or left so as to bring the luminous point upon the noon line; and, as the hands will follow its motion, the hour will be read upon the dial. While travelling, the owner may regulate the apparatus by the aid of a good watch, having seconds hands, which has been set by observatory time, or by the aid of a good chronometer. The instructions that accompany the instrument indicate the inclination to be given the sector to make it correspond with the latitude. What will bring this little apparatus into favour with amateurs is the fact that, unlike the sundial, which is always fixed, it may easily change place, and the hour be read upon it just as is done with a watch.—*La Nature.*



HOW A BONE IS BUILT.

A LECTURE on this subject was delivered at the London Institution last week by Mr. Donald M'Alister, of St. John's College, Cambridge. In introducing the subject, the lecturer explained that he would treat the construction of a bone as a question of architecture or engineering rather than of anatomy. In looking at an ordinary marrow-bone two points would strike one. In the first place, the shank or shaft of the bone was hollow, forming a somewhat thin-walled tube; secondly, the end of the bone next the joint appeared on section to be not hollow but filled with a spongy or "cancellous" meshwork of bony tissue. The tube-form appeared not only in bones, but in many other structures characterised by combined lightness and strength—such as the stalks of plants, seeds, bamboos, quills of feathers; and among human constructions in a vast variety of shapes, from tubular bridges to backbones of bicycles or tricycles. What was the common principle underlying all these manifold varieties? Why was it that, weight for weight, a hollow column was so much stronger than a solid one? The lecturer then showed that when an ordinary rectangular cross-beam was slightly deflected by a load, the upper fibres were in a state of compression, while the under fibres were in a state of tension; whereas in the middle of the beam there was a neutral region neither compressed nor stretched. For load-bearing purposes this region might be removed: the beam would thereby be made appreciably lighter but not appreciably weaker. The tube-form of a bone was thus due to the fact that the material was concentrated at those parts which were most under strain and where it was most useful; it was removed from those parts where it added to the weight without adding to the strength. Tables were exhibited from which it appeared that bone in its physical properties resembled steel much more than such a material as cast-iron. Bone, like steel, was almost as strong to resist tearing as to resist crushing. The spongy or cancellous ends of bone were next considered, and by photographs of actual specimens the lecturer showed that the apparently confused and irregular character of the tissue resolved itself on examination into a very beautiful and harmonious regularity. In the construction of such great structures as the Forth Bridge and the large cranes seen at the docks, engineers had found it useful to investigate the lines of the structure along which the pressure or the tension was at a maximum; the lines might be called stress-lines par excellence. The material at disposal was most economically arranged when it was concentrated along these lines, leaving empty the mesh-like spaces corresponding to the neutral region of a cross-beam. A skeleton or lattice frame-work might thus be built up, having all the strength of a solid structure of the same shape or loading, but with much less expenditure of substance. Such a structure would, moreover, be free from the danger of giving way by "shearing" or "faulting" in the geological sense. In other words, its parts would have no tendency to give way by sliding or slipping over each other; they could only be directly crushed or directly torn asunder. This was, therefore, an ideal mode of building such structures, and it was only because skilled workmanship was more expensive than material that engineers did not oftener put it into practice. In bone building, the lecturer said, there were no such obstacles in the way of perfect construction, and in such a part as the head of the thigh-bone the principle was carried oui in ideal perfection. The cancellous network in this bone was a material embodiment of the engineer's ideal lattice-work of true stress-lines, so much so that in the Zürich School of Engineering thin sections of the thigh-bone were placed before the pupils as the best possible illustration of the true principle of construction. In conclusion, the lecturer remarked that when such instances of adaptation as appeared in the eye and hand, and, perhaps, he might now add the common marrow-bone, were brought before us we were filled with wonder, and some saw in them evidences of what was called direct design. These evidences might nowadays be interpreted in perhaps a worthier and grander sense, but the wonder would remain for all who had eyes to see. At any rate, apart from all teleology, and taking only the strict architectural sense of the words, we must agree that a marrow-bone was well and admirably designed.

CROTON OIL.

THE investigations of Mr. Harold Senier, Fellow of the Chemical Society, into the active principles of croton oil are not without considerable interest to the physician. Mr. Senier read to the Pharmaceutical Society on Dec. 5th a paper in two parts—one on the vesicating principle in croton oil, the other on the purgative principle in croton oil. In 1878, in a former paper, he gave the results of an investigation into the action of alcohol on croton oil, and showed that under certain conditions it separated the oil into two parts—the one part vesicating, the other non-vesicating. The non-vesicating oil Mr. Senier has since shown to be purgative. The conditions referred to are that the alcohol shall be of specific gravity ·794 to ·800, and in the proportion of seven volumes to six, or any larger proportion. If the alcohol and oil are mixed in equal volumes perfect solution takes place, and this holds of a mixture with any less quantity of alcohol. But when the volume of alcohol exceeds that of croton oil, a part of the croton oil separates. This part varies in quantity in different samples of the oil. The part so separated is afterwards insoluble in any proportion of alcohol. But that portion of oil dissolved by alcohol is, when separated, soluble in all proportions. Mr. Senier has found that the part soluble in alcohol as above used was, or contained, the vesicating principle, and that the vesicating activity does not exist in the free acids, nor in any basic constituent, but resides in the combined non-volatile fatty acids. Mr. Senier further finds that the purgative constituent does not reside in the alcohol-soluble vesicating oil, but entirely in the alcohol non-soluble, non-vesicating oil. In support of this conclusion he refers in his paper to experiments on himself and others. He further says that the conclusion is borne out by a study of the therapeutic action of this non-vesicating oil by Dr. J. W. Meek. The general result of these experiments

[illegible]

ON "OPTICAL TUBE LENGTH" AN UNCONSIDERED ELEMENT IN THE THEORY OF THE MICROSCOPE.

By [illegible] Sec. R.M.S.

It is a little strange that at this late period in the development of the microscope an element [illegible] the theory of the microscope.

[illegible]

[illegible] the matter it will be [illegible] in regard to magnifying power.

[illegible] of a lens depends, of [illegible] and varies inversely with it: the ordinary mode of obtaining the power being to divide the distance of distinct vision l (assumed as 10in.) by the focal length, or expressing it by a formula $N = \frac{l}{f}$. Thus, if the focal length f of an objective is ⅛in., 10 ÷ ⅛ = 80. The same applies to the action of the microscope as a whole—that is, with eyepiece and objective combined. When we have determined its focal length we similarly obtain its magnifying power.*

We have, therefore, to ascertain the proper mode of determining the focal length f of the entire microscope, having given the focal length f^1 of the objective and the focal length f^2 of the eyepiece.

The usual assumption hitherto has been that f is determined by multiplying f^1 and f^2 together and dividing by the length of the tube 10in., or—

$$f = \frac{f^1 f^2}{10},$$

so that if we had an objective of ⅛in. and an eyepiece of 2in. the focal length of the microscope—

$$f = \frac{\frac{1}{8} \times 2}{10} = \frac{1}{40}.$$

A microscope of a focal length $\frac{1}{40}$in. would magnify 400 times, so that if this method of arriving at the focal length of the microscrope were correct, we should only have to multiply the power of the ⅛in. objective (80) by that of the (2in.) eyepiece (5), to have the total magnifying power (400), the brass tube being assumed to be constant at 10in.

The fallacy of this method lies in the fact that the true formula is not—

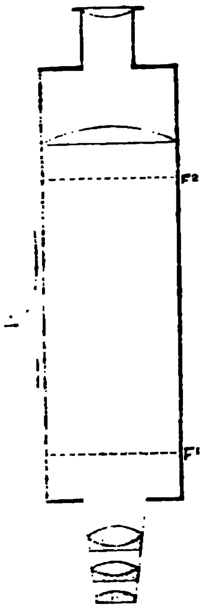
$$f = \frac{f^1 f^2}{10},$$

but—

$$f = \frac{f^1 f^2}{\Delta}.$$

Δ being the distance between the posterior principal† focal plane of the objective and the anterior principal focal plane of the eyepiece, or, as Professor Abbe terms it, the rational or optical tube-length, in contradistinction to the mechanical or physical length.

The accompanying Fig., where F¹ is the posterior focal plane of the objective and F² the anterior focal plane of the eyepiece, will illustrate this more clearly.



As Δ is the divisor of the fraction which represents the focal length, the latter is, of course, larger or smaller according as Δ is smaller or larger, that is, it varies inversely as Δ; and as the magnifying power is inversely to the focal length, the magnifying power varies directly as Δ, which is therefore seen to be a fundamental factor of microscopic amplification.

We can now see how it is that two objectives of the same focal length may yet give different magnifying powers with the same tube and eyepiece. By the different methods of construction adopted by their makers, the focal plane of the one objective may be further off the back lens than is the case with the other. The distance Δ between the focal planes of the objective and eyepiece will be correspondingly diminished, and the focal length of the whole microscope increased. The magnifying power will therefore be diminished.

Again, take the case of an objective of, say, ⅛in. and 1in. focal length used with the same eyepiece (2in.) and tube. If the difference Δ remained constant, say 10in., the total focal length would vary with that of the objectives,

$$f = \frac{\frac{1}{8} \times 2}{10} = \frac{1}{40}, \text{ or } f = \frac{1 \times 2}{10} = \frac{1}{5}.$$

But the posterior focal planes of the two objectives instead of coinciding may have different positions, every variation producing, of course, a change in the value of Δ. With the ⅛in. objective the posterior focal plane will be very near the back lens, and we have a long Δ: with a 1in. objective its posterior focal plane may be further from the back lens (higher up the tube), and we have a diminished Δ. We might have the ⅛in. objective Δ = 10in., and a power of (80 × 10 =) 800, but with the 1in. objective we should not have (10 × 10 =) 100, or a total power in proportion to the powers of the objectives. Δ might be 8in. only instead of 10in., and the total power would be only 80.

The converse case of different eyepieces with the same objective is similarly explicable. The anterior focal planes of the eyepieces may be at different points of the tube, and we shall have a varying Δ.

As to the general character of the variations in Δ, it may be noted that the position of the anterior focal plane of the eyepiece does not vary very much in the Huyghenian form: a substantial difference is, however, found in this respect between the Ramsden and Huyghenian, the former having its anterior focal plane at some distance below the field lens, and the latter above it. With the objective, however, a very wide range is possible. Its posterior focal plane may be (1) some distance above the last surface of the objective; (2) close to this surface outside or within the objective; or (3)—though a more exceptional case—as a virtual focus below the stage or even below the table. Practically, however, with objectives of ordinary construction the difference in position of the posterior focal plane is not great with powers higher than ⅛in., and it is only when we come to the lower powers that the difference is a substantial one.

Greater differences in the power will also be found with short tubes than with long ones. With a 10in. tube a difference of 2in. reduces the 10 to 8, but with a 6in. tube from 6 to 4—quite different percentages of variation.

The process, therefore, of multiplying together the powers of the eyepiece and the objective to obtain the total power of the microscope is a fallacious one, as it supposes a constant tube length; whilst, as we have seen, the true tube-length varies with the different objectives and eyepieces used.

To determine the power of the microscope from the powers of the eyepiece and objective, it is necessary, in addition, to know the position of the focal planes of each of the latter. How these may be readily determined must be deferred for a subsequent occasion.

[illegible] Microscopical Society.

[illegible] it to Dr. Dippel, [illegible] edition of "Das Mikroskop."

* The quotient obtained by dividing 10in. by the focal length gives the linear amplification of an image—real or virtual—which is projected by an objective to a distance of 10in. [illegible] and not from the objective, as has been so commonly assumed.

† The principal focal planes are the planes passing through the point on the axis in which parallel rays coming from the opposite side of the lens are brought to a focus. "Anterior" and "posterior" are used in reference to the direction in which the rays come to the observer.

ALCHEMY AND MODERN SCIENCE.

CONTINUING his course of lectures to juveniles (see p. 382) Prof. Dewar, F.R.S., said they had now reached the epoch of the Greek philosophers. They were in the front rank of the intellectual teachers of mankind, inquisitive and acute searchers after truth, deep thinkers, and earnest students. Their *forte* was ingenious and profound speculation which they extended into the most intricate regions of metaphysics. But notwithstanding their excellent mathematical training they did not seem to have been at home in describing matter and studying physical problems. From the very earliest ages the doctrine that the world of visible things is made up of the four elements, earth, air, fire, and water, was current. No sooner, however, did Greek philosophy begin to grapple with the question than attempts were made to simplify the explanation. About B.C. 600 Thales taught that water was the primordial element, in opposition to whom Heraclitus held that it was fire, and others that it was air or even earth. The current idea of matter was that it was built up of infinitely small particles, all homogeneous and endued with motion. It was this necessity of motion that led Heraclitus to make fire the primary element. The dance of atomi in the void was illustrated on the screen. In a general way the notion of the four elements held its ground during 25 centuries. Aristotle introduced a fifth element — ether, as a vehicle for the transmission of light among the heavenly bodies. The Greek philosophers were not great at experimenting. Even the famous experiment of Archimedes for testing the purity of the gold used in making the Sicilian king's crown belonged to physics rather than to chemistry. Between Archimedes and the beginning of our era a real hygrometer was devised, but the invention was lost before Pliny wrote, since he never mentioned it, and it was not re-invented until about 1,600 years afterwards. The Roman emperor Diocletian ordered all writings on alchemy found in Egypt, including those in the great Alexandrian library, to be burnt, lest by a resort to the occult science the Egyptians should grow too rich and should rebel against him. Meanwhile, the great discovery of the famous Greek fire not so very long afterwards proved that the knowledge of chemical science had by no means wholly died out. The lecturer said it was probably a mixture of petroleum with sulphur and nitre—in fact, a rude sort of gunpowder. To the great delight of the young folks, he extemporised a kind of gunpowder, which exploded in quite orthodox style. Coming down to the Mohammedan conquest of Egypt, he showed the survival of the chemical tradition in the Arabic records. Representations of the apparatus used by the alchemists, their retorts, crucibles, and alembics, taken from these authoritative sources, were reproduced on the screen. The vessels were mostly those employed in the important process of distillation. In explaining this process, it was demonstrated by a beautiful experiment, how greatly ebullition is hastened if the water contains air. In like manner the insertion of a single tiny crystal in a saline solution brought about, almost instantaneously, the crystallisation of the entire mass.

USFEUL AND SCIENTIFIC NOTES.

The Manufacture of Buttons.—It is a curious fact that although the button trade of New York is estimated at from 8,000,000dols. to 10,000,000 dols. per annum at the American rate of wages, many of the imported buttons could not be put upon their cards for the price they sell for. Europe is still the great seat of the button manufacture. Glass buttons are chiefly made in Bohemia, where children are largely employed. The children get 10c. a day, women from 30c. to 40c., and men from 40c. to 50c. Pearl buttons are almost exclusively a Vienna product; but shirt buttons are chiefly made in Birmingham, which is also the seat of the metal button trade. But the most extensive of all the button manufacturing is that of the Parisian and Berlin novelties. In one manufacturing village near Paris, containing from 5,000 to 6,000 inhabitants, all the working people are engaged in making agate buttons, which, even with 30 per cent. duty added to the cost, sell, when imported into America, at about 31c. per great gross. It is stated that the material alone could not be produced in the States for double that amount. Yet while American manufacturers make no attempt to compete with European producers employing hand processes, they excel in making bone, composition, brass, ivory, and gold buttons by machinery, and are able to export considerable quantities of these goods. For example, in Providence, Rhode Island, sleeve buttons and jewellery buttons are largely manufactured for exportation.

Longevity in the United States.—A further volume in connection with the tenth census of the United States has just been published. It gives separately and distinctly for every State the population from one year and under, to every 100 years and over. By taking in each State the number of the very aged, that is of those from 90 to 100 years and upwards, and finding how many times it is contained in the total population, the interesting result obtained is, that the proportion of the very aged to the total population is greatest in the Southern States. Louisiana stands at the head of the list in regard to extraordinary cases of longevity, Mississippi comes second, and Alabama third. The rest of the States come in the following order:—South Carolina, Florida, Georgia, North Carolina, Virginia, Tennessee, Texas, Arkansas, Kentucky, District of Columbia, Maryland, California, Delaware, Nevada, Colorado, West Virginia, Missouri, Vermont, New Hampshire, Ohio, Rhode Island, Indiana, New York, Michigan, Pennsylvania, Massachusetts, Wisconsin, New Jersey, Minnesota, Illinois, Oregon, Kansas, Maine, Connecticut, Iowa, and Nebraska. It is demonstrated, for example, from the tables that there are proportionally to the total population, nine times more of the age of 100 years in Alabama than in New York, and 15 times more than in Maine.

Interesting trials were made last month—December—by the telegraph engineers to the German Government in substituting a Siemens and Halske dynamo-electric machine for voltaic batteries. From the 4th to 7th December inclusive the current was sent simultaneously through from fourteen to eighteen lines with excellent results. Very powerful batteries had before been required.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

THE third meeting of the session of the above society was held on the 12th ult., at King's College, Strand, James Glaisher, Esq., F.R.S., vice president, in the chair.

The chairman said it was his painful duty to announce that since their last meeting the death had occurred of one of their members, who during almost the whole of his life had been held in the highest esteem and respect by all microscopists. He referred to Mr. Hugh Powell, of the firm of Powell and Lealand. It was truly a ripe old age to which he had attained, but, nevertheless, it was always painful when at length the time of parting came, and both as a society and as individuals, he was sure they must deeply regret the removal of one whom they had always held in such respect. It was by an unfortunate coincidence that it fell to his lot to announce to the same meeting the death of Mr. Powell's most distinguished rival in America—Mr. R. B. Tolles, of Boston—who had also done so much for the improvement of objectives. Peace be to both of them; with the kindliest feelings of sympathy towards their respective families of every Fellow of the society.

Mr. Crisp exhibited Mr. H. P. Aylward's microscope, having a swinging tailpiece rotating completely round the stage, so that the mirror and sub-stage could be set in any required azimuth.

Mr. Crisp also exhibited (1) a microscope by Mr. A. McLaren, which was made to rotate upon the horseshoe foot, so as to secure greater stability to the instrument when the body was inclined at any considerable angle; (2) a microscope by F. W. Schieck, with a number of objects inserted in the circumference of a revolving drum, so that each could be passed in turn beneath the objective. A translation of the inventor's description of the instrument and its advantages was read to the meeting, and his claim to absolute originality shown to be erroneous by the exhibition of Harris's microscope, obviously of considerable age, in which the same idea had been carried out.

Mr. W. H. Walmsley's photo-micrographs were exhibited, two of which in particular (of Möller's diatoms) were characterised by the Chairman as very excellent examples of photo-micrography.

Mr. W. M. Bale's note on Mounting in Glycerine was read.

Dr. J. H. Flögel's paper "On Researches on the Structure of the Cell-walls of Diatoms" was brought before the meeting by Mr. J. Mayall, jun., who, in his preliminary remarks, said that it would be remembered that some time ago they had heard reports that someone abroad was making sections of diatoms, and he was requested by Mr. Crisp to institute inquiries with the view of bringing the method before the Society. He subsequently found that this work was being done by Dr. Flögel, of Holstein, who, there appeared no reason to doubt, was not only a skilled and competent observer, but that he possessed every kind of appliance for making careful observations. Having ascertained this, the next thing was to obtain specimens of actual sections of diatoms, without which it was, of course, not possible to form any satisfactory judgment on the matter. He was fortunate in persuading Dr. Schröder, now resident in London, to write to Dr. Flögel upon the subject, and in the result they had received a very elaborate paper, accompanied by a dozen slides and a number of photographs and drawings in illustration. A careful examination of the slides showed that Dr. Flögel was thoroughly familiar with the finest processes of mounting, and with all that had been done by Möller. One of the slides was exhibited in the room under a [illegible]in. objective by Mr. Powell. It was a section of *[illegible]*, and the excellence of the specimen gave rise to the impression that something even more difficult than this could be accomplished. Amongst the other specimens sent were some very clean cut sections, giving an exceptionally clear image. It was stated by Dr. Flögel that as many as 174 transverse sections had been made of one diatom, all of which could be plainly identified as belonging to the same diatom Mr. Mayall said that he could not pledge himself as to the correctness or otherwise of the theory set up by the author of the paper, as the subject was not one which he had made his own, although he had taken some pains to translate the paper for publication in the *Journal* of the Society.

Mr. Mayall then read an abstract of the paper to the meeting, and the subject was discussed by Mr. Curties, Mr. Crisp, and other Fellows.

The Chairman, in proposing a vote of thanks to Dr. Flögel for his paper, said that he was sure the Society would feel doubly indebted to Mr. Mayall for the exertions which he had made to procure the paper, and also for the trouble he had taken in the matter of its translation.

SCIENTIFIC NEWS.

THE death is announced of Mr. C. W. Merrifield, F.R.S., at Brighton, last week. The deceased gentleman was well known as an active member of the Institute of Naval Architects (he was one of the honorary associates), and as an authority on wave-motion, the seagoing qualities of ships, and the resistance of air to projectiles. He was born in 1827, and was elected a Fellow of the Royal Society 20 years ago.

In an interesting lecture on the Eskimos, delivered by Dr. Rae at the London Institution last week, the lecturer expressed the belief that they were originally an Asiatic race, who crossed from Siberia by Behring's Straits. They speak, with slight dialectical variation, one language from Labrador to Alaska; are physically very strong; have an unbounded love for their children, and are intelligent and faithful. The tallest male measured by Dr. Simpson near Behring's Straits was 5ft. 10½in., and the shortest 5ft. 1in.; the heaviest weighed 195lb., the lightest 125lb. The eyes have a fold of skin across the inner angle, giving the countenance a cast which is all but perfectly Chinese. An Eskimo's meal is often as much as 8lb. of seal or 12lb. of fish, while the clothing is made almost wholly of the skin of the reindeer. The dwellings consist of stone and mud kraals, wooden huts, and snow houses, according to locality, and are generally very snug and comfortable.

It is stated that Dr. N. de Konkoly, of the observatory, O-Gyalla, Hungary, will succeed M. Houzeau as director of the Brussels Observatory.

From an analysis of a sample of water taken from the famous well at Mecca, known as Hagar's or the Zemzem well, Mr. C. W. Heaton gives the following rather extraordinary figures:—Total solid matter per gallon, 464·4 grains; chlorine, 75·5 grains; nitrogen (as nitrates), 13·75 grains; nitrogen (as nitrites ·09 grain; ammonia ·358 grain. No albuminoid ammonia was found, probably due, says Mr. Heaton, to the completion of the putrefactive process. The fearful nature of this "holy water," which is used as a medicine, can be judged by comparing the following figures, which are those obtained from an analysis of London water supplied by the Thames companies: Total solid matter per gallon, 18 grains; chlorine, 1·5 grain; nitrogen (as nitrates), ·18 grain; ammonia, ·001 grain; albuminoid ammonia, ·004 grain.

In connection with the Turin Exhibition the Italian Government have offered a prize of £400 (10,000 lire) to any one who shall perfect the most useful and practical system of generating and transmitting electrical energy.

An experiment with the electric light is being tried on one of the trains of the Metropolitan District Railway. A Siemens dynamo and a Willans engine are placed in a van, steam being raised in a small boiler also placed in the van. Should this tentative trial prove satisfactory, the Willans engine and the dynamo will be placed on the locomotive, the boiler of which will supply the steam. The train being a short one, there are only 28 Swan 20-candle lamps in the carriages, but 22 or more are placed in the van, the object being to ascertain the cost of working 50 lamps, the number required for one of the ordinary trains.

Mr. Barnett has had his system of distribution at work in the offices of Mr. Spagnoletti at Paddington Station. He has invented an improved accumulator, which is stated to be superior to anything known, for the loss of current in ordinary work is "less than 10 per cent." Each battery for use in train lighting measures 22in. by 7in. by 7½in.; it is provided with footplates, by which means the connections are made when the battery is simply put into position. One battery will, it is stated, maintain a 12-candle Swan lamp from 10 to 20 hours—rather a wide margin. The system has been under trial at Paddington for three months, and is said to have worked satisfactorily.

There is a deficit of about £6,000 in the finances of the late Vienna Electrical Exhibition.

Mr. Baird, of the U.S. Fish Commissioners' steamer, *Albatross*, gives an account of the success attending his endeavours to use an incandescend a lamp at a depth of a hundred fathoms. The pressure is so great at that depth that several failures followed the earlier attempts, then the Edison Company made a lamp in which the fine platinum wires were soldered to pieces of No. 16 copper in a glass cavity which was then filled in with resin. These copper wires were coiled into spirals and soldered to the heavy wires in the cable, and the joint was covered with two coats of "gullock" and tape, and finally with guttapercha, which was seared over with a warm iron. Instead of a cut out plug in the deep sea circuit, another lamp is put in, and that being kept on board indicates by its condition that the the lamp at the bottom is burning all right.

Capt. Poly has, it is stated, introduced a new bridge signal and helm indicator, with the view of preventing collisions at sea. The indicator exhibits red or green flares of from ten to fifteen seconds duration, according to the position of the helm.

According to M. Mering, of Strasburg, chlorate of potash passes through the organism without, in great part, undergoing any change. Methæmoglobin is formed when blood and chlorate of potash are mixed, and a part of the latter is reduced.

Prof. McIntosh, of St. Andrews, will make a series of periodical excursions to the trawling grounds on the East Coast of Scotland, between Aberdeen and Berwick, during the next six months, for the purpose of making certain investigations into the trawling grounds, their inhabitants and surroundings, required by the Trawling Commissioners.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, [illegible] Covent-garden, W.C.

All Cheques and Post-Office Orders to be made payable to J. Passmore Edwards.

In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects. For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—Montaigne's Essays.

FRACASTORIUS SATURN COMET PONS

[illegible]

Pons been made? If any have, it would be interesting to have them published. On the 30th I saw it; I thought it about 3½° in length. The night was misty, and the comet must have been very bright to have been seen so well. I estimated in an opera-glass the total light of the head to equal ζ Cygni, but it was perhaps brighter.

G. Maitland Baird Gemmill.

SATURN.

[22219.] Dr. Kitchener used some such powers as W. C. Gurley mentions (letter 22190), and he comments:—"Such powers are very useful for showing the uselessness of any such enormous magnifiers." Allow me to ask whether Mr. Gurley is sure of the odd 4 diameters in his highest power, and if he will tell us how to distinguish or measure the difference betwixt 1,300 diameters and 1,304? Is not the letter a hoax? The drawing by Trouvelot is well known to be the utmost the Washington telescope would show, yet here is a 6¼in. equalling it in every respect, and I should say surpassing it in some.

Edwin Holmes.

A PHOTOGRAPH OF COMET PONS-BROOKS.

[22220.]—We beg to inform you that on December 24th we succeeded in photographing comet Pons-Brooks. The exposure was 53 minutes. The comet comes out on the plate as a circular haze, without any trace of a tail. The star magnitude is about equal to γ (gamma) Cygni. The comet at the time was near ε (Epsilon) Cygni, and was inferior to that star according to an eye estimate. On the plate, however, the brightness is very considerably greater. A heavy dew was falling, and the lenses were badly covered.

T. E. Espin.

The Observatory of the Liverpool Astronomical Society, West Kirby, Jan. 1, 1884.

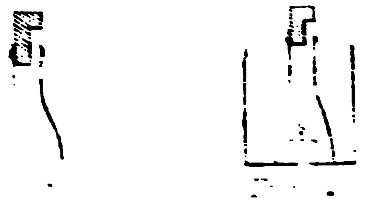
AFTER-GLOW.

[22221.]—Some 22 or 23 years ago, whilst in Cornwall, I observed some beautiful colour effects in the clouds at sunrise during several successive spring mornings. The clouds appeared to form several lines of diversely-tinted strata—some red, some orange, some golden yellow, some purple; whilst between these streaks of blue sky could be seen which seemed to merge into a decided green tint where they touched the golden or orange clouds. I have not seen any equal to those since that date.

Galvanoplast.

A CHEAP LANTERN FOR GELATINE PLATES.

[22222.]—The cost of this lantern is nothing at all, for every amateur who practises photography has the materials required—viz., a green glass bottle and a jam-pot of white earthenware large enough to admit of the bottle being placed within it. Next cut off the bottom half of the bottle, by first holding the bottle over a candle, and then plunging it into cold water; this will establish a crack which is led round the bottle with a red-hot poker, thus cutting it into two parts; then place the upper portion, with the neck into the jam-pot, neck upwards, and observe how far the neck appears above the jam-pot; this portion blacken with Brunswick or Japan black. Then take the cork belonging to the bottle and cut a piece out of it, like Fig. 1; the



cork being placed so that the heat and smoke can escape.

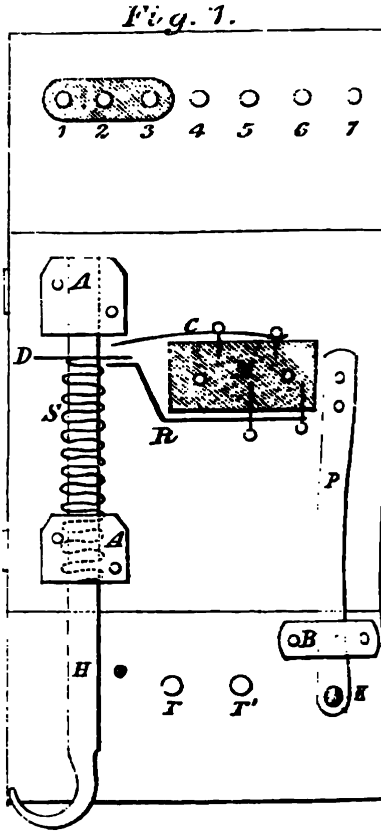
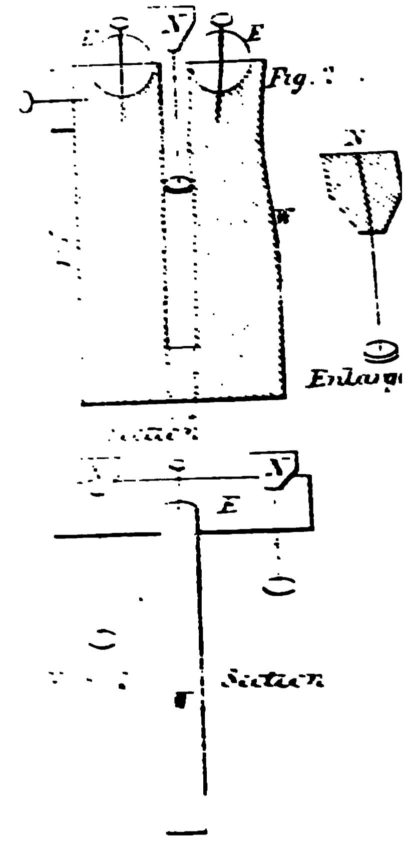
patent for the arrangement could only be val
for a particular combination of parts, as rec
decided in respect to the Bell telephone, and a
combination of parts is susceptible of so
variations that a patent would be practically

Fig. 1.



less, I send you for publication a sketch of
arrangements, with such a full description as
enable any amateur to make them. The sketch
switch-board, as I send it, is the actual s



though it will probably be reduced by [illegible] graver. The parts are slightly in excess [illegible] as I have drawn them by [illegible] round the pieces. Fig. 2 is [illegible] but the dimensions are given in the [illegible]

Switch-Board.—Take a piece of mahogany 8 by 4 by 1, plane it up and varnish it. On the top, at a distance of ¾ of an inch from the top, fix seven terminals ½in. apart; these are numbered in the sketch 1, 2, 3, 4, 5, 6, 7, and are for the following connections: 1 2 3 are connected together by the brass plate as shown; 1 is connected to the return line or earth wire; 2 to the zinc pole of the battery; 3 and 4 to the bell wires; 5 to the carbon pole of the first cell; 6 to the carbon pole of the last cell; and 7 to the line wire. P is a strip of brass with the knob K at the lower end; it is secured by two screws at the upper end, and is then bent upwards so as to press against the bridge B, which is a strip of brass secured by the screws at each end, each of which screws passes through a piece of brass tube which keeps the plate B about ¼in. from the board. The piece P is connected by a wire underneath the board (all the connections are made underneath), with the terminal screw 7. Underthe knob K is a screw with a flattened head, which isconnected with terminal screw 6: this constitutes the ringing key. H is a piece of ¼in. brass rod with the hook at the bottom, and the round brass disc D about ⅞in. in diameter, soldered about ½in. from the upper end; this rod works freely up and down through the two pieces of angle brass A A. S is a spiral spring of brass wire which, when the telephone is taken off the hook, causes this rod to rise, and the disc D then presses the thin piece of hammer-hardened brass C against the upper angle brass A. In order to insure a good contact this strip of brass C is slightly canted at the end so as to give two rubbing contacts, one against the disc D and the other against the upper angle brass A. When the telephone is on the hook the disc D rests on the piece of brass R, which acts as a contact and as a stop. The total play allowed to D is about $\frac{3}{16}$in.; the lower angle brass A is connected with the bridge B; the piece of brass R is connected with the terminal 4; and the thin piece of brass C with the upper hinge. T and T¹ are brass screws to which the flexible wires of the telephone receiver are attached; T is connected with terminal 5, and T¹ with the lower hinge. M is merely a piece of mahogany to which the pieces C and R are attached.

We now require a square frame of ¼in. mahogany, 4in. square in outside measurement, and 1⅜in. deep; apertures are cut in the bottom side of this to allow the rod H and the ringing key P to move freely. This case is attached to the hinges marked, and with a face piece of pine about ⅛in. thick, boxes up the whole of the apparatus, leaving on y 2in. of the board at the top, and the same at the bottom uncovered; a small plate of brass is screwed to this box opposite to the hinges, and one screw into the switch-board prevents the box from being opened.

To the centre of this piece of pine the microphone transmitter shown in Fig. 2 is attached.

This microphone is thus constructed:—Take a piece of pine about $\frac{5}{16}$in. thick, ⅞in. wide, and 1⅜in. long, remove part of one edge so as to leave a projection as shown, and about $\frac{1}{16}$in. deep and $\frac{3}{16}$in. square, by which it is attached to the centre of the pine face of the box; put a sawcut down through it to within about ¼in. from the bottom. Take two pieces of ¼in. carbon rod 1¼in. long, E E, and cut a recess in the middle of each half-way through, and a little more than $\frac{3}{16}$in. wide; drill a small hole in the middle of each recess; bend a narrow piece of very thin sheet brass over the top of each arm or leg of the piece of pine; solder a wire to each piece of brass, and then secure the carbons by screws to the piece of pine as shown in E E. These pieces of carbon should be parallel, level, and a little less than ⅛in. apart; the wire from one carbon is taken to the top hinge, and from the other to the bottom hinge. I find that some of the carbon rods now sold have a coating of glaze, which is almost a non-conductor. I therefore always remove this with emery paper. This piece of pine with the carbons attached is now screwed to the centre of the pine cover of the box, and care must be taken that it does not touch anywhere else, and is not touched by anything. The microphone is completed by making two small conical pieces of carbon as shown, N, with a small hole in the centre of each; a lucifer match or other small piece of light wood is then filed or sand-papered down until it is as small as a knitting-needle, and will just go into the holes in the carbon cones. In one carbon cone I put a piece of this wood about ¼in. long, and in the other carbon cone a piece about ⅜in. long, and round the bottom of each of these pieces of wood I put a small ring of lead wire, they are then put in position on the carbon rods, and appear as shown in Fig. 2, end view, where E is one of the horizontal pieces of carbon rod, and N N the carbon cones: they should oscillate freely. I cut these carbon cones from $\frac{5}{16}$ rod.

I have long been of opinion that the hard carbon microphone works by make-and-break as completely as the Morse tapping key, and that the suggestions as to minute arcs, &c., were unwarranted by facts. I have also satisfied myself that the Bell telephone or my clear-speaking telephone, and certainly the latter, will reproduce human speech when actuated by an intermittent current, or current of sudden impulses, and that the idea that what Bell describes as an undulatory current is essential to the reproduction of human speech, is altogether untenable. I wanted to get rid of the spark so often seen in the microphone when a strong battery is used, and which has been the subject of so much learned writing. I believed that this spark was merely due to the well known "extra current," and I determined to try the plan that has for very many years been in use for getting rid of the spark at the contacts of electric clocks and other apparatus. I therefore made a resistance coil of 54ft. or 55ft. of No. 36 B.W.G. German-silver silk-covered wire, which gives a resistance of a little more than 100 ohms. I connected the ends of this resistance coil to the two hinges; no spark is perceptible, and the articulation with my clear-speaking telephone as a receiver, is as nearly perfect as anything I have met with in the telephone line. This coil is fastened inside the case above the hinges by a small screw.

I do not advise the use of induction coils with transmitters, and the above-described switch-board must be altered and made more complicated if they are used; but the arrangement is suited for any good receiver. In connecting up two stations, it will, of course, be remembered that the battery connections at one station must be reversed; that is, the carbon wire attached where I have directed the zinc wire to be attached, and the zinc wire attached where I have directed the carbon.

For battery power, I find that the battery required to ring a fairly good, ordinary bell works this arrangement well; thus if two Leclanché cells ring the ordinary bell nicely, then put one Leclanché cell at each end of the line in circuit with the telephone; if three Leclanché cells are required to ring the bell, then put two cells at one end of the line, and one cell at the other end in circuit with the telephone.

I have omitted to mention that outside the pine cover to which the microphone transmitter is fixed, I screw by its four corners a piece of cork 3½in. square and about ¼in. thick, with a ⅝in. hole punched out of the centre. This damps all the sound vibrations, except where they are alone required, that is, in the centre where the microphone is attached, and is a great improvement.

A Royal Academician, on seeing this apparatus, might perhaps declare that it was "entirely devoid of all artistic merit." An ornamental and costly affair it has not been my object to produce: simplicity and efficiency I have alone had in view, and I believe that any one, amateur or professional, who may try this arrangement will say that I have fully succeeded; whilst as to cost, this switch-board and transmitter can be made and sold with a fair trade profit for about fifteen shillings.

H. B. T. Strangways.
